SECRETARY—CLINTON P. ANDERSON

## AGRICULTURAL RESEARCH ADMINISTRATION

ADMINISTRATOR—W. V. LAMBERT

### OFFICE OF EXPERIMENT STATIONS

CHIEF—R. W. TRULLINGER

ASSOCIATE CHIEF—E. C. ELTING

## THE AGRICULTURAL EXPERIMENT STATIONS

ALABAMA—*Auburn*: M. J. Funchess.<sup>1</sup>

ALASKA—*College*: D. L. Irwin.<sup>1</sup>

ARIZONA—*Tucson*: P. S. Burgess.<sup>1</sup>

ARKANSAS—*Fayetteville*: L. S. Ellis.<sup>1</sup>

CALIFORNIA—*Berkeley* 4: C. B. Hutchison.<sup>1</sup>

COLORADO—*Fort Collins*: H. J. Henney.<sup>1</sup>

CONNECTICUT—

[New Haven] Station: *New Haven* 4:  
J. G. Horsfall.<sup>2</sup>

Storrs Station: *Storrs*; W. B. Young.<sup>1</sup>

DELAWARE—*Newark*: G. M. Worrlow.<sup>1</sup>

FLORIDA—*Gainesville*: Harold Mowry.<sup>1</sup>

GEORGIA—

*Experiment*: H. P. Stuckey.<sup>1</sup>

Coastal Plain Station: *Tifton*; G. H.  
King.<sup>1</sup>

HAWAII—*Honolulu* 10: J. H. Beaumont.<sup>1</sup>

IDAHO—*Moscow*: D. R. Theophilus.<sup>1</sup>

ILLINOIS—*Urbana*: H. P. Rusk.<sup>1</sup>

INDIANA—*La Fayette*: H. J. Reed.<sup>1</sup>

IOWA—*Ames*: R. E. Buchanan.<sup>1</sup>

KANSAS—*Manhattan*: R. I. Throckmorton.<sup>1</sup>

KENTUCKY—*Lexington* 29: T. P. Cooper.<sup>1</sup>

LOUISIANA—*University Station, Baton Rouge*  
3: W. G. Taggart.<sup>1</sup>

MAINE—*Orono*: Fred Griffee.<sup>1</sup>

MARYLAND—*College Park*: W. B. Kemp.<sup>1</sup>

MASSACHUSETTS—*Amherst*: F. J. Sievers.<sup>1</sup>

MICHIGAN—*East Lansing*: V. R. Gardner.<sup>1</sup>

MINNESOTA—*University Farm, St. Paul* 1:  
C. H. Bailey.<sup>1</sup>

MISSISSIPPI—*State College*: Russell Cole-  
man.<sup>1</sup>

MISSOURI—

College Station: *Columbia*; E. A. Trow-  
bridge.<sup>1</sup>

Fruit Station: *Mountain Grove*; P. H.  
Shepard.<sup>1</sup>

Poultry Station: *Mountain Grove*; T.  
W. Noland.<sup>1</sup>

MONTANA—*Bozeman*: Clyde McKee.<sup>1</sup>

NEBRASKA—*Lincoln* 1: W. W. Burr.<sup>1</sup>

NEVADA—*Reno*: C. E. Fleming.<sup>1</sup>

NEW HAMPSHIRE—*Durham*: R. F. Chandler,  
Jr.<sup>1</sup>

NEW JERSEY—*New Brunswick*: W. H. Mar-  
tin.<sup>1</sup>

NEW MEXICO—*State College*: H. R. Varney.<sup>1</sup>

NEW YORK—

State Station: *Geneva*; A. J. Heinicke.<sup>1</sup>

Cornell Station: *Ithaca*; C. E. F. Guter-  
man.<sup>1</sup>

NORTH CAROLINA—*State College Station, Ra-*  
*leigh*; J. H. Hilton.<sup>1</sup>

NORTH DAKOTA—*State College Station*;  
*Fargo*: H. L. Walster.<sup>1</sup>

OHIO—*Wooster*: L. L. Rummell.<sup>1</sup>

OKLAHOMA—*Stillwater*: W. L. Blizzard.<sup>1</sup>

OREGON—*Corvallis*: W. A. Schoenfeld.<sup>1</sup>

PENNSYLVANIA—*State College*: F. F. Linin-  
ger.<sup>1</sup>

PUERTO RICO—

Federal Station: *Mayaguez*; K. A. Bart-  
lett.<sup>1</sup>

University Station: *Rio Piedras*; Arturo  
Roque.<sup>1</sup>

RHODE ISLAND—*Kingston*: M. H. Campbell.<sup>1</sup>

SOUTH CAROLINA—*Clemson*: H. P. Cooper.<sup>1</sup>

SOUTH DAKOTA—*Brookings*: I. B. Johnson.<sup>1</sup>

TENNESSEE—*Knowville*: C. E. Brehm.<sup>1</sup>

TEXAS—*College Station*: R. D. Lewis.<sup>1</sup>

UTAH—*Logan*: R. H. Walker.<sup>1</sup>

VERMONT—*Burlington*: J. E. Carrigan.<sup>1</sup>

VIRGINIA—

*Blacksburg*: H. N. Young.<sup>1</sup>

Truck Station: *Norfolk* 1; V. A. Tied-  
jens.<sup>1</sup>

WASHINGTON—*Pullman*: M. T. Buchanan.<sup>1</sup>

WEST VIRGINIA—*Morgantown*: C. R. Orton.<sup>1</sup>

WISCONSIN—*Madison* 6: I. L. Baldwin.<sup>1</sup>

WYOMING—*Laramie*: J. A. Hill.<sup>1</sup>

<sup>1</sup> Director.

<sup>2</sup> Vice Director.

JULY 1946

No. 1

## RECENT WORK IN AGRICULTURAL SCIENCE<sup>1</sup>

### AGRICULTURAL AND BIOLOGICAL CHEMISTRY

**Efficient statistical methods in chemistry**, J. MANDEL (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 4, pp. 201-206).—"Statistical procedures are described for the evaluation and comparison of precisions, and for the estimation of accuracies . . . Special emphasis is placed on the practical interpretation of the statistical tests and computations."

**Organic preparations**, C. WEYGAND (*New York 3: Interscience Pubs.*, 1945, pp. 534+, illus. 12).—This volume is a translation of part II, "Reaktionen," *Organisch-chemische Experimentierkunst*, published in Leipzig in 1938. In this translation the extensive quotations from Organic Syntheses have been reduced to references.

The more important general reactions are taken up by classes indicated by the contents, in related groups under these main headings, and with relation to the preparation of compounds of the specific types. Each reaction is discussed rather in terms of its general application than in connection with a single typical preparation. Detailed procedures for the preparation of individual compounds are abundantly used as illustrations of points brought up in discussions of general technics, however, both typical instances and those requiring special treatment being used in this way.

Following a publisher's note, prefaces, and a general introduction, the contents are: Formation of carbon-hydrogen bonds, formation of carbon-halogen bonds, formation of carbon-oxygen bonds, cleavage of carbon-oxygen bonds, formation of organic derivatives of trivalent nitrogen, cleavage of carbon-nitrogen bonds, formation of carbon-pentavalent nitrogen linkages, carbon-divalent sulfur bonds, carbon-hexavalent sulfur bonds, unsaturated carbon bonds, formation of carbon-carbon bonds, fission of carbon-carbon bonds, rearrangements of carbon compounds with the exception of steric rearrangements, and index.

**Leucine content of proteins and foodstuffs**, E. BRAND, F. J. RYAN, and E. M. DISKANT (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 9, pp. 1532-1534).—A strain of *neurospora crassa* containing no leucine was used for the determination of this amino acid in the hydrolyzates of a number of proteins and of a few foodstuffs. The

<sup>1</sup> The publications abstracted in these columns are seldom available for distribution by the Office of Experiment Stations. In general, application should be made to the Office of Information of the U. S. Department of Agriculture, Washington 25, D. C., for publications of the Department; to the directors of the State agricultural experiment stations, as listed on page 3 of the cover of this issue, for publications of the several experiment stations; and to publishers of books and journals for material issued by them. Microfilms and photostatic copies, the latter legible without magnifying equipment, may be purchased from the Library, U. S. Department of Agriculture, Washington 25, D. C. Rates and other details will be supplied by the Library on request.

accuracy of this procedure was indicated by an independent determination of the leucine content of  $\beta$ -lactalbumin made by means of an isotope dilution method, the respective figures being 15.4 and 15.7 percent.

Ribonuclease was the only protein in which no leucine could be detected. Of the proteins examined, silk fibroin had the lowest leucine content (0.8 percent). Gelatin (containing 3.6 percent) was next. Leucine was found to account for an appreciable part of the molecule in zein (15.4 percent), bovine (13.7 percent), human (11.9 percent) and horse (13.0 percent) serum albumin, horse (15.7 percent) and human (14.7 percent) hemoglobin, insulin (13.4 percent) and  $\beta$ -lactoglobulin (15.6 percent). Chymotrypsinogen, insulin, and  $\beta$ -lactoglobulin were calculated to contain 29, 45, and 50 residues of leucine, respectively, per mole of protein.

**Viscosity patterns of peanut protein solutions: Comparison with other vegetable proteins and with casein.** R. S. BURNETT, E. J. ROBERTS, and E. D. PARKER. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 3, pp. 276-281, illus. 7).—Methods for preparing and determining the viscosity of vegetable protein solutions at useful concentrations are described. Data presented show the influence of concentration, heat, pH, time, and other factors on the viscosity relations of peanut protein solutions made alkaline with sodium hydroxide. These factors were found to be, in turn, influenced by the conditions under which the peanut meal is prepared, by the methods employed in separating the protein from the meal, and by the subsequent treatment received by the separated protein. The viscosity behavior of peanut protein solutions is compared with that of solutions of casein and of soybean and cottonseed proteins.

**The reaction of formaldehyde with *l*(-)-histidine.** D. C. CARPENTER. (N. Y. State Expt. Sta.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 8, pp. 1247-1249, illus. 3).—Having shown, by means of a polariscopic method devised for a previous investigation of the behavior of asparagine, aspartic acid, and glutamic acid, that formaldehyde reacts with amino acids in equimolecular proportions to form fairly stable compounds, and in the proportion of two molecules of the aldehyde to one of the amino acid to form highly unstable compounds (E. S. R., 89, p. 275), the author here reports upon the application of a similar procedure in an investigation of the reaction of formaldehyde with *l*(-)-histidine, the course of this reaction having been followed by means both of polariscopic and of hydrogen-ion concentration measurements.

In solutions containing *l*(-)-histidine with one molecular equivalent of sodium hydroxide, and under the experimental conditions here specified, two definite compounds appeared with the addition of increasing quantities of formaldehyde. One of these, formed from equimolecular proportions of the aldehyde and the amino acid, was stable and showed an angular rotation of  $-24.10^\circ$  [C.]. A second compound appeared when the proportion of formaldehyde added reached three molecular equivalents of the aldehyde to two equivalents of the amino acid. This second compound was not stable. Its angular rotation was  $-3.30^\circ$ . Because of the instability of the 2:3 compound, the author considers it more likely to have the structure  $R-NH.CH_2O-CH_2NH_2R$  than that which would result from the reaction of the formaldehyde with the imino groups of two imidazole rings. The equilibrium constant of the second reaction was calculated as  $k = 0.00658$ . A graphic method, based upon the logarithmic form of the equilibrium equation, gave  $k = 0.00652$ , in good agreement with the calculated value.

**The empirical formula of  $\beta$ -lactoglobulin.** E. BRAND, L. J. SAYDEL, W. H. GOLDWATER, B. KASSELL, and F. J. RYAN (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 9, pp. 1524-1532).—Data concerning the elementary and amino acid composition of crystalline  $\beta$ -lactoglobulin are presented. From the hydrolysis of 100 gm. of protein, 116.73 gm. of split products of 99.62 gm. on a residue basis were obtained;

17.11 gm. of water was taken up during hydrolysis. A minimum molecular weight ( $M_{min.}$ ) of  $42,020 \pm 105$  was calculated almost identical with the molecular weight ( $M_v = 41,600$ ).  $\beta$ -Lactoglobulin was, therefore, monomolecular in solution. The atomic empirical formula was found to be:  $C_{1881}H_{3012}N_{108}S_{21}O_{576}$ . The empirical formula in terms of amino acid residues (using the first three letters of each as the symbol for the amino acid residues) was found to be: Gly<sub>8</sub>Ala<sub>26</sub>Val<sub>21</sub>Leu<sub>50</sub>Ileu<sub>27</sub>-Pro<sub>16</sub>Phe<sub>6</sub>Cys<sub>11</sub>((Cys)<sub>4</sub>)Met<sub>6</sub>Try<sub>4</sub>Arg<sub>7</sub>Ile<sub>4</sub>Lys<sub>38</sub>Asp<sub>26</sub>Glu<sub>21</sub>(Glu-NH<sub>2</sub>)<sub>28</sub>Ser<sub>20</sub>Thr<sub>21</sub>Tyr<sub>0</sub>-(H<sub>2</sub>O)<sub>1</sub>.  $\beta$ -Lactoglobulin was found to consist of 370 amino acid residues with 366 peptide bonds, arranged in four subunits (polypeptide chains). The average residue weight was calculated as 113.7-113.9.

"It can be concluded that the constituent amino acids are primarily linked by typical peptide bonds; other linkages, such as atypical peptide bonds (as in glutathione), esters, anhydrides, or imides, if they are present at all, can be present only in extremely small numbers."

**Iodination of tyrosine groups in serum albumin and pepsin.** C. H. LI. (Univ. Calif.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 7, pp. 1065-1069, illus. 3).—Iodine was found to react, in human serum albumin, only with the tyrosine groups. Urea was found to accelerate the rate of diiodotyrosine formation. The rate of iodination of the serum albumin and of pepsin was measured in an acetate buffer solution and in urea solution, not all of the tyrosine groups being reactive toward iodine in the acetate buffer solution. In the presence of urea, some, though not all, of the non-reacting tyrosine groups became reactive. When both heat and urea were used as denaturing agents, all tyrosine groups became available for iodination. From the kinetic data, a computation of the number of free tyrosine groups in pepsin and in serum albumin was made.

**Isolation of betaine from guayule.** C. W. MURRAY and E. D. WALTER. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 8, p. 1422).—Because of the discard of much plant material in the processing of *Parthenium argentatum* for the isolation of the natural rubber content, the authors considered it important to ascertain if useful substances can be recovered from such wastes. They point out also the possibility that nonrubber constituents of the shrub may affect the quality of the rubber.

From the water soluble fraction of the leaves and from the defoliated shrub, betaine was isolated as the hydrochloride in yields of about 0.9 percent and 0.4 to 0.5 percent, respectively. The authors also isolated betaine from the acetone and benzene insoluble fraction of guayule rubber, thus proving the presence of betaine in the crude pebble milled rubber. Betaine was also obtained from the product of each step in the extraction of the rubber, such as the dispersion prepared by cutting or comminuting the shrub in water and used for separation of rubber as latex, the solution obtained in parboiling of shrub to remove leaves, and the pebble mill slurry.

**The extraction of fat and phosphorus from wheat starch.** L. LEHRMAN (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 9, pp. 1541-1542).—Extraction of raw and disintegrated wheat starch with methanol removed most of the fat and phosphorus. Extraction of disintegrated wheat starch with 80 percent dioxane-water solution (constant boiling mixture) removed all the fat but not all the phosphorus. It was therefore concluded that a small amount of the phosphorus was present not as a phospholipid, but possibly linked in some way with the starch. The extracted starch was more nearly free of phosphorus than any starch previously reported.

**Reversible effect of stannic chloride on the rotation of starch dispersions.** C. L. HOFFHAUER and J. D. GUTHRIE. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 7, pp. 1225-1226, illus. 1).—The optical rotation of a dispersion of starch in a calcium chloride solution was found to be reduced appreciably by the addition of stannic chloride. The original optical rotation could be restored by the

addition either of uranyl acetate or of sodium acetate. A similar result was obtained by the addition of stannic chloride to a dispersion of glycogen. The laevorotation of inulin, on the other hand, was increased by the same addition. In view of the fact that stannic chloride is a protein precipitant in general use in a method for the determination of starch, the observations noted may be of practical as well as of theoretical importance.

**Isolation and structure of an enzymatically synthesized crystalline disaccharide, D-glucosido-L-sorbose, W. Z. HASSID, M. DOUDOROFF, H. A. BARKER, and W. H. DORE. (Univ. Calif.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 8, pp. 1394-1397, illus. 3).**—A crystalline nonreducing disaccharide consisting of D-glucose and L-sorbose has been synthesized from glucose-1-phosphate and L-sorbose through the action of a phosphorylase from *Pseudomonas saccharophila*. Periodate oxidation data indicated that the glucose residue in the disaccharide possesses the pyranose, and the sorbose residue possesses the fufanose configuration. Evidence indicating that both D-glucose and L-sorbose were joined through  $\alpha$ -linkages was found. It is concluded that the disaccharide was probably  $\alpha$ -D-glucopyranosido- $\alpha$ -L-sorbofuranoside.

**Acetates, propionates, and butyrates of simple saccharides, I. A. WOLFF. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 9, pp. 1623-1624).**—The author prepared 22 esters of saccharides and saccharide derivatives by acylation with the anhydride of the corresponding acid in pyridine, purifying the reaction product by vacuum distillation of the excess reactants and byproducts. He found that the sugar esters can be obtained in quantitative yield by concentration of the reaction mixture in vacuo after the esterification process is complete. The excess pyridine, anhydride, and fatty acid formed are removed, leaving the ester in a good state of purity. "Further appropriate purification procedures can then be applied if desired, depending on the properties of and intended uses for the particular ester. This method of operation has the following advantages: (1) Ease of operation with a minimum of manipulative steps, and (2) increased yields of esters in many cases. It is particularly useful as compared to the conventional procedure when the desired ester is moderately water soluble (e. g., levoglucosan triacetate)."

**Catalytic air oxidation of methyl oleate and characterization of the polymers formed, D. SWERN, H. B. KNIGHT, J. T. SCANLAN, and W. C. AULT. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 7, pp. 1132-1135).**—The authors studied the catalytic air oxidation of methyl oleate. The high-boiling, previously uncharacterized portion of the oxidation products obtained in 30 to 40 percent yield was fractionated by molecular distillation, yielding oxygenated polymers of dimeric and higher complexity. It is believed that these polymers are oxygen linked. A methyl ester fraction with a boiling point intermediate between that of methyl oleate and the polymers was isolated and extensively studied for the first time. By oxidative splitting of this fraction with potassium permanganate in acetone solution, it was shown to consist mainly of methyl esters of several isomeric monohydroxy derivatives of one or more mono-unsaturated acids in which the double bond was shifted from the 9,10-position, and methyl esters of dimeric acids.

**Photochemical dimerization of n-butyl mesityl oxide oxalate, S. A. HALL, R. K. ADAMS, JR., and H. L. HALLER. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 7, pp. 1224-1225).**—The n-butyl ester of mesityl oxide oxalic acid, patented under the trade name "Indalone," is used as an insect repellent to protect against the bites of mosquitoes and flies. The authors found that the exposure of thin films of this compound to ultraviolet light caused irreversible and quantitative polymerization of the liquid ester to a crystalline solid, m. p. 106°-107° [C.], which was identified as a dimer of Indalone. That this dimerization will take place completely in 3½ hr. on exposure of a thin layer to March sunlight, or in 1 hr. on

exposure to an ultraviolet lamp, is of special interest because of the loss in insect-repellent properties involved after dimerization.

**Chemical reactivity of myosmine**, P. G. GAINES, A. EISNER, and C. F. WOODWARD. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 8, pp. 1258-1262).—Having obtained myosmine, 2-(3-pyridyl)- $\Delta^2$ -pyrroline, in fair yields by the pyrolysis of nicotine, the authors gave special attention in the investigation here noted to reduction products and to derivatives of 3-pyridyl- $\omega$ -aminopropyl ketone, the open chain hydrolytic product of myosmine.

It was shown that myosmine hydrolyzes readily to 3-pyridyl- $\omega$ -aminopropyl ketone in aqueous solution, whereas N-methylmyosmine is resistant to hydrolysis. Nicotine, hexahydronicotine, and octahydronicotine were prepared by the reduction of myosmine and by confirmatory syntheses. 3-(1,4-Diaminobutyl)-pyridine, 3-(4-aminobutyl)-pyridine, and 2-(3-pyridyl)-3-(2-aminoethyl)-indole dihydrochloride were also prepared.

**Acceleration by electrolytes of alkaline de-esterification of pectin**, H. LINEWEAVER. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 8, pp. 1292-1293).—The effects of sodium, calcium, and magnesium chlorides on the rate of de-esterification of pectin by alkali in aqueous solution were studied, these electrolytes, and especially their cations, having been found to accelerate the rate of alkaline de-esterification of pectin as much as 400 percent. This acceleration contrasts with the small effect of electrolytes on the rate of hydrolysis of simple esters.

The results led to the interpretation that the negatively charged carboxyl groups of pectin are close enough to the ester bonds to interact with the hydroxyl ions as they approach the ester bonds. The salt decreased the interaction (repulsion). As has been found for the primary salt effect in other systems, the acceleration of de-esterification of pectin by salt reflected largely a change in the entropy of activation rather than in the energy of activation.

**The enzyme activities of Pectinol A on pectin and other substances**, V. B. FISH and R. B. DUSTMAN. (W. Va. Expt. Sta.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 7, pp. 1155-1157).—A commercial enzyme preparation designated Pectinol A was found to contain about 91.5 percent sugar, principally dextrose and levulose. These sugars may be extracted with cold 80 percent ethanol, leaving an active sugar-free enzyme mixture. Using optical rotation and iodine reduction methods, the sugar-free Pectinol A was found to completely hydrolyze 10 times its weight of pectin to galacturonic acid in about 24 hr. at a temperature of from 37.5° to 40° [C.], while the pH of the reaction mixture changed from 3.6 to 2.8. The pectase activity of Pectinol A, Pectinol 1001, and two samples of sugar-free Pectinol A were found to be as follows: Pectinol A, 4.2; Pectinol 1001, 38.7; sugar-free Pectinol A<sub>1</sub> 47.0; and sugar-free Pectinol A<sub>2</sub> 30.6, all measured at 31° and pH 4.5. The optimal pH range for the pectase activity of these samples of Pectinol A was found to be from 4.3 to 4.6. It was found by optical rotation methods that sugar-free Pectinol A will bring about the hydrolysis of sucrose, starch, and maltose at 37.5° and pH 3.3. This enzyme showed only slight hydrolysis of inuline and gave no indication of hydrolysis of a suspension of xylan under these conditions.

**Physical constants of methyl esters of commonly occurring fatty acids: Vapor pressure**, P. M. ALTHOUSE and H. C. TRIEBOLD. (Pa. Expt. Sta.). (*Indus. and Engin. Chem. Analyt., Ed.*, 16 (1944), No. 10, pp. 605-606, illus. 2).—Methyl esters of caproic, caprylic, capric, lauric, myristic, palmitic, stearic, oleic, and linolic acids were obtained in a pure state by repeated fractional distillation. Vapor pressure curves and decomposition pressures and temperatures have been determined for each of the methyl esters. With the exception of the C<sub>18</sub> series, it was shown that an ester fraction can be identified and its purity ascertained by means of its vapor

pressure curve. With the aid of the decomposition data, it was possible to eliminate excess decomposition by controlling the pressure and hence the boiling temperature of fractional distillation.

**Nicotinic acid: Water-insoluble esters and amides**, C. O. BADGETT, R. C. PROVOST, JR., C. L. OGG, and C. F. WOODWARD. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 7, pp. 1135-1138).—The authors describe the preparation of 10 new esters and 13 new N-(n-alkyl) amides of nicotinic acid. Preliminary biological trials and determinations of the solubility data indicated that these new compounds may be suitable water-insoluble anti-pellagra materials for the fortification of food products which are rinsed prior to cooking. It is pointed out, however, that the actual value of the new compounds can be ascertained only by trials carried out under the conditions of their intended use.

**Gossypol as a carotene-protecting antioxidant, in vivo and in vitro**, E. L. HOVE. (Ala. Expt. Sta.). (*Jour. Biol. Chem.*, 156 (1944), No. 2, pp. 633-642, illus. 2).—Rats were fed a diet in which gossypol, dianilnogossypol, or  $\alpha$ -tocopherol were given as 1 mg. daily supplements in addition to 2 $\gamma$  of carotene and either 0.1 gm. of lard or 25 mg. ethyl linolate. Under the experimental conditions used, gossypol or cottonseed products containing this factor were nearly as effective as  $\alpha$ -tocopherol as an antioxidant. Cottonseed oil meal was equal to wheat germ in stabilizing a carotene solution in ethyl oleate, in vitro. The significance of these findings is discussed in relation to the toxic effect of cottonseed oil meal or other cottonseed products.

**The effect of temperature on the relative antioxidant activity of  $\alpha$ -,  $\beta$ -, and  $\gamma$ -tocopherols and of gossypol**, E. L. and Z. HOVE. (Ala. Expt. Sta.). (*Jour. Biol. Chem.*, 156 (1944), No. 2, pp. 623-632, illus. 2).—Employing the methods outlined above, the authors have studied the relative antioxidant activity of  $\alpha$ -,  $\beta$ -, and  $\gamma$ -tocopherol as influenced by various temperatures ranging from 40° to 98° C.

"At low temperatures the three compounds showed approximately equal activity, while at elevated temperatures the  $\gamma$ -tocopherol was several times more active than the  $\alpha$  form. This held true both for the protection of carotene against preformed fat peroxides and for the inhibition of peroxide formation in aerated ethyl oleate. . .

"A distinction is pointed out between antioxidant potency and activity. Evidence was obtained that at physiological temperatures  $\alpha$ -tocopherol had the greatest anti-oxygenic potency, followed in order by  $\beta$ - and  $\gamma$ -tocopherols and gossypol."

**Loss of furfural-yielding constituents from wheat straw on treatment with alcoholic and aqueous sodium hydroxide solutions**, H. D. WHITE and M. PHILLIPS (*Jour. Agr. Res. [U. S.]*, 72 (1946), No. 4, pp. 163-167).—In a study of the extent of the loss of furfural-yielding constituents at different stages in the isolation of the hemicelluloses of wheat straw, partial delignification of the straw with a 2-percent solution of sodium hydroxide in 50-percent ethanol caused a loss of furfural-yielding constituents which amounted to 7.79 percent of the total furfural. Wheat straw which had been partially delignified with a 2-percent solution of sodium hydroxide in 50-percent ethanol and then subjected to the successive action of cold 4-percent aqueous sodium hydroxide solution, cold 2-percent solution of sodium hydroxide in 50-percent ethanol, cold 4-percent aqueous sodium hydroxide solution, and finally boiling 4-percent aqueous sodium hydroxide solution, suffered little or no loss of furfural-yielding constituents.

**A comparison of the chemical composition of diploid and tetraploid corn**, G. H. ELLIS, L. F. RANDOLPH, and G. MATRONE. (U. S. D. A.). (*Jour. Agr. Res. [U. S.]*, 72 (1946), No. 3, pp. 123-130).—In certain stocks of corn (*Zea mays* L.), doubling the number of chromosomes was accompanied by an increase in the amount of nitrogen present in the grain and in the stover, the average increase being 15 percent in the grain and from 20 to 34 percent in the stover. The chemical com-

position of the grain in diploid and tetraploid maize was essentially the same with respect to ether extract, ash, and crude fiber. The diploid and tetraploid corn stover contained essentially the same relative amounts of ash, ether extract, and lignin. The higher crude protein ( $N \times 6.25$ ) content of the tetraploid stover was accompanied by a correspondingly lower content of crude fiber and cellulose.

The changes in chemical composition that accompanied the transformation from diploidy to tetraploidy are assumed to be due to the cumulative action of certain genes, notably those concerned with protein metabolism, and the noncumulative action of other genes.

**Comparative chemical studies on pea seed and canned soaked dry peas, V. B. BONNEY and H. FISCHBACH** (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 2, pp. 409-417, illus. 2).—No determinable invert sugar was found in the pea seed. All seed contained from 4.7 to 10.2 percent of sucrose. Appreciable proportions of the sugar, ash, and crude dextrin of the dry peas were leached out prior to canning; i.e., in the soaking and blanching phases. The drained liquor of the canned peas contained appreciable quantities of ash, protein, and sugar—more sugar than the drained peas. The pectic acid content of the drained canned peas did not differ sufficiently, among the varieties examined, to furnish a valuable objective test for varietal discrimination. Alcohol-insoluble solids, and the ratio of crude starch to protein, were found in much higher percentages in the Alaska peas than in any of the sweet, wrinkled varieties.

**Lactic acid in dairy products.—IV, Effect of storage of evaporated milk on lactic and formic acid production, on pH, and on acidity and formol titrations, I. A. GOULD, E. WEAVER, and R. S. FRANTZ.** (Mich. Expt. Sta.). (*Jour. Dairy Sci.*, 29 (1946), No. 1, pp. 33-40, illus. 4).—Preceding papers of this series (E. S. R., 94, p. 145) have dealt with microbiological changes and with effects of heat treatment at relatively high temperatures.

In the storage studies reported upon in the present paper, increases in lactic acid in evaporated milk stored at 35°, 70°, and 100° F. for 7 mo. averaged 1.1, 1.7, and 2.4 mg. per 100 gm., respectively. These small increases are considered to be, for all practical purposes, insignificant. Storage of the milk at 120° for 6 mo. resulted in an average lactic acid increase of 14.6 mg. per 100 gm., but at this time the milk had deteriorated far beyond the marketable stage. In an additional experiment in which evaporated milk was stored at 100° for 7 mo., lactic acid changes were again insignificant, but marked increases in titrable acidity and formic acid, accompanied by a decrease in pH, did occur. Titrations of oxalated samples indicated much larger acidity increases than were revealed by the standard titration procedure. Formol titrations were essentially unaffected by storage. Formic acid constituted a significant portion of the total acid produced in evaporated milk as a result of storage. Under the conditions of this experiment, and when the recovery of formic acid was corrected by retention, the increase in formic acid during storage was equivalent to 71.3 percent of the total acidity increase as determined by titration.

Limitations of the methods and possible applications of the findings are discussed.

**Lactic acid in dairy products.—V, The accuracy of the Hillig method in determining lactic acid in heated milk, I. A. GOULD** (*Michigan Sta. Quart. Bul.*, 28 (1945), No. 2, pp. 115-118).—This is a continuation of the series noted above. To determine if high temperature heat treatment interferes with the Hillig method of measuring lactic acid (E. S. R., 78, p. 447), milk was permitted to develop acidity, then was neutralized with disodium phosphate and heated in sealed cans for 1- and 2-hr. periods. Lactic acid determinations were made before and after heating.

The results showed that the lactic acid content of the milk before and after heating was only slightly different, the lactic acid being slightly higher in the heated milk as a result of the heat treatment. It is concluded that the accuracy of the

Hillig lactic acid method in measuring the lactic acid content of milk is not affected by subjecting the milk to high temperatures prior to the determination. These results are in agreement with previous findings (see preceding abstract), which showed that heat treatment of milk produces only small increases in lactic acid in comparison to the total acidity change created.

**Preservative, chemical, and bacteriological effect by hypochlorite solution added to milk,** G. H. GAUSER and W. H. KING (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 2, pp. 417-424, illus. 4).—Experimenting upon a single lot of milk, the authors concluded that under the conditions of the experiments the addition of hypochlorite to fresh milk may appreciably reduce the bacteria count whether or not there is subsequent pasteurization, and that hypochlorites in quantities having little or no effect on flavor may exert a slight but definite preservative effect. More than 10 p. p. m. had to be added to the milk before the Rupp test became positive. Proper use of sterilizing solutions would not result in a positive Rupp test in market milk.

**Low pressure-low temperature system for decomposition studies in food,** H. FISCHBACH (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 3, pp. 639-643, illus. 1).—A new technic for the study of decomposed foods, based on a low temperature-low pressure system with suitable chemical and cold traps, permitted separation of very weakly dissociated volatile bases ( $K$  as low as  $10^{-10}$ ) from those more strongly dissociated, together with separation of neutral volatiles, was possible in one operation. In like manner volatile acids could be separated from non-acidic material.

**Experimental studies on decomposition of oysters used for canning,** W. H. KING, F. F. FLYNN, and J. N. GOWANLOCH (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 2, pp. 385-398, illus. 1).—A detailed report of a study of spoilage of raw and of canned oysters is accompanied by directions for a steam-distillation method for determining indole, this compound being extracted from the steam-distillate and determined by a modification of the usual *p*-dimethylaminobenzaldehyde test.

**Persistence of monochloroacetic acid in wine,** J. B. WILSON (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 3, pp. 627-633).—It was found that monochloroacetic acid does not hydrolyze when added to wine at any point during the process of manufacture, and the quantities added remained unchanged even after 2 yr. of storage. When fermentable sugars were present, the addition of 0.01 percent of monochloroacetic acid did not prevent secondary fermentation of wine containing more than 12 percent of alcohol by volume, nor did the addition of 0.05 percent to wine containing less than 12 percent.

**The chemical composition of technical DDT,** H. L. HALLER, P. D. BARTLETT, N. L. DRAKE, M. S. NEWMAN, S. J. CRISTOL, C. M. EAKER, R. A. HAYES, G. W. KILMER, B. MAGERLEIN, G. P. MUELLER, A. SCHNEIDER, and W. WHEATLEY. (U. S. D. A., Univ. Md., Ohio State Col., et al.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 9, pp. 1591-1602).—These authors report a study of the composition of several samples of technical DDT and a sample of "byproduct oil" recovered from a process of refinement of crude DDT prepared from "chlorinated alcohol" and chlorobenzene. Technical DDT was found to contain upward of 70 percent of 1-trichloro-2,2-bis-(*p*-chlorophenyl)-ethane (*p,p'*-DDT, the most active insecticidal ingredient. The major impurity is 1-trichloro-2-*o*-chlorophenyl-2-*p*-chlorophenylethane (*o,p'*-DDT). Lesser amounts of 12 other organic impurities were found, the presence of which may be explained on the basis of side reactions involving chloral, chlorobenzene, sulfuric acid, and impurities in the starting materials. Work on the proof of structure, including synthesis of the byproduct materials, is described. The synthesis of all the isomeric dichlorobenzophenones with one chlorine atom on each ring and of the 2,4-dinitrophenylhydrazones of these ketones is described.

**Optical crystallographic properties of DDT,** E. L. GOODEN. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 9, pp. 1616-1617).—The compound referred

to in this use of the term DDT is the purified single isomer, 1,1,1-trichloro-2,2-bis-(4-chlorophenyl)-ethane. The optical crystallographic characteristics observed are thus described: "Habit (from ethanol): needles or long prisms, more or less flattened, with elongation parallel to Y (vibration direction for  $\beta$ ). Refractive indices (sodium light):  $\alpha$ , 1.618;  $\beta$ , 1.626;  $\gamma$ , 1.755. Optical character positive, shown decisively both by refractive indices and by the selenite plate. Sign of elongation variable, depending on the position at which the rolling needle comes to rest, since the lengthwise apparent index is  $\beta$  and the other may be either above or below. Optic axial angle calculated from refractive indices,  $30^\circ$  [C.]; agrees with Bertrand lens measurements within normal observational error. Extinction, in general, parallel to crystal length; thorough study of extinction angles complicated by marked tendency to twinning. Crystal system probably orthorhombic; which is in agreement with X-ray diffraction evidence reported by others."

**A kinetic study of the dehydrochlorination of substituted 2,2-diphenylchloroethanes related to DDT, S. J. CRISTOL.** (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 9, pp. 1494-1498, illus. 3).—This study concerns the dehydrochlorination with sodium hydroxide of 11 2,2-diarylchloroethanes related to DDT. The reactions were found to be of the second-order  $E_a$  type. The effects of changes in solvent and of increase from chloromethyl to dichloromethyl and trichloromethyl in one group of compounds were shown to be as predicted for the  $E_a$  type. The experimental values of reaction rate constants for eight diaryltrichloroethanes with para substituents were found to be in fair agreement with those predicted by theory. The scale of the deviations suggested, however, that there may be necessary a slight difference in treatment of disubstituted-diaryl derivatives as compared with monosubstituted-diaryl derivatives.

The rate constant for the *o,p'*-DDT isomer, which is the principal impurity in technical DDT, was shown to be 1/67 that of the *p,p'*-DDT isomer, which is the principal insecticidal agent.

**sym-Tetraphenylethane from DDT and related compounds, E. E. FLECK, R. K. PRESTON, and H. L. HALLER.** (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 8, pp. 1419-1420).—In an investigation of the effect of various solvents upon the dehydrochlorination of 1,1,1-trichloro-2,2-bis(4-chlorophenyl)ethane ("DDT"), the authors observed an abnormal reaction with anhydrous aluminium chloride and benzene, one molecular equivalent of aluminium chloride in the presence of a large excess of benzene causing the evolution of approximately two equivalents of hydrogen chloride in a reaction which appeared to be of the Friedel-Crafts type. From an experiment, described in some detail, in which about a 10 percent yield of tetraphenylethane and unidentified colored substances were produced, it is concluded a number of competing reactions were involved. Several compounds related to DDT gave similar results.

**Isolation of rutin from *Hydrangea paniculata*, var. *Grandiflora* sieb, J. F. COUCH and J. NAGHSKI.** (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 8, p. 1419).—This paper reports the isolation and identification of rutin 3,5,7,3',4'-pentahydroxyflavone-3-rutinoside in the flowers of a common garden species of *Hydrangea*. The presence of rutin in relatively large quantities in the flowers has not previously been reported.

**Constituents of the insecticidal resin of the yam bean (*Pachyrrhizus erosus*) L. B. NORTON and R. HANSBERRY.** (N. Y. State Expt. Sta.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 9, pp. 1609-1614, illus. 1).—The ether extract of yam beans was separated into a nontoxic oil and a resin toxic to insects. The resin, fractionated by chromatographic methods, yielded one noncrystalline and six crystalline compounds and three heterogeneous fractions. One of the crystalline compounds was identified as rotenone, and a second, designated "erosone," was shown to be closely related to

elliptone. Four of the compounds showed evidence of a relation to the rotenoid structure, but differed in containing a single methoxyl group. Three of the compounds and one of the heterogeneous fractions were toxic to the silkworm, but two of these compounds were of low toxicity to the Mexican bean beetle. The toxic heterogeneous fraction probably contained at least one toxic compound not isolated.

**A simplified conductometric titration apparatus**, E. M. BURAS, JR., and J. D. REID. (U. S. D. A.). (*Indus. and Engin. Chem. Analyt., Ed., 16 (1944), No. 9, p. 591, illus. 1*).—In a set-up considered by the authors to be one of the simplest available for such titrations, the voltage is adjusted to a constant value after each addition of titrating solution and the current passing through the conductivity cell is measured. By plotting milliliters of solution added against milliamperes, a typical conductometric curve is obtained. By the use of a constant-voltage transformer and an alternating-current milliammeter, the authors eliminated the adjustment of a fluctuating voltage with a potentiometer, reading this on a voltmeter, and simultaneously reading the milliammeter.

**Washing Selas filtering crucibles by reverse flow**, E. J. BENNE. (Mich. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed., 16 (1944), No. 4, pp. 277-278, illus. 1*).—To provide for the reversed-flow washing of the porous-bottom type of filtering crucible, the author fits the top of the reversed crucible into a circular groove in the top of a rubber stopper in a filter flask, and provides a reservoir for the washing liquid by fitting onto the bottom of the crucible a rubber pipette bulb cut at one end with a cork borer to fit the crucible and at the other end with scissors. It is noted that a short length of Gooch-crucible tubing would also serve this purpose. Some supplementary devices are indicated in a photograph reproduced with the note.

**Device for rapid closing of weighing bottles**, S. M. CHASTAIN. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed., 16 (1944), No. 9, p. 579, illus. 2*).—The device here described and figured consists essentially of two plates, the upper holding the stoppers of a considerable number of bottles, the lower plate keeping the bottles in fixed positions. The top plate, by means of which all of the bottles are simultaneously opened or closed, is drilled at one end to fit a guide post fixed in a corresponding position in the lower plate. In the oven, the plates rest on the brackets designed to hold the oven shelves.

**Apparatus for the determination of volatile citrus oils**, E. T. BARTHOLOMEW and W. B. SINCLAIR. (Calif. Citrus Expt. Sta.). (*Jour. Assoc. Off. Agr. Chem., 28 (1945), No. 2, pp. 339-345, illus. 1*).—The apparatus here described and figured was found to reduce to a minimum opportunities for vaporized oil to escape, or for condensed oil to adhere to the condenser where it cannot be washed down. The condensed oil remained in a single small mass; it was not broken into droplets by the dripping effect of condensed liquids or by puffs of air originating in the distilling flask. The apparatus was so constructed that puffs of air did not tend to drive the condensed oil down into the water in the receiving flask, or to evaporate it. The calibrated measuring tube was long enough so that comparatively large amounts of oil, as well as small amounts, could be measured accurately. All inner walls of the apparatus were readily accessible for cleaning. Results of determinations of volatile oils in samples of lemon peel were presented to demonstrate the usefulness and accuracy of the apparatus.

**Elimination of nitrate impurities from 30 percent hydrogen peroxide**, E. C. CANTINO. (Univ. Calif.). (*Indus. and Engin. Chem., Analyt. Ed., 16 (1944), No. 3, pp. 181-182, illus. 1*).—The author finds the available hydrogen peroxide of 30 percent strength to contain about 200 p. p. m. of nitrate, and distillation under reduced pressure to reduce the peroxide content to a concentration seldom over 20 percent. Removal of the greater part of the nitrate impurity could be effected, however, by drawing the reagent through suitably separated layers of an activated carbon. A

water-cooled adsorption column was found to be required for the purification. A suitable apparatus is described and figured. This column is represented as 3 cm. in diameter, 45 cm. long in its water-jacketed portion, with additional head and foot-space, and packed loosely with 5- to 10-gm. portions of a specified commercial type of activated carbon separated by layers of glass beads, glass-wool plugs, and perforated porcelain plates. In an apparatus of the form and dimensions specified, a percolation rate of 200 cc. per minute was the most effective. A charge of 35 gm. of the activated carbon sufficed for the purification of more than 500 cc. of the peroxide reagent. The nitrate content was reduced to less than 10 p. p. m., and the concentration of the purified reagent was about 27 to 29 percent, which was found sufficient for the oxidation of the organic matter of plant tissue of which the nitrate content was to be determined.

**Working with the microscope**, J. D. CORRINGTON (*New York and London: McGraw-Hill Book Co., 1941, pp. 418+, illus. 121*).—The author notes that most books on microtechnic are either "rankly juvenile and unscientific . . . or they are highly professional and technical, designed for the upper collegiate level, and presupposing some classroom supervision." Stressing the need of the serious amateur for a more suitable book, the author announces his purpose as to provide "a graded series of exercises in the mounting of materials for observation under the microscope. Beginning with the simplest and proceeding by easy stages to advanced operations, the explanations have been made as detailed and nontechnical as possible." In accordance with this purpose, the treatment of the technic of the microscope itself is rudimentary, but the preparation exercises grade upward to highly skilled technics. The book also contains useful hints on finding and identifying botanical and zoological material and clear directions for dissecting out required parts, usually neglected in manuals of microtechnic.

The contents are, in part: The microscope; temporary mounts for immediate study; simple balsam mounts; procedures in microtechnic; processed balsam mounts; cell mounts; stained whole mounts; smear preparations; bacteria; microscopic skeletons, grinding hard objects; sectioning—manual and freezing methods, celloidin method, and paraffin method; the newer technics; special preparations; preparation and use of reagents; sources of supplies; literature of microtechnic; reference tables; and index.

**Anilin oil-methylene blue stain for the direct microscopic count of bacteria in dried milk and dried eggs**, W. R. NORTH (*Jour. Assoc. Off. Agr. Chem., 28 (1945), No. 2, pp. 424-426*).—The staining of smears with a staining reagent made up of 3 cc. of aniline, 10 cc. of 95 percent alcohol, 1.5 cc. of hydrochloric acid added slowly to the alcoholic aniline solution, 30 cc. of saturated alcoholic solution of methylene blue, and water sufficient to make a total volume of 100 cc., resulted in deeply stained organisms and a very pale blue background. The numbers counted were very much higher than those found by the use of the 1 percent alcoholic methylene blue without acid or aniline, and exceptionally close agreement among the counts made by several observers was obtained.

**Color measurement and its application to the grading of agricultural products: A handbook on the method of disk colorimetry**, D. NICKERSON. (*U. S. Dept. Agr., Misc. Pub. 580 (1946), pp. 62+, illus. 47*).—This publication is intended (1) as a general introduction to the subject of color measurement, especially in its application to grading work (as in the grading of food products of various types, and of cotton, hay, etc.), and (2) as a handbook of the special method of disk colorimetry (E. S. R., 62, p. 503) in its various forms. Abundant references to original papers and standard works are given, "in order that students who care to do so may become familiar with a general background of authoritative information on problems involving color measurement and specification." Following the very brief introduction, the contents

are: Color-grading problems; color charts in grading work; transparent-color standards in grading work; standards need measuring; several methods of expressing results of color measurement (International Commission on Illumination method of color notation, homogeneous-heterogeneous method of color notation, Munsell method of color notation, and relation between methods); disk colorimetry (early method, present method, instruments, choice of disks, and conversion to Munsell notation); application of disk colorimetry to grading problems (sample preparation and preparation of conversion data); applications of Munsell notations in related problems; the Kelly mask method for color matching; standard names for colors; American Standards Association standard for the specification and description of color; color-tolerance specifications; artificial daylighting for grading work; color-vision testing; and literature cited.

**Fluorimetry:** The estimation of the concentration of fluorescent pigments from their fluorescence intensity, P. ELLINGER and M. HOLDEN (*Jour. Soc. Chem. Indus., Trans. and Commun.*, 63 (1944), No. 4, pp. 115-121, illus. 6).—A detailed discussion is presented on the principles of fluorimetric determinations, including the relative accuracy of various methods, influence of concentration of the solution, position and shape of the container, intensity and absorption of the primary light beam, and various other factors. Both direct deflection and balancing methods were used. The solutions studied included thiochrome, chlorophyll, uranine, riboflavin, and quinine sulfate in various solvents.

**Accelerated method for determining moisture absorption,** J. Y. YEE and R. O. E. DAVIS. (U. S. D. A.). (*Indus. and Engin. Chem. Analyt. Ed.*, 16 (1944), No. 8, pp. 487-490, illus. 4).—The authors point out that the ordinary procedure, consisting essentially in exposing the samples in weighing bottles or on watch glasses in an enclosed space over a solution designed to give the desired relative humidity, usually produces results neither consistent nor reproducible. An accelerated method for the moisture-absorption measurements is described, one of the essential features of which consists in the use of a humidifying chamber provided with a four-bladed aluminum fan rotating in a plane parallel with the surface of the humidity-standard liquid and directly over it. Factors such as temperature, the size, depth, and number of dishes, and the arrangement in the humidity chamber were found to influence the final results. Careful standardization of all conditions, therefore, is essential in order to obtain reproducible results. Devices introduced for this purpose include sample dishes and covers of standardized form and size, an instrument for the uniform spreading of the sample dish, and a leveling device, designed to be placed on the sample under an additional weight of 1 kg., to give the sample a uniformly smooth surface and uniform packing. Considerable time can be saved by the accelerated method in making equilibrium moisture-absorption measurements of fertilizers.

**Determination of large amounts of manganese: Modified persulfate method,** H. D. HILLSON. (Univ. Maine). (*Indus. and Engin. Chem. Analyt. Ed.*, 16 (1944), No. 9, pp. 560-562).—In a study of the reaction of ammonium persulfate with manganous salts in acid solution, it was discovered that by the addition of disodium hydrogen phosphate, the manganese can be oxidized and the excess persulfate decomposed by boiling. By the use of osmic acid, the permanganate may be stoichiometrically titrated with sodium arsenite solution. These modifications adapt the persulfate method to the accurate determination of manganese in concentrations larger than it has been possible heretofore to deal with and extend the usefulness of the procedure. A further necessary modification consisted in the establishment of carefully specified conditions for the heating by which the excess persulfate is decomposed, such that removal of the persulfate is complete without concomitant decomposition of any of the permanganate. Full manipulative detail of the determination is given.

**Some checks on methods and solutions used in the analysis of fertilizers,** H. R. ALLEN. (Ky. Expt. Sta.). (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 2, pp. 345-351).—Averages of results of analyses of the Magruder check samples showed that the overall variations between different analysts are too great. Procedures for checking nitrogen, phosphoric acid, and potash determinations on standard samples are given, and reasons for some variations in results are stated. Advantages of using the normality of the standard alkali as determined by titration in the same buret used in the routine nitrogen determination are pointed out. It was shown by analysis of standard samples that high results may be obtained with the A. O. A. C. volumetric method for phosphoric acid when sulfuric acid is used for solution of sample. Differences of about 1 percent potassium oxide could be obtained in analysis of reagent grade potassium chloride by varying the strength of the alcohol from 80 to 95 percent and by varying the amount of washing. An acid alcohol prepared with 84 percent alcohol and 84 percent washing gave theoretical results. A procedure for preparing the neutral ammonium citrate solution at the prevailing room temperature by determining the ammonia and citric acid contents is given. This served to standardize the hydrometer at this same temperature.

**Titritative determination of the neutralization value of calcium silicate slags,** W. M. SHAW. (Tenn. Expt. Sta.). (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 2, pp. 310-335, illus. 6).—Solution of 0.5 gm. samples of blast furnace slags was found to be effected by boiling 5 min. in 35 cc. of 0.5 N acid; but 25 cc. of such acid, though containing 30 percent in excess of the acid required by the calcium and magnesium content of most slag samples, failed to effect solution of samples of a high aluminum content even when the digestion was prolonged. Titration curves for solutions of calcium silicate, containing aluminum chloride, demonstrated that the equivalence pH is governed by the ratio of  $\text{SiO}_2:\text{Al}_2\text{O}_3$  in the titrated system. In general, the equivalence pH of the blast furnace slag solutions fell within the range of pH 4.8-pH 5.4. Fluorine content was the chief cause of irregularity in the titration curves for phosphate furnace slags, the equivalence pH of which developed in the region between pH 6 and 8, wherein the aluminosilicate precipitate exerted considerable cation sorption. Phenolphthalein gave an error of about -6 percent in the slag titrations, methyl orange an error of +6 to +24 percent. Titration to pH 5.2 with bromocresol green gave only approximate values. Undissolved matter and precipitates formed during titration impaired the clarity of indicator end-point observation.

Two procedures are proposed to obviate both direct titration, technic and complete analysis of slags. One procedure directs the dissolution of the slag in acetic acid, dehydration of silica and its elimination jointly with  $\text{R}_2\text{O}_3$ , evaporation of the acetate solution, ignition, and titration of the resultant calcine. The other prescribes dissolution in hydrochloric acid, joint elimination of silica and  $\text{R}_2\text{O}_3$ , evaporation of filtrate with nitric acid, oxalate precipitation and ignition, and titration of the calcine. The first-mentioned procedure was found especially applicable to slags that contain fluorides and phosphates, and to slags in general when complete acetic acid dissolution of the charge is effected. The last-mentioned procedure was found appropriate for slags devoid of fluorides and phosphates.

**Further studies of the molybdenum blue reaction,** R. E. KITSON and M. G. MELLON. (Purdue Univ.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 7, pp. 466-469, illus. 3).—As a result of a spectrophotometric study of the determination of phosphorus, a modified A. O. A. C. procedure is presented. The new procedure was found to give solutions of greater color stability and of equal color intensity. The work included a determination of the effects of the following variables: Reagent concentration, temperature of color development, order of addition of reagents, phosphorus concentration, and 60 diverse ions.

**Application of a modified red-color test for rotenone and related compounds to *Derris* and *Lonchocarpus*.** M. A. JONES. (P. R. Fed. Expt. Sta.). (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 2, pp. 352-359, illus. 1).—The author describes modifications of the red-color test for rotenone and related compounds present in samples of plant material. The analysis of mixed plant extracts by differential spectrophotometric analysis of the red-color test was found impracticable. The ratio of rotenone content to red-color value as observed in root samples of *Derris* and *Lonchocarpus* was measured. The applicability of the red-color test to the analysis of small samples and in plant selection is discussed.

**Determination of thiocyanate nitrogen in organic thiocyanates and mixtures.** J. W. ELMORE (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 2, pp. 363-371).—For the analysis of insecticidal sprays and dusts containing organic thiocyanates, the author proposes a method consisting essentially in the decomposition of the organic combination by treatment with an aqueous sodium polysulfide solution at 70° C., separation of the thiocyanate radical as cuprous thiocyanate, and determination of the nitrogen content of this copper salt by the Kjeldahl method, the percentage of the organic thiocyanate being calculated from the thiocyanate nitrogen.

**Determination of carbon-linked methyl groups.** W. F. BARTHEL and F. B. LAForge. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 7, pp. 434-435, illus. 1).—The terminal-methyl determination of Pregl for carbon-linked methyl groups was modified for more rapid determinations. The terminal-methyl number, or the number of mole equivalents of acetic acid produced from a mole equivalent of substance, was determined for certain reference compounds. Detailed dimension specifications for the refluxing and distillation apparatus to be used are shown in a diagrammatic drawing.

**Determination of citric acid in fermentation media and biological materials.** D. PERLMAN, H. A. LARDY, and M. J. JOHNSON. (Wis. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 8, pp. 515-516).—The authors modified the method of Pucher, Sherman, and Vickery (*E. S. R.*, 76, p. 585) to obtain greater rapidity without sacrifice of the accuracy of the original procedure. The altered technic was found to be satisfactorily adapted to the determination of the citric acid content of fermented media and of tissue extracts.

**Quantitative determination of extractable gossypol in cottonseed and cottonseed meal: A spectrophotometric method.** C. H. BOATNER, M. CARAVILLA, and L. KYAME. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 9, pp. 566-572, illus. 4).—The authors point out that the reaction of gossypol with antimony trichloride in ether and chloroform extracts of cottonseed is specific and the reaction product is sufficiently stable to permit accurate spectrophotometric determination of the gossypol concentration of such extracts. A rapid direct method for determination of free gossypol in cottonseed is reported, the gossypol being extracted by equilibrating ground cottonseed and chloroform, treating the extract with concentrated hydrochloric acid, and applying the antimony trichloride reaction directly to the treated extract.

**Investigations of amino acids, peptides, and proteins, XVIII-XX** (Univ. Calif. et al.). (*Jour. Biol. Chem.*, 156 (1944), No. 2, pp. 703-724, illus. 22; 157 (1945), No. 1, pp. 387-394).

XVIII. *The amino acid requirements of *Leuconostoc mesenteroides* P-60.* M. S. Dunn, S. Shankman, M. N. Camien, W. Frankl, and L. B. Rockland (pp. 703-713).—Continuing the investigations of Dunn et al. (*E. S. R.*, 93, p. 677) on the use of micro-organisms in the assay of amino acids, the authors have studied the nutritional requirements of *L. mesenteroides* P-60. In the basal medium tested, 21 amino acids were substituted for the casein hydrolysate fraction. Varying concentrations of these amino acids were tried in an attempt to determine the optimum concentration

needed. Preliminary results indicated that alanine, hydroxyproline, norleucine, and norvaline were nonessential or auxiliary growth substances. From the standard curves obtained from these experiments, the authors conclude that the method might be useful in the assay of a number of amino acids.

**XIX. The determination of lysine in protein hydrolysates by a microbiological method**, M. S. Dunn, M. N. Camien, S. Shankman, W. Frankl, and L. B. Rockland (pp. 715-724).—The method described above has been applied to the assay of 1(+)-lysine in protein hydrolysates. Casein and silk fibroin were found to contain 8.3 and 0.6 percent, respectively, of lysine. Comparisons of these data with values obtained by other methods of assay are made, and the relative accuracies of the various methods are discussed. The authors consider this method to give results of satisfactory precision and accuracy.

**XX. The determination of apparent free tryptophan in blood by a microbiological method**, M. S. Dunn, H. F. Schott, W. Frankl, and L. B. Rockland (pp. 387-394).—Based upon the *Lactobacillus arabinosus* assay for nicotinic acid of Snell and Wright (E. S. R., 87, p. 12), a method has been devised for the determination of tryptophan in tungstic acid filtrates of blood fractions.

Results indicate that the apparent free tryptophan content of human blood fractions averages 1.21 mg. percent for serum (5 samples), 1.14 mg. percent for plasma (10 samples), and approximately one-fifth of these values for blood cells. The apparent free tryptophan content of plasma or serum is considered to be approximately 1 percent of the total tryptophan content of serum.

The authors conclude tentatively that "the tryptophan values for plasma and serum are correct in order of magnitude and may be accurate to within about 10 percent."

**Separation of amylose and amylopectin by certain nitroparaffins**, R. L. WHISTLER and G. E. HILBERT. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 7, pp. 1161-1165).—In addition to alcohols, representatives of many different classes of organic compounds such as esters, ketones, mercaptans, carboxylic acids, nitroparaffins, and pyridine, which are capable of forming hydrogen bonds with amylose, were found to form complexes with this carbohydrate and can serve as agents for fractionating starch.

"Crystalline" amylose-nitroparaffin complexes were formed when starches were fractionated with nitroethane, 1-nitropropane, and 2-nitropropane. The yields of amylose, using 1-nitropropane and 2-nitropropane as fractionating agents, from cornstarch, potato starch, tapioca starch, and wheat starch are about the same as those obtained using butanol. Some of the properties of amylose-nitroparaffin complexes are described. The X-ray diffraction patterns of the three nitroparaffin complexes were identical. The amylose fractions were characterized by potentiometric iodine titration, retrogradation, and the film-forming properties of the triacetate derivative.

**Determination of dextrose, levulose, invert sugar, and sucrose-invert sugar mixtures by copper reduction, using citrate-carbonate reagent**, R. F. JACKSON and E. J. McDONALD (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 2, pp. 371-385, *illus.* 4).—In general, and in harmony with previous experience with the carbonate method, it is concluded that this method is inferior in respect of precision to the methods in which caustic alkali is a constituent of the copper reagent. It is, however, valuable, because of its convenience for rapid work that does not require a precision greater than 0.5 percent. It is particularly useful to those who make only occasional analyses, since if care is taken to preserve the standard iodate solution no further standardization is required.

**An observation of possible value for sugar determinations**, D. L. MORRIS (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 8, p. 537).—In adapting for use in micro-determinations of glucose a copper sulfate + sodium acetate reagent,

the author added potassium iodide. He found that when this iodide-containing reagent was heated with a glucose solution a precipitate which could be identified as cuprous iodide was formed, and that the speed of the reduction reaction was increased. The cuprous iodide precipitate could be determined either iodometrically in the solution or by separating and weighing the cuprous iodide directly. The weight of the cuprous iodide precipitate was shown to be of the order of 10 times that of the glucose oxidized. The possible value of this observation in the determination of sugars is pointed out.

**Quantitative method for determination of maltose in the presence of glucose,** H. H. BROWNE. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 9, pp. 582-583).—The authors base a polarimetric method on the fact that the optical rotation of glucose may be reduced to zero by addition of a sufficient quantity of soluble bisulfite, but the rotation of maltose and dextrans is affected only very slightly. The rotation of lactose and other reducing sugars is also lowered by the presence of bisulfites, and the rotation of the sugar alcohols is unaffected. The speed and accuracy of this method are comparable with those of polarimetric determinations in general, but the sensitiveness is somewhat less.

To establish a graph from which the maltose percentages could be read or determined by multiplying the polarimeter readings by the tangent of the line, the authors prepared a series of seven solutions, each solution containing 10 gm. of total sugar and not less than 75 cc. of water. The proportion of glucose to maltose was 10 gm. to 0, 8 to 2, 6 to 4, 5 to 5, 4 to 6, 2 to 8, and 0 to 10. To each of seven sugar flasks graduated to 110 cc. were added 30 gm. of sodium metabisulfite or its equivalent of sodium bisulfite, and one of the sugar solutions was transferred to each. The flasks were shaken to dissolve the metabisulfite, cooled at 20° C., the contents made up to a volume of 110 cc. with distilled water, mixed, and polarized at 20°. The length of the polariscope tube did not need to be specified, but had to be the same for all determinations. The observed rotations were then plotted against the percentage of maltose and lay practically on a straight line defined by these points. The percentage of maltose present could be determined by referring the readings to the graph or by multiplying (° S.) by the tangent of the line, in the experiments here reported.

**Separation and identification of the volatile saturated fatty acids (C<sub>1</sub> to C<sub>4</sub>),** L. L. RAMSEY and W. I. PATTERSON (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 3, pp. 644-656, illus. 5).—The volatile acids are separated on a chromatographic partition column of silicic acid, saturated with an aqueous solution of a suitable indicator, using butanol-chloroform as the second solvent. Formic, acetic, and propionic acids are separated completely from one another, but *n*-butyric and isobutyric acids are obtained together, although free of their homologs. Positive identification of all the acids except isobutyric is based upon the microscopic examination of a characteristic crystalline salt. Identification of isobutyric acid is based upon its oxidation to acetone by acid potassium permanganate.

**Determination and detection of dichloroacetic acid in food products,** C. F. BRUENING (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 3, pp. 620-627).—A method designed for application to food products consisted essentially in extracting the acid with ether, converting the organically combined chlorine to the ionic condition by ignition of the extract with sodium carbonate or by hydrolysis with alcoholic potassium hydroxide solution, and Volhard titration of the resulting soluble chloride.

**Determination of 2,3-butylene glycol in fermentations,** M. J. JOHNSON. (Wis. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 10, pp. 626-627).—The butylene glycol was separated from the culture by continuous extraction with ether, water was added to the extract, the ether was evaporated, and the glycol was oxidized to acetaldehyde by boiling with periodate and dilute sulfuric acid. The

acetaldehyde was absorbed in a standard bisulfite solution, and the excess bisulfite was determined iodometrically. There was little interference from constituents of culture media. From 2 to 10 mg. of butylene glycol were required.

**Extraction and estimation of carotene from foodstuffs,** V. H. BOOTH (*Jour. Soc. Chem. Indus., Trans. and Commun.*, 64 (1945), No. 6, pp. 162-169, illus. 4).—A detailed description is given of the method evolved to eliminate many of the difficulties still present in the determination of carotene in foodstuffs. A discussion is included of the other methods used, the modifications tried, or sources of error introduced (47 references are listed). The method is recommended by the author for its simplicity, accuracy, speed, and avoidance of emulsion. "No distinction is made between  $\alpha$ -,  $\beta$ -, and  $\gamma$ -carotenes, but lycopene, kryptoxanthin, and carotenoid esters are eliminable." Emphasis is laid on: (1) The minimization of mechanical damage by the rapid extraction of the sample by maceration with quartz under a solution of 3 : 2 light petroleum-acetone containing 0.1 percent quinol; (2) the removal of water-soluble substances by continuous washing (in an apparatus described and illustrated); (3) the removal of unwanted pigments by one of two methods (a) chromatographic adsorption on a specially prepared aluminium oxide-anhydrous sodium sulfate mixture followed by elution with 1.2 percent acetone in light-petroleum ether, or (b) extraction of the washed solution by diacetonol alone, or, following cold saponification, with a mixture of propanol and methanol and saturated aqueous potassium hydroxide.

Comparative tests with various other methods leads the author to state "this method gives higher results than a typical alkaline digestion method. The destructive effect of hot alkali is proved. Higher values than those in the literature are obtained for carrots and for grass. Recovery tests yield an average of 98.7 percent. Accuracy and recovery tests have an average coefficient of variation of 1.5. Both esters and lycopene are excludable. Eighteen estimations can be completed in an 8-hr. day."

**Determination of carotene in dehydrated alfalfa: A simplified method,** R. E. SILKER, W. G. SCHRENK, and H. H. KING. (*Kans. Expt. Sta.*). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 8, pp. 513-515).—In a procedure which combined much improved simplicity and rapidity with an accuracy equal to or better than that of other methods with which it was compared, a simplified method was developed for the determination of carotene in dehydrated alfalfa. The finely ground alfalfa was allowed to stand for 16 to 18 hr. in a mixture of acetone and a commercial light-petroleum solvent, the extract was concentrated on a steam bath to remove the acetone, the pigments were adsorbed by drawing the mixture through a magnesia column, and the carotene was then eluted with a 4 percent solution of acetone in the light-petroleum solvent above specified. Refluxing and phasic separations were avoided, and many more samples could be handled per day than by other methods in common use.

**Simplified procedure for estimation of total carotenoids in carrots,** V. H. BOOTH (*Jour. Soc. Chem. Indus., Trans. and Commun.*, 64 (1945), No. 7, pp. 194-196, illus. 3).—A detailed illustrated description is given of two methods used in obtaining small representative samples from carrots. Narrow disks are cut at several levels of the carrot, and small sectors are removed from each disk; or small holes are bored diagonally through the carrot at different levels, and the cylinders removed and analyzed.

The above assay method has been adapted and simplified for measuring total carotenoids in carrots. The author bases his modification on the assumption that, in mature carrots, carotene ( $\alpha + \beta$  and other isomerides) approximates 90 percent of the total carotenoids. The carrot samples are ground with quartz in a 3 : 2 light petroleum-acetone solution. If the extract solution is clear, it may be used directly in a photometer where the reading obtained corresponds to the total amount of carotenoids present.

A method for estimating total fat-soluble antioxidants based on the relation between fat peroxides and carotene destruction, E. L. and Z. HOVE. (Ala. Expt. Sta.). (*Jour. Biol. Chem.*, 156 (1944), No. 2, pp. 611-621, illus. 2).—This method, developed for estimating total fat-soluble antioxidants, is based upon the protection of carotene against preformed fat peroxides. Best results were obtained when a concentration equivalent to 160 gm. per liter of peroxidized peanut oil in Skellysolve E and a carotene concentration of 1.2 mg. per liter were used.

Tests with  $\alpha$ -,  $\beta$ -, and  $\gamma$ -tocopherols, or mixtures of the three, and gossypol, showed them all to be essentially equivalent in protecting carotene against preformed fat peroxides. Cholesterol and lecithin were inactive. Dry yeast and rat liver, as well as peanut, cottonseed, soybean, and corn oils, also were tested for their antioxidant activity.

**Polarographic determination of vitamin C in fruits and vegetables**, W. S. GILLAM. (Ind. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 4, pp. 217-221, illus. 4).—Advantages of the described polarographic method are listed as follows: After initial calibration, no standardization of solutions is necessary; if oxalic acid is the extracting agent, all solutions used are relatively stable; no pretreatment of the extract is needed; and neither suspended matter nor colored substances will normally interfere with the reaction.

Diffusion current constants, half-wave potentials, and diffusion coefficients were calculated for the four supporting electrolytes used: (1) Potassium biphthalate buffer and oxalic acid; (2) phosphate buffer in metaphosphoric acid; (3) biphthalate buffer and oxalic acid in alcohol; and (4) biphthalate buffer in metaphosphoric acid.

Vitamin C values ranging from 4 to 85  $\mu$ g. per cubic centimeter of solution could be measured with an accuracy estimated as 3.3 to 4.3 percent.

Assays on various citrus fruits, tomatoes, fresh vegetables, dehydrated carrots, potatoes, and onions were compared with results obtained by three other methods—visual titration, photometric using 2,6-dichlorophenolindophenol, or Roe and Oesterling's 2,4-dinitrophenylhydrazine method (E. S. R., 93, p. 537). Difficulties occurred in the assays of some of the dehydrated products. In general, results obtained by the polarographic method were lower than those obtained by both the visual titration or phenylhydrazine methods. In the latter case, this difference could not be accounted for by the presence of dehydroascorbic acid.

**New colorimetric reaction of vitamins D<sub>2</sub> and D<sub>3</sub> and their provitamins**, A. E. SOBEL, A. M. MAYER, and B. KRAMER (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 3, pp. 160-165, illus. 5).—A new colorimetric reaction of vitamins D<sub>2</sub> and D<sub>3</sub> has been studied spectrographically and described and illustrated in detail. This reaction occurs when glycerol dichlorohydrin or related compounds are added in the presence of acetyl chloride or other acid halides. "With calciferol an immediate yellow color is formed which turns green in 1 min., reaches a maximum in 15 min., and remains stable at 625 m $\mu$  for several hours. With ergosterol a weak pink color is observed immediately, which turns to orange in 15 to 20 min. and later to a fluorescent green. With 7-dehydrocholesterol no color is observed for several minutes; then a faint pink color appears, which becomes more intense in 24 hr. No color is produced with cholesterol. Under conditions suitable for quantitative estimations at 625 m $\mu$ , ergosterol has less than 4 percent and 7-dehydrocholesterol less than 0.3 percent of the absorption produced by vitamins D<sub>2</sub> and D<sub>3</sub>. Cholesterol has no absorption. Conditions have been developed for differentiating vitamins D<sub>2</sub> and D<sub>3</sub> from ergosterol and 7-dehydrocholesterol, ergosterol from 7-dehydrocholesterol, and the dinitrobenzoate esters of these compounds from the free sterols."

**Modified extraction procedures for use with certain foodstuffs in the estimation of vitamin-B<sub>1</sub> by the thiochrome method**, Y. L. WANG (*Jour. Soc. Chem.*

*Indus., Trans. and Commun.*, 64 (1945), No. 7, p. 220).—Further modifications of the Harris and Wang thiochrome method (E. S. R., 87, p. 762) are described for use with dried egg, meat, and plain, fortified, or milk chocolate. With the dried egg powder, a preliminary removal of fat is required, followed by digestion at pH 4 with papain and takadiastase or at pH 1.5–2.0 with pepsin and takadiastase. With fresh, cooked, or dried meat, acidification with 0.1 N HCl precedes heating on a water bath; then, after cooling to 40°–50° C., NaCl is added to induce precipitation and the pH is adjusted to 4.0, and digestion by takadiastase and papain is carried out. Slight modifications of the above treatment are used for the chocolate analyses.

**Determination of thiamine by the thiochrome method—effects of temperature and dissolved oxygen on fluorescence of quinine standard and of thiochrome,** D. F. CLAUSEN and R. E. BROWN (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 9, pp. 572–574, illus. 2).—It is recommended that all solutions be brought to room temperature before reading. Because of the heat which may be produced by the instrument, the authors suggest that the quinine standard be removed from the instrument when not in actual use as the temperature changes thus produced could exert an appreciable effect upon the fluorometric readings.

**The chemical estimation of  $\alpha$ -tocopherol and total tocopherol in mixtures of the  $\alpha$ ,  $\beta$ , and  $\gamma$  forms,** E. L. and Z. HOVE. (Ala. Expt. Sta.). (*Jour. Biol. Chem.*, 156 (1944), No. 2, pp. 601–610, illus. 3).—The authors have modified the procedures of Hines and Mattill (E. S. R., 90, p. 440) and of Parker and McFarlane (E. S. R., 86, p. 443) in developing a method capable of determining  $\alpha$ -tocopherol in the presence of  $\beta$ - and  $\gamma$ -tocopherols. By specifically regulating the concentrations of the reagents ( $\alpha$ ,  $\alpha'$ -bipyridine and ferric chloride) and carefully controlling the temperatures at 35° and 15° C., readings made at regular intervals over a 15-min. period can be used to estimate  $\alpha$ -tocopherol (by difference). Peanut, cottonseed, soybean, corn, and wheat-germ oils have been studied, and the values found are considered in agreement with those obtained by isolation procedures. Best results were obtained on 1 percent oil solutions. The accuracy of the method was found to decrease as the concentration of  $\alpha$ -tocopherol in the mixture decreased.

**Determination of fatty acid monoesters of l-ascorbic and d-isoascorbic acids in fats and oils,** J. TURER and R. M. SPECK. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 7, pp. 464–465).—It is shown that the 2,6-dichlorophenolindophenol reagent in acetone can be successfully used for the determination of the fatty acid monoesters of l-ascorbic and d-isoascorbic acids in fat and oil substrates. The data given indicate that the proposed method can be used for the determination of the ascorbyl palmitates in concentrations between 0.1 and 10 mg. per gram of sample (0.01 to 1.0 percent). The presence of tocopherol or phospholipids did not interfere with the determination. Tests on ascorbyl monostearates were made, and comparable results were obtained.

**Determination of fluorine in minerals and bones,** P. R. GODFREY and C. L. SHREWSBURY. (Ind. Expt. Sta.). (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 2, pp. 335–338, illus. 1).—The authors combined features of the method of Willard and Winter (E. S. R., 69, p. 489) with parts of two other methods, making a number of modifications of their own. The essential steps of the resulting procedure include ashing with magnesium acetate, distillation from perchloric acid, and titration with thorium nitrate and sodium fluoride. A procedure is described for the determination of fluorine, which is a combination of three published methods. Improved apparatus facilitates the distillation and titration of fluorine. Results showed an average deviation between samples of 3.6 percent. Recoveries of 95–99 percent of fluorine from solutions of known content were obtained.

**A rapid method for the determination of iron in enriched bread,** W. R. RUEGAMER and C. A. ELVEHJEM. (Univ. Wis.). (*Science*, 101 (1945), No. 2617,

p. 206).—A modification of the method of Kitzes et al. (E. S. R., 93, p. 245) has been devised which permits assay of enriched bread without preliminary ashing. In brief, an aliquot of the bread is heated twice with solutions of thioglycolic acid, hydrochloric acid, and trichloroacetic acid. The supernatant liquids are decanted and treated with ammonia until the appearance of a yellow color with *p*-nitrophenol as the indicator, then acidified, buffered, and diluted to volume.

An aliquot is treated with thioglycolic acid to reduce any ferric iron present and the galvanometric reading taken. The  $\alpha$ - $\alpha'$  bipyridine reagent is then added and the new reading made.

Iron, when added to enriched bread, has given recovery values ranging from 94 to 105 percent. In the bread samples tested, less than 5 percent of the total iron accounted for could be found in the ashed residues.

**The use of *Neurospora* for the determination of choline and biotin in milk products**, A. Z. HODSON (*Jour. Biol. Chem.*, 157 (1945), No. 1, pp. 383–385, illus. 1).—A modification in the *Neurospora* method of Horowitz and Beadle (E. S. R., 92, p. 8) has been described for use in choline assays on milk products. The permutit step can be omitted provided the data are selected from the lower steep portion of the assay curves. Biotin assays were also carried out with the same organism and the same milk extracts.

**Development of a phosphatase test applicable to Cheddar cheese**, G. P. SANDERS and O. S. SAGER. (U. S. D. A.). (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 3, pp. 656–675, illus. 3).—The authors report upon a detailed investigation of the optimal pH range for the test, the suitability of different buffers and precipitants, the effects of various quantities of cheese samples, the sensitivity of the test, and the advantages of using butyl alcohol for extracting the blue color and evaluating the results.

The optimal pH was found to be approximately 9.6, and a pH not lower than approximately 9.4 or not higher than approximately 9.8 was almost equally satisfactory. The use of a barium borate-hydroxide buffer for establishing the pH uniformly within the proper range and for precipitating proteins and certain other interfering substances is proposed. Application of this test to more than 350 samples of Cheddar cheese, of which records of the milk treatment were available, showed that a very slight lowering below the proper pasteurizing temperature and contamination with as little as 0.1 percent of raw milk in pasteurized milk could be detected in the cheese test. The activity of the phosphatase enzyme in raw-milk cheese was detected very readily in all instances, regardless of the age of the cheese. No instances of phosphatase activity produced in the cheese by starter organisms or by other organisms that occur commonly in the interior of Cheddar cheese were observed.

**Comparison of several methods for determining the sulfur content of feeds**, R. J. EVANS and J. L. ST. JOHN. (Wash. Expt. Sta.). (*Jour. Assoc. Off. Agr. Chem.*, 28 (1945), No. 2, pp. 360–363).—In a comparison of the official A. O. A. C. magnesium nitrate and sodium peroxide methods, the alkaline permanganate method, the Benedict-Denis method, and two nitric-perchloric acid digestion methods with the Parr bomb method for determining the total sulfur content of feeds, only one of the nitric-perchloric acid digestion methods and the sodium peroxide method gave as high values as did the Parr bomb method. The magnesium nitrate method gave low and variable methods for the sulfur content of the feed samples studied.

**The estimation of tryptophane in human urine**, A. A. ALBANESE and J. E. FRANKSTON (*Jour. Biol. Chem.*, 157 (1945), No. 1, pp. 59–68, illus. 2).—Samples of urine are passed through permutit to remove some of the nitrogenous bases present which form a mercury complex. The filtrate produced is then acidified and treated with ether to extract any nontryptophan indoles which might be present. The

aqueous fraction is treated with acid mercuric sulfate reagent in order to precipitate and concentrate the tryptophan fraction, and the precipitate thus formed is dissolved in a minimum amount of acid reagent. The authors' previously described method (E. S. R., 88, p. 730) is used for the remainder of the procedure.

"Application of the procedure to 24-hr. specimens of seven normal male subjects on normal diets has revealed that  $281 \pm 30$  mg. of tryptophan are excreted daily, and that the output approximates the value 3.3 mg. of tryptophan per kilo of body weight per day. The origin and physiological implications of urinary tryptophan are discussed."

**Analysis of bodied drying and semidrying oils**, J. C. COWAN, L. B. FALKENBURG, and H. M. TEETER. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 2, pp. 90-92, illus. 4).—Operating details for a determination of the proportions and nature of those polymers in a heat-bodied vegetable oil resulting from self-addition of the fatty acid portions of the oil are described. The method was applied to the analysis of methyl esters bodied in the laboratory and that of commercial oils.

**Analysis data for the ternary system acetone-benzene-water**, E. HONOLD and H. WAKEHAM. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 8, pp. 499-501, illus. 2).—Using the densities and refractive indices of mixtures of the compounds named, as measured at 25° C., the authors were able to develop an accurate and rapid method for determining each component. The procedure described proved practical and satisfactory in connection with pilot-plant solvent recovery problems arising from experiments on the extraction of rubber from goldenrod leaves.

**Staining rubber in ground or milled plant tissues**, F. W. HAASIS. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 7, pp. 480-481).—Following suitable pretreatment of samples, differential staining with Sudan IV and iodine green proved a useful and relatively rapid aid in the microscopic study of rubber in ground guayule tissues, mounts in many cases being ready for examination within 90 min. after starting the schedule.

According to the method here given, the material is to be treated for 15 min. with a 10 percent solution of potassium hydroxide in alcohol. A specified commercial hyochlorite solution is then to be added, and this bleaching reagent allowed to act for 10 min., after which the material is rinsed with water for half an hour. The stain is applied as a weak solution of the two dyes in equal volumes of acetone and 70 percent alcohol for half an hour, the material is rinsed in water, and a mount is made in a glucose sirup.

**Detection of destructively distilled wood turpentine**: In other kinds of turpentine by means of the aniline point, S. R. SNIDER and H. N. BURSTEIN. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 10, pp. 603-605, illus. 1).—It was found that the presence of destructively distilled wood turpentine in gum spirits, and perhaps also in steam-distilled wood turpentine, may be detected by aniline point tests on the high-boiling fraction distilling above 170° C., obtained as described in this paper.

**Kinetics of wood saccharification: Hydrolysis of cellulose and decomposition of sugars in dilute acid at high temperature**, J. F. SAEMAN. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 1, pp. 43-52, illus. 16).—The author describes a method for hydrolyzing small samples of cellulosic materials in glass bombs by heating with direct steam in a rotating autoclave. Much of the convenience and success of the method depended on the fact that the small quantities used made sampling of the products unnecessary; all the hydrolyzate and all the residue were used for the analysis. The work described in this paper was confined to the use of finely divided wood with high liquid-solid ratios. The general principles derived, however, appeared to be confirmed by large-scale operation.

The decomposition of all sugars tested followed the laws of a first-order reaction. The energy of activation of the decomposition of glucose appeared to be independent of the acid concentration over the range 0.4 to 1.6 percent sulfuric acid, and averaged 32,800 calories. As an approximation, the rate of reaction increased 125 percent with a  $10^{\circ}$  [C.] rise in temperature over the range  $170^{\circ}$  to  $190^{\circ}$ . A 100 percent increase in acid concentration resulted in a 102 percent increase in speed.

Of the cellulosic materials of which the hydrolysis was studied, all contained an easily hydrolyzed portion, not further investigated, and a more resistant portion, the hydrolysis of which was a first-order reaction. The hydrolysis of Douglas fir was investigated under conditions ranging from  $170^{\circ}$  to  $190^{\circ}$  and 0.4 to 1.6 percent sulfuric acid. A 100 percent increase in acid concentration resulted in a 153 percent increase in hydrolysis rate. The energy of activation of the reaction was independent of the acid concentration and averaged 42,900 calories. As an approximation it may be considered that a  $10^{\circ}$  rise in temperature resulted in a 186 percent increase in reaction rate.

Theoretical considerations, involving the application of the theory of consecutive reactions to the data indicated above, are discussed.

**The rotary digester in wood saccharification**, R. H. FLOW, J. F. SAEMAN, H. D. TURNER, and E. C. SHERRARD. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 1, pp. 36-43, illus. 9).—A pilot-plant investigation of the dilute acid hydrolysis of wood to sugar was carried out with the use of a 30-in. spherical rotary digester. A schedule for the multistage hydrolysis of wood was established by small-scale laboratory studies and by interrupted cooks. Yields, 50 to 60 gal. of alcohol per ton of wood, approximated those obtained in the stationary percolator. The retention of sugar by the residue remaining in the digester was the principal factor limiting yields obtained by this process. The rate of conversion of cellulose to sugar did not alter with increasing time of exposure to hydrolytic conditions. Limited multistage processes gave yields, including the sugar in the residue, of approximately 75 percent of those obtained in completed multistage operations but required only 25 percent as much time. Single-stage hydrolyses resulted in yields of about 30 gal. per ton in one-tenth the time required for multistage operation. Because of changes in fermentability, maximum yield of alcohol did not coincide with maximum yield of reducing sugar. In both single-stage and limited multistage operations it was necessary to extract sugar remaining in the residue after the last worthwhile withdrawal. Results indicated that increased yields and improved conversion efficiency can be obtained in less time by higher temperatures and acid concentration.

**Studies on rum**, R. ARROYO (*Puerto Rico Univ. Sta. Res. Bul.* 5 (1945), pp. 272+, illus. 38; *Span. abs.* pp. 261-270).—When work on this project was begun, methods were found to be those of a very old industry, being especially primitive and empirical in the fermentation process. "The nature and necessary characteristics of the fermentation agents employed were utterly unknown or disregarded, and absurd . . . curing practices" were applied to the raw rums. The results of 6 yr. of work (1936-42) designed to provide a sound technological basis for rum manufacture are here presented. Following a brief introduction, the principal contents are: The raw material; yeast selection; mashing operations; mitogenetic radiation; rum fermentation; rum distillation; rum curing and maturing; rum aroma; rum composition and appraisal; and biological and chemical control of the rum distillery.

## AGRICULTURAL METEOROLOGY

**Upper-air trajectories and weather forecasting**, D. FULTZ (*Univ. Chicago, Dept. Met., Misc. Rpts. No.* 19 (1945), pp. 123+, illus. 46).—This report is an

attempt to improve forecasting of the surface and upper pressure distributions by means of a trajectory technic applied primarily to the 10,000-ft. chart in coordination with such other aids as are ordinary or were found useful. Consideration is given to some of the theoretical principles involved, the procedure as developed to date, some empirical ideas which appeared to be of value, and an account of the verification obtained. The information presented should serve to show under what conditions profitable use can be made of the full procedure, where it would be impractical, and what additional indications may be derived from a careful inspection of the ordinary charts in view of the ideas here expressed.

**Comparison of lower-cloud bases with condensation levels**, R. C. BUNDGAARD (*Amer. Met. Soc. Bul.*, 27 (1946), No. 1, pp. 1-5, illus. 2).

**Is there a ring of violent upward convection in hurricanes and typhoons?** C. E. DEPPERMAN (*Amer. Met. Soc. Bul.*, 27 (1946), No. 1, pp. 6-8, illus. 1).

**An analysis of an unusual rainfall distribution in a hurricane**, E. M. BROOKS (*Amer. Met. Soc. Bul.*, 27 (1946), No. 1, pp. 9-14, illus. 4).—The author presents an attempt to account for the unusual distribution of rainfall observed in the tropical hurricane of October 6-8, 1941, in the southeastern United States.

**Foreshadowing the winter precipitation in Montana and Florida**, I. I. SCHELL (*Amer. Met. Soc. Bul.*, 27 (1946), No. 1, pp. 33-34).—Presentation of hitherto unpublished foreshadowing of precipitation in these two States for the winter of 1942-43, prepared at the time. Tropical Australasia pressure of the preceding September-November formed the basis for computing the deviations in winter precipitation.

**Climatic factors affecting crop production**, E. C. STACEY (*Sci. Agr.*, 26 (1946), No. 2, pp. 79-82).—The Dominion Experimental Station at Beaverlodge, Alberta, "has on record perhaps the largest body of meteorological data of any of the northern stations and is situated on what might be regarded as the southern fringe of northern agriculture." For this reason its records are used to a considerable extent in the survey here presented, which includes information on precipitation, evaporation, air and soil temperatures, sunshine, and wind. The crops of the northern area—including wheat, alfalfa, cereals, grasses, and clovers—and the climate in general are discussed briefly.

**Weather and climate of the Northwest Territories**, J. L. ROBINSON (*Canad. Geog. Jour.*, 32 (1946), No. 3, pp. 124-139, illus. 35).—"Many misconceptions and misstatements as to actual conditions and future possibilities of the Northwest Territories have been based upon an inadequate knowledge of climatic conditions." One of the causes is undoubtedly that these areas comprise one-third of Canada and that the climate thus differs markedly from one region to another. The basic difference lies in the type and length of summer: The eastern areas are Arctic, but have a short cool summer; the Northwest—despite its northern latitude—has summer periods often as warm as in more southerly parts of the country. The information here presented is based on the findings of the governmental meteorological stations established throughout the Northland. It is concluded that if resources are found which are rich enough to compete with those closer to present markets, climate will not be a principal obstacle impeding development of the Canadian Northwest.

**Anuario meteorológico, 1937-1943 [Meteorological Yearbook, 1937-43]**, L. H. OSORIO (*Bogotá, Colombia: Min. Econ. Nac.*, 1944, pp. 332).—A compilation of meteorological data for Colombia, 1937-43.

**Problems of Scottish climatology**, G. MANLEY (*Scot. Geog. Mag.*, 61 (1945), No. 3, pp. 73-76).—An address.

**Climate and China's agricultural industry**, E.-L. LIU (*Jour. Geog.*, 45 (1946), No. 3, pp. 90-96).—A general discussion of the influence of climate on China's agriculture—past and present.

Solar heat in relation to bacterial soft rot of early Irish potatoes, L. W. NIELSEN. (N. C. Expt. Sta.). (*Amer. Potato Jour.*, 23 (1946), No. 2, pp. 41-57, illus. 3).—Tubers exposed to direct sunlight during June and July for as little as 60 min. developed more bacterial soft rot than those picked up and packed as soon as dug. Prolonged exposure may cause two changes: (1) The tuber tissues may be killed, or (2) if the absorbed heat causes the temperature to rise to 113° F. or above (sublethal) there will be no symptoms of injury, though the tubers become more susceptible to the soft rot when inoculated through bruises made during harvesting. The latter change is apparently a reversible process from which tubers recover if not spontaneously or artificially inoculated. The results of the laboratory studies on temperatures and intervals of exposure were first interpreted as the thermal death point. As the work progressed, it became evident that this was incorrect. The thermal death point of tuber tissues at 1 hr. of exposure is believed to be above 122°. The temperatures determined in the laboratory tests were more likely those at which changes in tuber susceptibility take place.

Bacterial soft rot of Irish potatoes as influenced by sublethal temperatures—sugar and permeability changes in the tubers, L. W. NIELSEN and F. A. TODD. (N. C. Expt. Sta.). (*Amer. Potato Jour.*, 23 (1946), No. 3, pp. 73-87, illus. 2).—Recent studies indicated that tubers exposed to solar or artificial heat become more susceptible to bacterial soft rot (see preceding entry). In the present study, the reducing and total sugar concentrations in the juice of the tubers was found to be greatest in those stored at 4° and 40° C.; the amount of sugar was not correlated with the heat-induced susceptibility. An inverse relationship existed between the H-ion concentration and that of total sugars in the juice at 4° to 40°. Cell membrane permeability increased at high storage temperatures and following sublethal heat treatments; this increase is believed to play a role in bacterial infection of the tubers by permitting the diffusion of sugars (and probably other nutrients) into the cell walls and intercellular spaces, where they become more accessible to soft rot bacteria on artificial or spontaneous inoculation through wounds. There are 14 references.

## SOILS—FERTILIZERS

Soils and soil management, A. F. GUSTAFSON (*New York and London: McGraw-Hill Book Co., 1941, pp. 424+, illus. 165*).—The purpose of this book is the presentation of information dealing with the management of soils in the field. Emphasis is placed on ways and means of handling soils for economic production of crops. The book was written for the student of practical soil management on the farm and in the classroom, but has much of interest also to owners and operators of farm land. The contents are: The origin and placement of soil materials and soil formation; the physical properties of soils; soil organisms; the organic matter of mineral soils; the relation of water to soils and plants; the control of water in the soil; tillage; erosion and its control; soil acidity and its control by liming; the management of alkali soils; nitrogen and its importance to the farmer; the production, conservation, and utilization of farm manures; the production and utilization of green-manure crops; fertilizer materials and their effects on soils and crops; commercial fertilizers and their use; the rotation of crops; the fertilization and the long-term maintenance of the productivity of mineral soils; and the origin of organic deposits and peat soils and their management. Appendix A lists the common and botanical names of a number of common plants, and Appendix B gives some approximate equivalents and formulae.

Collecting soil samples for chemical analysis, L. C. OLSON and R. P. BLEDSOE (*Georgia Sta. Cir. 148 (1945), pp. 7, illus. 3*).—This circular presents in detail information on time of sampling; how to obtain representative samples, with a

schematic illustration for taking samples that can be worked out for fields of various sizes and shapes; depth of sampling; technic of sampling; and shipping of sample.

**Soil sampling tube**, J. B. HESTER and K. HANKINSON (*Jour. Amer. Soc. Agron.*, 37 (1945), No. 12, pp. 1041-1042, illus. 1).—The authors briefly describe and illustrate in a dimensioned drawing a sampling tube of which the principal feature consists in the insertion of a choke ring, sharpened to constitute the cutting edge of the instrument, such that the core of soil is cut slightly smaller than the bore of the main part of the tube. The upper end of the tube is of unobstructed internal diameter, and the core is slid out by inverting the tube. The sampler is described as being constructed from stainless steel or hard brass. It is shown in the drawing as 3 ft. in over-all length, the tubing being of 1 in. internal diameter with wall  $\frac{1}{8}$  in. thick. The inserted choke and cutting edge is indicated to be of 1 in. outside diameter,  $\frac{3}{8}$  in. wall thickness, and  $\frac{3}{8}$  in. deep. The cutting edge is sharpened to an angle of about  $10^\circ$ .

This tube was found "not entirely satisfactory for stony or extremely dry soils," but satisfactory for moist clay or for sandy soils, simple of construction, and easy to twist into the soil by hand.

**Soil survey of Lincoln County, Tennessee**, F. RUDOLPH ET AL. (Coop. Tenn. Expt. Sta. et al.). (*U. S. Dept. Agr., Bur. Plant Indus., Soils, and Agr. Engin. [Soil Survey Rpt.], Ser. 1937, No. 16, pp. 135+*, about 8 illus.).

**The occurrence of *Clostridium botulinum* and *Clostridium tetani* in certain plots of soil**, E. W. COOK, JR. (*Ohio State Univ., Abs. Doctoral Diss., No. 47* (1945), pp. 9-14).—The occurrence of *C. botulinum* and *C. tetani* was investigated in 131 samples of soils obtained from field plots receiving different treatments. The study revealed that the population of *C. botulinum* in the soil of the plots used remained approximately the same over a long period of time and with a variety of treatments. On the other hand, the population of *C. tetani* in the soil of these plots varied. The best treatment for the occurrence of *C. botulinum* in the plots was manure only, but any combination of manure and chemicals, such as phosphate and lime, used as fertilizer was also good. *C. tetani* was more often found in the soil of plots which had been treated with a combination of manure and chemicals, such as lime and phosphate, though the chemicals alone were also good.

Both *C. botulinum* and *C. tetani* were more often found in those plots that were sown to wheat than in any other crop studied. Most of the plots yielded strains of *C. botulinum* and *C. tetani* which were highly toxic. The toxicity of samples from which these strains came followed those treatments of the plots which best maintained *C. botulinum* and *C. tetani* in them.

**Lipid production by a soil yeast**, R. L. STARKEY. (N. J. Expt. Stas.). (*Jour. Bact.*, 51 (1946), No. 1, pp. 33-50, illus. 14).—The yeast was recovered from several soils and thus is thought to be a common soil inhabitant. The yeast cultures considered in this article were obtained from colonies which developed on a nitrogen-free agar medium. The yeast is of interest because of its high lipid content and because of unusual spore formation. The sequence of changes observed in cultures is illustrated. The metabolism of the yeast was investigated.

The characteristics of the yeast are different from those of previously described yeasts which have been studied for lipid synthesis. It was not possible to identify the yeast with known species. The yeast may be a new species or a yeast already described but with certain characteristics which have not been recognized up to this time. Growth and lipid production were good in aerated glucose solutions containing small amounts of yeast extract as the nitrogen source. Under favorable conditions, 20 to 25 percent of the consumed glucose was converted to yeast cells which contained 50 to 63 percent lipid. From 10 to 14 percent of the consumed glucose was recovered as lipid. The lipid content of the cells decreased as the

nitrogen content of the medium increased. Only a small portion of the lipide could be extracted from the cells directly with fat solvents, but it became released by hydrolysis with dilute acid.

**The land renewed: The story of soil conservation,** W. R. VAN DERSAL and E. H. GRAHAM (*New York: Oxford Univ. Press, 1946, pp. 109+, about 50 illus.*).—This well illustrated book presents in popular form the history of the development of practices of land use in America and the importance of preservation of topsoil to the security of the country. Different types of erosion and the extent of different kinds of damage are considered. Present remedies for control of erosion and renewal of soil productivity are outlined.

**Report of the Chief of the Soil Conservation Service, 1945,** H. H. BENNETT (*U. S. Dept. Agr., Soil Conserv. Serv. Rpt., 1945, pp. 55*).—A summary of the year's activity in applying soil conservation practices to the land, with a consideration of the benefits of conservation farming and the conservation job ahead. Brief statements are presented on various phases of the soil and water conservation research program, including brief notes on research findings.

**Bamboo for controlling soil erosion,** D. G. WHITE and N. F. CHILDERS. (P. R. Fed. Expt. Sta.). (*Jour. Amer. Soc. Agron., 37 (1945), No. 10, pp. 839-847, illus. 7*).—Among various advantages of several of the *Bambusa* species as erosion control plants the matted, extensive, and comparatively shallow root systems are emphasized. A hillside clump of *B. tulda*, for example, was found to have roots extending 17 ft. from the culm, with 83 percent of the root system in the top foot of soil and only 1 percent between 3 and 4 ft., below the surface. A 4-year-old planting of *B. longispiculata* on a 52-percent slope was found to have deposited a leaf mulch from 2 to 4 in. in thickness during a dry period of from 3 to 4 mo., and erosion, which had begun gully formation on this slope before the bamboo planting, not only showed no further advance but the ditches already formed were covered with leaves and the soil well penetrated by roots. Bamboo species are recommended for the reinforcement of embankments of mountain roads and for stream bank protection. In use for the last-named purpose, a bamboo revetment, with growing bamboo in the stream bank behind this retaining wall, is illustrated. Culms may be cut for commercial uses without loss of the soil holding value of the plantings.

**Relation of vegetative cover to the plant growth conditions of eroded soils,** R. M. WARNER. (Iowa Expt. Sta. coop. U. S. D. A.). (*Iowa State Col. Jour. Sci., 20 (1945), No. 1, pp. 101-153, illus. 17*).—This paper covers qualitative and quantitative tests of soil conditions where plant communities were found, the changes brought about by natural and introduced vegetation, and the changes in vegetation and soil structure resulting from water conservation practices in the eroded soils of southeastern Iowa. Plant cover changes to the conditions of the habitat were studied on a site where change was accelerated by basin-listing. The second situation studied was a series of plant communities representing stages in secondary plant succession. A marked increase in soil moisture was evident from the fact that the available moisture, although fluctuating greatly in the surface 6 in., was below the wilting point only twice in the basin-listed area. In an adjacent comparable area, not so treated, the soil was below the wilting percent during most of the growing season. This area supported only plants of the weed and perennial forb stages. Depth of percolation of water was approximately three times as great in the basin-listed area as in a comparable eroded Lindley loam area without basin-listing treatment. Noncapillary porosity was generally higher and volume-weight lower in the soil under the advanced plant cover types than under the weedy types. A high correlation was found between volume-weight determinations and total porosity of the same samples. A lower correlation was

found between volume-weight and noncapillary porosity. The former was considered to be a good measurement of soil structure as related to plant development because of its relationship to percolation rate and soil aeration. Runoff percentages tended to be lower and depth of penetration higher as the stages of the succession approached the climax.

**The effect of plowing under and the time of plowing under legumes on the conservation of nitrogen.** J. W. TIDMORE and N. J. VOLK. (Ala. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 37 (1945), No. 12, pp. 1005-1010).—With the purpose of observing the effect of the time of plowing under legumes on the conservation of the nitrogen in the legumes, the effect on succeeding crops, and the effect on the chemical composition of the soil, six cropping systems were used in four series of 1/600-acre concrete bins.

Plowing under soybeans in the spring was superior to plowing them under in the fall because in the latter case nitrogen in the soybeans was lost by leaching during the winter as a result of nitrification during the warm fall months. Allowing soybeans to remain on top of the ground all winter gave quite satisfactory results with respect to conservation of nitrogen, as did cutting them and storing them in the barn until spring. The loss of nitrogen by leaching following the plowing under of soybeans in the fall is believed to have been undoubtedly in excess of 25 lb. per acre. Plowing under soybeans for 9 yr. had practically no effect on the exchange capacity, exchangeable hydrogen, calcium, and magnesium, or the pH of the soil. Total organic matter was increased about 60 percent over the 9-yr. period by plowing under legumes every other year. At the end of the 9-yr. period, soils on which legumes were plowed under contained about 30 percent more nitrogen than did soils that received no legumes.

**Effect of crop residues on soil temperature.** T. M. MCCALLA and F. L. DULEY. (Nebr. Expt. Sta. coop U. S. D. A.). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 1, pp. 75-89, illus. 3).—Soil temperatures were determined under the quantities of residues used in the system of subsurface tillage, or stubble mulching, as compared with soil temperatures when using heavy mulches or the conventional system of plowing. Heavy mulches, such as an 8-ton per acre application of straw, lowered soil temperatures as much as 17.7° C. at the 1-in. depth. For a period of 3 or 4 mo. after the application of a straw mulch at the rate of 2 or 3 tons per acre, soil temperatures may be reduced from 3° to 6° at the 1-in. depth and 2° to 4° at the 4-in. depth. In the stubble mulch system of farming, soil temperatures were not reduced appreciably below that of plowed land after 6 to 9 mo. In such farming, only quantities of residues equal to those grown on the land were returned to the surface of the soil, while decay and fragmentation of the residue continued. Soil temperature of the mulched plots lagged behind air temperature. This difference reached a peak on clear days at about 1 to 2 o'clock. Soil temperature reached the lowest point for the day along with the air temperature at about 5 a. m. At this time mulched and bare plots usually had almost the same temperature. After considerable decay had taken place, the temperature at the time of widest differences was only a few degrees lower on the mulched soil. Generally, soil temperature under mulches did not appear to be unfavorable to plant growth where a quantity of residues equal to that grown on the field was used. Mainly because of shading, a growing crop on the land decreased the temperature differences between the mulched and unmulched soil.

**Yield-depression effect of fertilizers.—IV, Initial or "near-end depression,"** O. W. WILLCOX (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 2, pp. 99-107, illus. 4).—The author subjects two field experiments carried out by the Maine Experiment Station (E. S. R., 89, p. 209) to an agrobiological analysis as indicated in the previous papers of this series (E. S. R., 94, p. 23), with the aid of the standard

yield diagram. In the one test where nitrogen was applied together with a base fertilization of phosphorus and potassium, the resulting yield curve followed a normal course, but where only the base fertilization was applied the yield was far below normal expectancy, despite the indicated presence of 1.8 baules (401.4 lb.) of original soil nitrogen. A parallel situation was found in this test where potassium was varied against a base fertilization of nitrogen and phosphorus. From these relations it is deduced that the original and part of the added increments of nitrogen and potassium were inhibited by some unknown soil condition, and that the normal yield curves found for the nitrogen and potassium treatments are the traces of the action of the uninhibited portions of these nutrients. This type of yield depression, or yield depreciation, is called "near-end depression" because it is observed at the beginning of the curve. In the phosphorus series of this test near-end depression appears to be absent; that is, there was no clear evidence of inhibition of the original soil  $P_2O_5$ . On the other hand, the superior increments of phosphorus in this series produced a mild example of the much more common "far-end depression," by which is designated the direct depressive effect observed when a plant nutrient is added to the soil in excess. In the other field test, which was made with graded increments of a 4-8-7 fertilizer, near-end depression was also observed in the control plots.

**Sodium as a plant nutrient and substitute for potassium**, M. E. HOLT and N. J. VOLK. (Ala. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 37 (1945), No. 10, pp. 821-827, illus. 1).—Sodium applied to sand cultures in the absence of potassium increased the growth of the seven crops tested by an average of 53 percent, the smallest increase being 17.1 percent for Austrian winter peas and the largest 185.8 percent for cotton. The beneficial effect of sodium on plant growth in the greenhouse, in general, decreased as the potassium level of the nutrient media increased, but not in direct proportion to it. Sodium increased the number of bolls that matured on cotton grown in the greenhouse on both sand and soil cultures when the potassium concentration in the nutrient media was less than about 300 lb. of potassium per acre in the sand cultures and less than 72 lb. of available potassium per acre in the soil cultures. The concentration of sodium in the plant tissue, after a severe initial decrease from the application of a small amount of potassium, became with additional potassium application approximately inversely proportional to the potassium concentration in the plants. Results obtained from 47 field tests with cotton grown on sandy soils of low productivity show that the addition of sodium increased the yields of seed cotton by 98 to 213 lb. per acre. The results indicate that plants vary in their need for and capacity to utilize sodium, that for some plants sodium may be an essential nutrient for maximum growth, and that sodium can be substituted for potassium to a variable extent, depending on the kind of plant. Beneficial results may be expected from the application of sodium to soils low in either available potassium or sodium, or both. The substitution of other forms of nitrogen in place of sodium nitrate as a source of nitrogen for sandy soils may in time necessitate the addition of sodium in some form to obtain maximum yields of some crops.

**Gypsum, a soil corrective and soil builder**, W. T. McGEORGE (*Arizona Sta. Bul.* 200 (1945), pp. 14+, illus. 3).—This bulletin presents, in popular form, information regarding the agricultural use of gypsum. Specific phases discussed include its solubility, fineness, and quality; reasons for its use; gypsum and black alkali; reclamation of black alkali soils, and preventing black alkali formation; reclamation of white alkali soils; gypsum and soil structure; prevention v. reclamation; and hard v. soft water. The author points out that gypsum and gypsite are excellent correctives, useful in the reclamation of both black alkali and white alkali soils and of value in improving the structure of irrigated soils. Two tons per

acre is recommended for black alkali soils and 500 to 2,000 lb. per acre for white alkali soils, depending upon the physical condition.

**Sulphur, a soil corrective and soil builder**, W. T. McGEORGE (*Arizona Sta. Bul.* 201 (1945), pp. 20+, illus. 1).—This bulletin presents information on the use of sulfur for direct application to the soil and other uses related to agriculture. Recommendations for its use suggest from 100 to 200 lb. per acre broadcast as a fertilizer; as an acidulating agent 200 to 400 lb. per ton of mixed fertilizer; for chlorosis 25 to 100 lb. per tree; for black alkali soils—100 to 200 lb. per acre as a preventive, 1,000 to 1,500 lb. for reclamation; for white alkali soils 200 to 400 lb. per acre; and for improving and maintaining soil structure 100 to 200 lb. per acre annually.

**Minor elements: Evidence and concepts on functions, deficiencies, and excesses**, edited by F. E. BEAR and H. B. KITCHEN (*Baltimore: Williams and Wilkins Co.*, 1945, pp. 189+, illus. 17).—This symposium contains reprints of papers previously noted. The general articles and specific summary articles by individual elements are as follows: The Geochemical Background of Minor-Element Distribution, by V. M. Goldschmidt (pp. 1-7) (E. S. R., 94, p. 165); The Occurrence of Mineral Nutritional Diseases of Plants and Animals in the United States, by K. C. Beeson (pp. 9-13) (U. S. D. A.) (E. S. R., 94, p. 202); Minor Elements in Plants, and Some Accumulator Plants, by W. O. Robinson and G. Edgington (pp. 15-28) (U. S. D. A.) (E. S. R., 94, p. 177); Minor Elements and Vitamin Content of Plants, by K. C. Hamner (pp. 165-171) (U. S. D. A.) (E. S. R., 94, p. 316); Biological Function of Minor Elements, by O. Baudisch (pp. 173-184); Use of Microorganisms to Determine Essentiality of Minor Elements, by R. A. Steinberg (pp. 185-189) (U. S. D. A.) (E. S. R., 94, p. 316); and—under the general heading, Minor Elements Essential to or Contained in Plants or Affecting Animals Consuming Them—Aluminum in Soils, Plants, and Animals, by G. E. Hutchinson (pp. 29-40), Boron in Plant Life, A Brief Historical Survey, by J. W. Shive (pp. 41-51) (N. J. Expt. Stas.), Influence of Chlorine on Plants, by A. R. C. Haas (pp. 53-61) (Calif. Citrus Sta.), Cobalt and Nickel in Soils and Plants, by R. L. Mitchell (pp. 63-70), Copper and Plant Growth, by A. L. Sommer (pp. 71-79) (Ala. Sta.), and Fluorine in Soils, Plants, and Animals, by H. H. Mitchell and M. Edman (pp. 81-90) (Univ. Ill.) (all E. S. R., 94, p. 178), Iron in Leaves, by J. P. Bennett (pp. 91-105) (Univ. Calif.), Certain Factors Affecting the Availability, Absorption, and Utilization of Magnesium by Plants, by H. P. Cooper (pp. 107-114) (S. C. Sta.), The Role of Manganese in Agriculture, by J. S. McHargue (pp. 115-118) (Ky. Sta.), Molybdenum in Relation to Plant Growth, by D. R. Hoagland (pp. 119-123) (Univ. Calif.), Selenium in Soils, Plants, and Animals, by S. F. Trelease (pp. 125-131), Silicon in Plant Growth, by G. J. Raleigh (pp. 133-135) (Cornell Univ.), Sodium as a Crop Nutrient, by P. M. Harmer and E. J. Benne (pp. 137-148) (Mich. Sta.) (all E. S. R., 94, pp. 316, 317, 319), Sulfur Deficiency in Soils, by W. Crocker (pp. 149-155) (E. S. R., 94, p. 165), and Zinc as a Nutrient in Plant Growth, by A. F. Camp (pp. 157-164) (Univ. Fla.) (E. S. R., 94, p. 319).

**Versuche und untersuchungen über die wirkungen des bors als spurenelement [Investigations on the effect of the minor element boron]**, E. TRUNINGER (*Landw. Jahrb. Schweiz*, 58 (1944), No. 1, pp. 1-36, illus. 9; *Fr. abs.*, pp. 35-36).—Soil and plant investigations are reported on the need for boron of various plants under different soil conditions and on the interrelationships of boron with other elements.

**Preliminary greenhouse studies of digested sludge as a fertilizer**, H. A. LUNT. (Conn. [New Haven] Expt. Sta.). (*Sewage Works Jour.*, 18 (1946), No. 1, pp. 46-53, illus. 2).—Conditional sewage sludge cake experimental tests designed for observational effect on yields of various crops gave results that do not appear too favorable for sludge as a fertilizer. Immediate increases in crop yields can hardly be expected under all conditions and all crops. Undoubtedly occasional or

frequent use of such material is beneficial to the soil in the long run, and the sandier in the texture and the lower fertility, the more likely this would be true. Inasmuch as sludge is not a balanced plant food, it is imperative that adequate supplies of potash be provided, particularly for those crops with high potash requirements.

From the standpoint of yield of the first crop as well as the matter of possible health hazard, sludge should be applied at least several months prior to planting. Supplementary applications of nitrogen can be made to advantage at planting time.

**Organic material and ammonium nitrate in fertilizer mixtures**, R. O. E. DAVIS and J. O. HARDESTY. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 1, pp. 59-63, illus. 3).—The authors point out that although ammonium nitrate shows a tolerance for small quantities of organic materials, its action upon larger proportions of organic components in mixtures in which the nitrate and organic combustibles are diluted with other fertilizer constituents has not hitherto been ascertained; and fires suspected of originating in such mixtures have occurred.

A base mixture containing 1,400 lb. of superphosphate and 400 lb. of ammonium nitrate with as little as 50 lb. of an organic meal was found capable of originating a fire under unusual conditions. Preliminary experiments showed that spontaneous combustion occurred in this mixture after storage for several weeks at 30° C. From tests with a variety of mixtures the conclusion was drawn that the presence or formation of free acid initiated exothermic reactions which between 90° and 110° resulted in spontaneous combustion. Proper neutralization with ammonia offered safety from fire under severe conditions, even with much larger ratios of organic meal to ammonium nitrate. Cooling or dissipation of heat will avoid reaching the critical temperature.

**Greenhouse and laboratory experiments with nitrogen-bearing aluminum dross as a fertilizer**, L. F. RADER, JR., D. S. REYNOLDS, and K. D. JACOB. (U. S. D. A.). (*Jour. Amer. Soc. Agron.*, 37 (1945), No. 12, pp. 1024-1032, illus. 2).—Dross from the melting and refining of aluminum and aluminum alloys contains nitrogen in the form of nitrides. The nitrogen content of 21 samples of the material from plants throughout the United States ranged from 0.43 to 10.35 percent and averaged 5.05 percent.

In greenhouse pot experiments with millet and tomatoes on Sassafras fine sandy loam and Sassafras sandy loam, respectively, the dross had only from 1 to 33 percent as much effect in increasing the dry-weight yields as had the same quantity of nitrogen in the form of ammonium sulfate. There were indications that some samples of dross contain substances which may have a small depressive effect on plant growth. The effect of dross on plant growth was directly related, in general, to the rate and extent of conversion of the nitrogen to ammonia in aqueous medium and to its nitrification in the Chester silty clay loam used in these experiments.

## AGRICULTURAL BOTANY

**The herbal of Rufinus**, edited by L. THORNDIKE (*Chicago: Univ. Chicago Press*, 1946, pp. 476+).—A printing of this late thirteenth century manuscript, with an introductory chapter by the editor.

**[Abstracts of bacteriological papers]** (*Jour. Bact.*, 51 (1946), No. 1, pp. 125, 129).—The following are included: Bacterial Penicillinase—Production, Nature, and Significance, by A. Bondi, Jr., and C. Dietz; and The Antagonistic Action of the By-Products of a Culture of *Aspergillus wentii* on the Legume Bacteria, by R. S. Robison, and Spontaneous Development of Bubbles of Gas in Agar Medium, by J. K. Wilson (both Cornell Univ.).

**Marine microbiology: A monograph on hydrobacteriology**, C. E. ZOBELL (*Waltham, Mass.: Chron. Bot. Co.*, 1946, pp. 240+, illus. 13).

On the existence, morphology, nature, and functions of the cytoplasmic membrane in the bacterial cell, G. KNAYSI. (Cornell Univ.). (*Jour. Bact.*, 51 (1946), No. 1, pp. 113-121, illus. 14).—The study of spontaneously autolyzed cells in cultures of *Bacillus cereus* and *B. megatherium* rendered possible the isolation and demonstration of the cytoplasmic membrane. The fact that this membrane is much more resistant to autolysis than the cytoplasm proper indicates considerable chemical or physicochemical differences between them. The cytoplasmic membrane stains with dyes of the Sudan series and gives the Sharp test for proteins and a positive Feulgen reaction; it consists principally of lipoids and proteins in a highly stable chemical combination. The significance of the positive Feulgen reaction is discussed. The internal surface of the cytoplasmic membrane is jagged and wavy; besides surrounding the cytoplasm, it forms plane films which separate the cells into compartments and which are potential places of cell division; it forms and eliminates into the cytoplasm granules similar to itself in chemical composition; its demonstrated roles are in cell division and in permeability. The thickness of the cytoplasmic membrane was found to vary even in a single cell; in young cells of *B. cereus* it was usually  $0.21\mu$  to  $0.35\mu$  in thickness.

Studies on cellulose fermentation.—II, An anaerobic cellulose-decomposing actinomycete, *Micromonospora propionici* n. sp., R. E. HUNGATE. (Wash. State Col.). (*Jour. Bact.*, 51 (1946), No. 1, pp. 51-56, illus. 2).—During studies of cellulose decomposition (E. S. R., 92, p. 479).—in this case by termites—anaerobic shake tubes of agar medium containing cellulose were inoculated with serial dilutions of the crushed alimentary tract of a worker termite; several large clear spots developing in the cellulose suggested the presence of an actinomycete and isolation indicated it to be this new species of *Micromonospora*. The further demonstration that it carried on a propionic acid fermentation provides physiological evidence supporting the hypothesis of an origin of the actinomycetes from the propionic acid bacteria.

Morphological characteristics of a purified thermophilic cellulose decomposing culture, D. B. PRATT. (Purdue Univ.). (*Ind. Acad. Sci. Proc.*, 54 (1944), pp. 75-78, illus. 1)—In culture tubes of ground up filter paper in peptone mineral salt solution two zones of development appeared to function—one near the surface and the other near the cellulose fibers at the bottom. At the top large uniform rods developed; in the bottom, a more filamentous form. "Amorphous cocci" were observed first at the bottom and later throughout the medium. Filaments bearing a large terminal spore—atypical in staining reactions—were noted after 48 hr.; thus the large oval body cannot properly be termed a spore. Observations of the development of the culture indicated that the evolution of gas is responsible for the mixture of types usually observed.

On the utilization and synthesis of sucrose and related compounds by some microorganisms, M. DONDOROFF. (Univ. Calif.). (*Fed. Proc. [Fed. Amer. Soc. Expt. Biol.]*, 4 (1945), No. 3, pp. 241-247)—A review (37 references) of the possible mechanisms of sucrose synthesis in certain bacteria and the suggestion that they might also apply to the problem of the production of polysaccharides and disaccharides other than sucrose in both plants and animals. It is concluded that the key to the formation of many disaccharides and polysaccharides appears near discovery, but up to the present it has in most cases eluded a direct approach. The roles of the exchange of phosphoric ester bonds for glycosidic linkages and of the exchange of glycosidic bonds themselves have given a clue to the types of reactions to be sought in carbohydrate syntheses. The mechanism of sucrose synthesis in plants seems to be one of the most promising reactions for study, and its understanding would contribute greatly to the elucidation of a number of related processes.

The inactivation of iron by 2,2'-bipyridine and its effect on riboflavin synthesis by *Clostridium acetobutylicum*, R. J. HICKEY (*Arch. Biochem.*, 8 (1945), No. 3, pp. 439-447, illus. 1).—2,2'-Bipyridine proved capable of inactivating Fe in the

fermentation of corn mash by *C. acetobutylicum* so that a marked increase in riboflavin production was promoted. Although it inactivated Fe in molasses fermentation by industrial molasses-fermenting strains of *C. acetobutylicum*, an increase in riboflavin production was not observed.

**The utilization of staled media by fungi, C. L. PORTER.** (Purdue Univ.). (*Ind. Acad. Sci. Proc.*, 54 (1944), pp. 81-83).—In the experiments reported, *Penicillium notatum* appeared unaffected by staling products in the medium; *Staphylococcus aureus* proved quite sensitive to them. A staled medium becomes progressively more acid; this affects the growth of most bacteria. *Bacillus brevis*—serving as the staling agent—influenced the growth of the two test organisms in the same way that growth had been affected by chance contaminating organisms. It is concluded that a medium remaining unsterilized is not one that will support the normal development of bacteria, nor probably of most fungi.

**The inhibition of sulphate-reducing bacteria by dyestuffs.—II, Practical applications in cable storage tanks and gas holders, T. H. ROGERS** (*Jour. Soc. Chem. Indus., Trans. and Commun.*, 64 (1945), No. 10, pp. 292-295).—A previous study<sup>2</sup> indicated that the sulfate-reducing bacteria could be inhibited by flavine-type dyestuffs. This paper describes their practical application in preventing corrosion of submarine cables, the fouling of gas holder waters, and the fouling of wheat washing plants by such bacteria producing  $H_2S$ . An appendix, Treatment of Sulphate-Reducing Bacteria in a Flour Mill (p. 295), is by E. C. Barton-Wright.

**Variation in *Penicillium notatum* induced by the bombardment of spores with neutrons, H. J. HANSON, W. G. MYERS, G. L. STAHL, and J. M. BIRKELAND.** (Ohio State Univ.). (*Jour. Bact.*, 51 (1946), No. 1, pp. 9-18, illus. 2).—Marked variation appeared in cultures from spore suspensions exposed to bombardment with slow neutrons for 1 hr. to 134 days, the number of variants increasing with duration of exposure. Actively growing cultures treated for 3 hr. showed no definite evidence of induced variation. Variation similar to that induced with slow neutrons occurred when moist and dry spores were bombarded with fast neutrons for 15 and 30 min.; 180 min. killed all spores. Isolations and studies were made of 150 variants characterized by differences in such aspects as color, texture, rate and quantity of vegetative growth and of sporulation, color and amount of transpired fluid, and color of the reverse of the colonies. A screening test, surface cultivation, and preliminary tests in submerged cultivation showed the variants to differ greatly in their capacity to produce penicillin, some no longer possessing this property and others giving yields considerably higher than those from the parent culture. Comparative studies on the morphology and on penicillin production in surface culture revealed the parent strain and a buff-colored variant to be nearly identical except for color. No qualitative differences were observed when the inhibitory substance produced by 62 variants was tested against 10 species of bacteria.

**Penicillin.—VII, Penicillinase, R. G. BENEDICT, W. H. SCHMIDT, and R. D. COGHILL.** (U. S. D. A.). (*Arch. Biochem.*, 8 (1945), No. 3, pp. 377-384).—In this phase of the investigation (E. S. R., 93, p. 410; 94, p. 168), papain, lysozyme, urease, peptidases from porcine duodenal mucosa, polidase, emulsin, ficin, trypsin, pure carbonic anhydrase, crude  $\alpha$ - and  $\beta$ -amylase, and one lot of takadiastase proved inactive against penicillin; concentrated pumpkin protease and high diastatic malt sirup showed some destructive activity. A method is described for producing a very potent exocellular penicillinase by using *Bacillus cereus* (NRRL B-569); 1 mg. destroyed 165,000 units of crystalline penicillin in 3 hr. at pH 7.0 and 30° C.

**Penicillin, VIII, IX, A. J. MOYER and R. D. COGHILL.** (U. S. D. A.). (*Jour. Bact.*, 51 (1946), No. 1, pp. 57-93, illus. 2).—The following in this series (E. S. R., 94, p. 168) are included:

<sup>2</sup> *Jour. Soc. Chem. Indus., Trans. and Commun.*, 59 (1940), No. 2, pp. 34-39.

VIII. *Production of penicillin in surface cultures* (pp. 57-78).—Several culture methods can be utilized to produce spores for the inoculation of production cultures. Spores for laboratory inoculations can be readily grown on agar slants or petri dish cultures. Use of dry spores mixed with a floating and spreading agent, such as whole-wheat flour, has given very satisfactory results in uniformity of surface growth and penicillin yield. In the search for a better organism for penicillin production in surface culture, none was found superior to one of the descendants of the original Fleming strain which had been freed, insofar as possible, from degenerate mutant strains. Continual precautions must be taken to guard against the appearance of these inferior forms. This special strain (NRRL 1249.B21) is now widely used for industrial production by the surface culture method. The penicillin yield produced in surface cultures by *Penicillium notatum* has been increased from 2 to 6 to over 200 units per cubic centimeter. Addition of corn steep liquor to the culture medium greatly increases the yield. Use of lactose or starch was found to give higher penicillin yields than can be obtained with glucose, sucrose, sorbitol, or glycerol. Strain NRRL 1249.B21 in a culture medium containing corn steep liquor and lactose has given penicillin yields of 190 units per cubic centimeter in 5 days; addition of nutrients during the course of the fermentation has given a further increase up to 220 units per cubic centimeter.

IX. *The laboratory scale production of penicillin in submerged cultures by Penicillium notatum Westling* (NRRL 832) (pp. 79-93).—A strain of *P. notatum*—NRRL 832 and not related to the Fleming strain—was found to give higher penicillin yields than any other fungus tested in submerged culture; this strain has been widely used in the industrial production of penicillin in tanks. The best medium for penicillin production contained lactose and corn steep liquor at about one-half the concentration found optimum for surface culture production. Penicillin yields of 112 Oxford Units per cubic centimeter have been obtained in 6 days by using a pregerminated inoculum. Some increase in penicillin yields was obtained by adding nutrients during the course of the fermentation.

Sur un facteur bactériostatique des tomates fraîches et desséchées [A bacteriostatic factor in fresh and dehydrated tomato fruit], A. SARTORY and J. MEYER (*Compt. Rend. Acad. Sci. [Paris]*, 222 (1946), No. 2, pp. 151-153).—The authors report a very active factor located principally in the pulpy pericarp, thermostable at 50° C., very soluble in ether and a little less so in chloroform, and insoluble in petroleum ether.

The cypericolous and junicolous species of *Sclerotinia*, H. H. WHETZEL (Cornell Univ.). (*Farlowia*, 2 (1946), No. 3, pp. 385-437, illus. 49).—The manuscript of this taxonomic study of the species of *Sclerotinia* occurring on members of the Cyperaceae and Juncaceae "was received and edited before Professor Whetzel's death on November 30, 1944. Realizing that he might not live to see the appearance of his paper, the author made all arrangements for its publication, including a generous gift to cover the extra cost of the halftone plates." The species here discussed were the only ones known to the author on sedges and rushes that could be properly referred to the genus *Sclerotinia* as characterized by him. A number of species of the Discomycetes recorded on various species of these plants and referred to that genus were not believed by him to qualify; these insofar as known to him are listed and briefly discussed at the end of the paper. Ten species of *Sclerotinia* occurring on 41 different hosts constitute the main part of this study. These are each largely restricted to a distinct suscept or set of susceptibles; only among the 4 species on *Carex* were there found a few cases of susceptibles common to 2 or more host species. In addition to references in the text, 24 are listed at the end of the paper.

Flora of Alaska and adjacent parts of Canada: An illustrated and descriptive text of all vascular plants known to occur within the region covered.—Part IV,

**Dicotyledoneae: Salicaceae (except Salix) to Caryophyllaceae**, J. P. ANDERSON (*Iowa State Col. Jour. Sci.*, 20 (1946), No. 2, pp. 213-257, illus. 104).—A further installment of the manual previously noted (E. S. R., 93, p. 19).

**Indiana plant distribution records, V—1944**, C. C. DEAM ET AL. (*Ind. Acad. Sci. Proc.*, 54 (1944), pp. 91-99).—A continuation of the series of annual reports intended to keep Deam's "Flora of Indiana" up to date (E. S. R., 92, p. 627).

**New bamboos from Szechwan Province, China**, Y.-L. and P.-C. KLENG (*Jour. Wash. Acad. Sci.*, 36 (1946), No. 3, pp. 76-86, illus. 3).—Four new species and one new variety are described under the genera *Sinocalamus*, *Bambusa*, and *Arundinaria*.

**New Asiatic species of the legume genus Campylotropis**, P. L. RICKER. (U. S. D. A.). (*Jour. Wash. Acad. Sci.*, 36 (1946), No. 2, pp. 37-40).—The author describes 12 new species.

**Aquilegia: The cultivated and wild columbinæ**, P. A. MUNZ. (Cornell Univ.). (*Gentes Herbarum*, 7 (1946), No. 1, pp. 150, illus. 38).—A taxonomic monograph involving some new nomenclature and including identification keys to the species (general and North American) and varieties.

**Observations sur l'écologie du Rhizobium leguminosarum (Bact. radicola)**, A. DEMOLON and A. DUNEZ (*Compt. Rend. Acad. Sci. [Paris]*, 221 (1945), No. 11, pp. 309-311).—As a result of their study of the comparative physiology and ecology of strains of *R. leguminosarum*, the authors show that a soil population not only exhibits great variability in the density of the nodule bacteria but also in the physiological properties of individuals in the same group. These findings they discuss in relation to N-fixing activities, to the "fatigue" of soils cropped to legumes v. bacterial symbiosis, and to the use of highly effective strains for inoculating legume seed.

**Effect of soluble nitrogenous compounds upon formation of nodules on roots of leguminous plants**, M. C. ČAJLACHJAN and A. A. MEGRABJAN (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 48 (1945), No. 2, pp. 138-141, illus. 1).—On the basis of experiments with soybean and bean it is concluded that the suppression of nodule formation and the penetration of the nodule bacteria into the roots is not controlled by the amount of soluble nitrogen contained in the substrate, but rather by that which has already penetrated into the plant tissues. As shown in previous studies of photoperiodism by the authors (E. S. R., 94, p. 603), agencies in the surrounding medium modify the physiological condition of the plant, and this in turn controls the susceptibility to inoculation with the nodule bacteria. A high content of carbohydrates and growth substances in the plant favors the formation of root nodules; the presence therein of a large quantity of soluble nitrates, on the contrary, acts adversely on bacterial penetration into the root cells and thus on the formation of nodules. Though in the course of their evolution the legumes have adapted their ability to a symbiosis with the nitrogen-fixing bacteria, this very nitrogen plays an outstanding role in the mechanisms of regulating in ontogeny the relations between the leguminous plant and the root-nodule bacteria.

**Red, brown, and green pigments in leguminous root nodules**, A. I. VIRTANEN and T. LAINE (*Nature [London]*, 157 (1946), No. 3975, pp. 25-26).—The results reported on the occurrence and significance of hemoglobin, methemoglobin, and the green pigment in root nodules are said to make possible the estimation of approximately the nitrogen-fixing efficiency of the nodules in cultivated soil simply by watching their color on the plane of intersection. If the color is red, the activity is high; if it is brown, the activity is lower and the balance lies too much on the side of methemoglobin; if the color is green, the activity is nil and the N fixation is irrevocably at an end. The names "leghemoglobin" and "legmethemoglobin" are suggested for the hemoglobin and methemoglobin of the root nodules.

**Neurospora, III, IV** (*Amer. Jour. Bot.*, 33 (1946), No. 1, pp. 15-20, illus. 1; pp. 31-35, illus. 2).—In continuation of the series (E. S. R., 94, p. 609), the following papers are included:

III. *Biosynthesis of thiamin*, E. L. Tatum and T. T. Bell.—Four mutant strains of this fungus requiring thiamine for growth were found to differ from the wild type by single genes. The evidence suggested that the thiazole analogs tested, and combinations of acetopropyl and chloroacetopropyl alcohols with thioformamide, are not normal precursors of thiazole in *Neurospora*, nor does the synthesis factor of Kidder and Dewey (E. S. R., 89, p. 185) have any demonstrable activity there. No apparent relation seems to exist between the type of thiamine deficiency in mutant strains and the inhibition by pyrithiamine. The utilization of cocarboxylase is inhibited to a greater extent than that of thiamine, while the utilization of thiazole is much less strongly inhibited by pyrithiamine. There are 21 references.

IV. *A temperature-sensitive riboflavinless mutant*, H. K. Mitchell and M. B. Houlahan.—It was demonstrated that one mutant (No. 51602) differs from the wild type by a single gene that normally controls a step in the biosynthesis of riboflavin. Riboflavin synthesis by it is shown to be a function of the temperature at which the fungus is allowed to grow. A brief discussion stresses the value of studies on mutations of this type in further elucidating the mechanism of gene action. It is shown that lumichrome, lumiflavin, and tissue extracts reversibly inhibited riboflavin utilization by the mutant here studied. There are 11 references.

**A gravimetric method for determining the activity of growth substances**, E. V. BOBKOV and N. I. YAKUSHIKINA (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 48 (1945), No. 2, pp. 132-134).—By the technic presented, fragments of pea stems are weighed in weighing glasses and placed in a solution of the substance to be tested. After a certain interval they are taken out, blotted with filter paper, and again weighed. The increase in weight against the controls (in tap water) expressed in percentage of the initial weight serves as a measure of the activity of growth in the substance tested. The detailed procedure is given.

**Isolation of 3-indoleacetic acid from immature corn kernels**, A. J. HAAGENS MITT, W. B. DANDLIKER, S. H. WITTEW, and A. E. MURNEEK. (Univ. Mo. et al.). (*Amer. Jour. Bot.*, 33 (1946), No. 2, pp. 118-120).—On the basis of acid and base destruction tests the free auxin extractable by 95 percent ethyl alcohol from immature corn kernels and detectable by the *Avena* test consisted chiefly of 3-indoleacetic acid. The total amount was calculated to be  $2.68 \times 10^{-8}$  gm. per 1 gm. of kernel; 9 percent of this was isolated in crystalline form and characterized as 3-indoleacetic acid.

**An analysis of the function of the leaf in the process of root formation in cuttings**, J. VAN OVERBEEK, S. A. GORDON, and L. E. GREGORY (*Amer. Jour. Bot.*, 33 (1946), No. 2, pp. 100-107, illus. 12).—The combined action of auxin and factors coming from the leaves proved essential for root formation in cuttings, the leaves exerting their influence in the dark as well as in the light. In red hibiscus the root-forming factors of the leaves could be entirely replaced by sucrose and nitrogenous substances. Quantitative chemical analyses indicated that these substances are actually contributed to the cuttings by the leaves; it is therefore concluded that the main function of leaves in root initiation is to supply the cutting with sugars and nitrogenous substances, factors which may be termed nutritional. There is no a priori reason to postulate the production of a special root-forming substance such as "rhizocaline" in the leaves of red hibiscus. In cuttings of this plant—following treatment with auxin in conjunction with leaves or with suitable carbohydrate and N sources—roots were found to originate in the secondary phloem of the ray parenchyma.

**A contribution to the study of heat resistance of the leaves of cotton grown on saline soils.** A. KLESHNIN (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 47 (1945), No. 8, pp. 587-589, illus. 1).—By the procedure used, leaves of a definite internode are cut off and placed in a beaker of water; the temperature of the water is gradually raised to 55° C., and the leaves are kept at 55°-60° for 10 min. After this they are transferred to containers of cold water, which is replaced by 0.2 N HCl. The appearance of yellow spots under the influence of the acid is considered an index of the heat resistance; the earlier they appear, the lower the resistance of the leaves tested. Experiments with different concentrations of HCl into which the petioles of cotton leaves were dipped for 2.5 hr. indicated that the decrease in heat resistance paralleled the concentration of the salt in the medium. The heat resistance of leaves on different internodes proved of considerable significance; the maximum resistance occurred in leaves of the midinternodes; the minimum, in the lowest and uppermost leaves.

**Physiological studies on sap flow in the sugar maple (*Acer saccharum* Marsh.).** L. P. V. JOHNSON (*Canad. Jour. Res.*, 23 (1945), No. 6, Sect. C, pp. 192-197).—Sap flow from the stumps of sugar maples was over five times as great as that from the trunks of the same trees which were detached in November, January, and March. There was no consistent variation in the sugar concentration of the sap samples drawn from stumps and trunks, but those taken from points above girdles were consistently higher in sugar than those taken from below. Sap flow is attributed mainly to the activities of living cells; it is suggested that the O<sub>2</sub> concentration of the sap and the release of hydrostatic pressure in tapped trees are related to cell activities. The beneficial effect of alternating cold nights and warm days on sap flow is attributed to an increase in the O<sub>2</sub> available to living cells through the agency of the relative solubility of O<sub>2</sub> in water at low and high temperatures.

**The absorption by roots of rubidium and phosphate ions at extremely small concentrations as revealed by experiments with Rb<sup>86</sup> and P<sup>32</sup> prepared without inert carrier.** R. OVERSTREET and L. JACOBSON. (Univ. Calif.). (*Amer. Jour. Bot.*, 33 (1946), No. 2, pp. 107-112, illus. 3).—Actively metabolizing barley roots were observed to accumulate radioactive Rb and PO<sub>4</sub> rapidly in solutions at concentrations of the order of 10<sup>-9</sup> moles per liter (Rb<sup>86</sup> and P<sup>32</sup> prepared without inert carrier). The nonmetabolic uptake of Rb and PO<sub>4</sub> by the roots in trace amounts was also studied. At 0° C. Rb\* was absorbed in a form easily removed by exchange for inert isotopes in the bathing solution; P\*O<sub>4</sub> was absorbed nonmetabolically in a form with difficulty removable by exchange for isotopes in the outside solution. The nonmetabolic uptake of trace amounts of Rb and PO<sub>4</sub> is to a high degree confined to the first few millimeters from the root tip; in this region the uptake represents an accumulation in that the concentration per unit volume of tissue is greater than in the bathing solution. The application of the technic to the general problem of ion uptake is discussed.

**Transplantation as applied to the study of nutrition of different plant species.** A. V. SOKOLOV (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 48 (1945), No. 2, pp. 135-137).—When one plant is grafted onto another, the scion is supplied with minerals whose intake depends on the root properties of the stock. The author used this method in studying the effects of elements supplied in the nutrient solution, using grafts in either direction between peas and lupines.

**The growth of yeast 6479 in ternary mixtures of various nitrogen nutrients.** R. S. W. THORNE (*Jour. Inst. Brewing*, 52 (1946), No. 1, pp. 5-14, illus. 9).—Recent work indicated that, as a rule, the mixing of two N nutrients is accompanied by a certain enhancement of yeast growth and fermentation. Experimental observation of yeast growth in graded mixtures of three N nutrients lent support

to the theory that a still further increase in the number would have a greater effect, since there was actually a progressive increase in the growth characteristics of the yeast under these conditions. The average magnitude of these enhancements (about 8 percent more than the corresponding binary mixtures) suggested that further increases in the number of nutrients would give rise to progressively smaller and smaller enhancements, approaching a limit perhaps in the neighborhood of 50 percent.

**A yeast growth inhibitive effect exhibited by tyrosine and glycine,** R. S. W. THORNE (*Jour. Inst. Brewing*, 52 (1946), No. 1, pp. 15-16, illus. 1).—It was shown in the paper noted above that mixing N sources generally induces improved growth and fermentation by yeast. This note records the only exception thus far met with, viz, the case of tyrosine mixed with glycine.

**Studies on the physiology of the germination of pollen.—I, Mutual stimulation in the germination of pollen grains,** I. N. HOLUBINSKY (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 48 (1945), No. 1, pp. 62-63).—In the 15 species of plants tested there was a clear correlation between the number of pollen grains in a drop of sugar solution and the percentage of germination and length of the pollen tubes; in view of the fact that these plants belonged to 14 genera in 11 families, it is believed justifiable to assume that such a stimulation exists in the angiosperms in general and that it will also occur during germination on the plant stigma. It is concluded that in breeding work an excess of pollen should be used.

**Respiration and cell division in plants.—I, Oxygen consumption and cell division in the leaves of *Ligustrum lucidum* and *Hedera helix*,** A. V. BEATTY (*Amer. Jour. Bot.*, 33 (1946), No. 2, pp. 145-148, illus. 2).—Using young leaves of these two species, the author determined the number of mitoses at hourly intervals and prepared graphs showing mitotic frequency plotted against time. Counts—by the sampling method—were also obtained from three acetocarmine preparations of millimeter disks of leaf tissue. The consumption of  $O_2$  was determined for the same period of time, and graphs were made showing the amount consumed per gram of wet leaf tissue plotted against time; the values for each hour were obtained by averaging the readings from four leaves. In each species the graphs showing  $O_2$  consumption and mitotic frequency exhibited common characteristics indicating a correlation between the two processes. There are 23 references.

**Respiration, II,** W. STILES (*Bot. Rev.*, 12 (1946), No. 3, pp. 165-204).—From this contribution (76 references) covering research published during the 10 yr. since the previous review (E. S. R., 74, p. 463) it will be seen that workers on plant respiration have been very active, and particularly on the mechanism of the respiratory processes. Other phases taken up are nomenclature and methods, drifts of respiratory activity, environal effects, the respiratory activity of different tissues, respiration in plants of various types, the effect of mechanism stimuli on the respiratory mechanism, and anaerobic respiration, the Pasteur effect, and anabolism.

**Torsion in protoplasm,** W. SEIFRIZ (*Jour. Colloid Sci.*, 1 (1946), No. 1, pp. 27-32, illus. 1).—"A delicate glass needle suspended in a horizontal position on the end of a freely hanging strand of myxomycete protoplasm swings alternately to the right and to the left through an arc of about  $40^\circ$  when the protoplasm is in a state of flow. The swing of the needle is the result of a twisting of the living thread brought about by streaming of the protoplasm. As a result of the spiral twist produced by streaming, a state of torsion is set up in the protoplasm. The period of swing of the needle is half the period of rhythmic flow in one direction. That the period of swing is but one-half the period of flow is due to a gradually increasing force brought about by increase in rate of flow up to the mid point of movement in one direction, after which there is a gradual lessening in the force applied and a consequent unwrapping of the protoplasmic thread. A molecular interpretation of the structural basis of spiral form and movement in protoplasm is given, based on the known asymmetry of molecules."

A note on the rate of morphogenetic movement in the slime mold, *Dictyostelium discoideum*, J. T. BONNER and D. ELDRIDGE, JR. (*Growth*, 9 (1945), No. 4, pp. 287-297, illus. 3).

Contribution à l'étude cytologique de *Penicillium notatum* Westling, B. DELAPORTE and A. SACCAS (*Compt. Rend. Acad. Sci. [Paris]*, 222 (1946), No. 3, pp. 196-198).

Relation between seeds and pericarp in the process of fruit growth and ripening, J. V. RAKITIN (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 47 (1945), No. 8, pp. 590-592).—The observations presented led the author to believe that the fundamental regularities typical of the development of seed-bearing fruits are the ultimate expression of the interrelations existing between seed and pericarp, and that a correct understanding of the characteristics of growth and maturation in fruits arising parthenocarpically is not possible without a clear knowledge of the regularities peculiar to seed-bearing fruits.

De terminologie van de bloemaanleg der bloembolgewassen (The terminology of the flower development in bulbous plants), J. J. BEYER (*Lab. Bloembollen Onderzoek, Lisse*, No. 68 (1942), pp. 16; *Eng., Ger. abs.*, pp. 13-15).

Growth and vascular development in the shoot apex of *Sequoia sempervirens* (Lamb.) Endl.—III, Cytological aspects of vascularization, C. STERLING. (Univ. Calif.). (*Amer. Jour. Bot.*, 33 (1946), No. 1, pp. 35-45, illus. 10).—In continuation (E. S. R., 94, p. 40), it is stated that "few reports have been concerned with the course of cambial development from its initiation at the growing point. The present paper attempts to portray this ontogeny as it occurs in the shoot of *S. sempervirens*."

A study of the stomate in sugarcane, L. H. FLINT and C. F. MORELAND. (La. State Univ.). (*Amer. Jour. Bot.*, 33 (1946), No. 1, pp. 80-82, illus. 17).—Studies of the red rot have included researches on hyphal penetration of the epidermal cells of sugarcane leaves and of the fungus fruiting structures occupying cells in the stomatal region. In the course of this work it became evident that the sugarcane stomate was appreciably more differentiated than those of the grasses; further investigation yielded the results here described and illustrated.

Epidermal characters in *Fraxinus*, J. W. WRIGHT. (Purdue Univ.). (*Ind. Acad. Sci. Proc.*, 54 (1944), pp. 84-90, illus. 8).—The identification of eastern American species of ash is often difficult. Particularly hard to separate are leaves of *F. biltmoreana* and *F. tomentosa*, as well as entire or nearly entire specimens of *F. americana* and *F. pennsylvanica lanceolata*. These species may be easily differentiated by certain microscopic characters of the lower epidermis; as such criteria appear not to have been used heretofore, they are here described and illustrated in detail.

Studies in the developmental anatomy of *Phlox drummondii* Hook.—III, The apices of the mature plant, H. A. MILLER and R. H. WETMORE (*Amer. Jour. Bot.*, 33 (1946), No. 1, pp. 1-10, illus. 12).—In this concluding section (E. S. R., 94, p. 608), attention is directed to the developmental changes in those parts of the older plant in which there is retention of meristematic activity, viz., the vegetative, floral, and root apices. A topographical interpretation is suggested for the primary tissue systems of the vascular plants.

## GENETICS

The improvement of naturally cross-pollinated plants by selection in self-fertilized lines.—IV, Combining ability of successive generation of inbred sweet corn, W. R. SINGLETON and O. E. NELSON, JR. (*Connecticut Station Bul.* 490 (1945), pp. 458-498, illus. 21).—In the autumn of 1934, 48 ears of several different types were selected from a grower's stock of Whipple Early Yellow. In 1935 one self-

pollination was made in each line and pollen from the selfed plant was put on Purdue 39, a uniform sweet corn inbred.

In 1936 the seed from the selfed ears was again grown and the process repeated. Preliminary observation rows of the hybrids P39  $\times$  Whipple lines O P were grown in 1936 and again in 1937 along with P39  $\times$  Whipple lines selfed once. In 1936 and 1937 hybrids were selected on the basis of yield, vigor, appearance, and uniformity of the ears. In 1938 the inbreds grown were reduced to 10, and 4 generations of each were grown for observation. In all the lines tasseling was earlier than silking, although in some the difference between tasseling and silking was greater than in others. The lines became slightly later upon inbreeding. The standard deviation for tasseling did not decrease upon inbreeding but tended to increase somewhat, indicating that the lines were as variable for tasseling at the end as at the beginning.

Height of all lines decreased rapidly in the first and second generations of inbreeding. There was a rise in height from the second to the third generation, due apparently to selection of the more thrifty plants in the second inbred generation. Standard deviation for height decreased as inbreeding was continued, suggesting that the lines were becoming more uniform for height. All lines became fixed for tillering fairly early in the inbreeding program.

The 10 Whipple lines in four generations of inbreeding were crossed by Purdue 39. Considering all varieties, selection within inbred lines was effective in raising combining ability significantly from the open-pollinated ear to the third inbred generation. A large part of the yield increase is due to an increase in the mean length of ear when outcrossed with P39. Since there was no correlation between yield of the open-pollinated generation and the third inbred generation or between the first and third, or second and third, it was not possible to detect combining ability in generations earlier than the third of selfing.

Since it appears necessary to inbreed for at least three generations before testing, inbreds should be obtained by the most direct method with the least amount of labeling of individual lines. This suggests the use of the nonindividual pedigree method of inbreeding.

**Altérations du développement et de la maturation du Zea mays var. polysperma par l'action de la colchicine.** L. BLARINGHEM and G. CHEVALIER (*Compt. Rend. Acad. Sci. [Paris]*, 221 (1945), No. 11, pp. 267-271).

**Genotype and temperature in relation to symptoms caused in Nicotiana by the mosaic virus.** H. H. MCKINNEY and E. E. CLAYTON. (U. S. D. A.). (*Jour. Hered.*, 36 (1945), No. 11, pp. 322-331, illus. 6).—Seven species carrying the necrosis factor (*N*) were inoculated with the tobacco mosaic virus and then cultured at several temperatures. Except possibly for *N. repanda*, each species carried one or more factors for mosaic susceptibility, the presence of which was apparent only at temperatures above those favoring severe secondary necrosis. When the *N* factor was transferred to plants carrying the mosaic-resistance factors from Ambalema and T. I. 448 tobaccos, secondary necrosis at high temperatures was greatly reduced or eliminated and mosaic was much reduced. Since it is apparent that the transfer of the *NN* gene from *N. glutinosa* to *N. tabacum* involves an entire chromosome, it is yet not clear that lines carrying the *N* factor are superior to those carrying the mosaic-resistance factors from Ambalema or T. I. 448 tobaccos.

**Interspecific hybridization in Parthenium.**—II, Crosses involving *P. argentatum*, *P. incanum*, *P. stramonium*, *P. tomentosum*, and *P. hysterophorus*, R. C. ROLLINS (*Amer. Jour. Bot.*, 33 (1946), No. 1, pp. 21-30, illus. 15).—A continuation of this series (F. S. R., 93, p. 699).

**Studies of a genetic disease of Trifolium repens simulating a virosis.** S. S. ATWOOD and K. W. KRETTLOW. (U. S. D. A. et al.). (*Amer. Jour. Bot.*, 33 (1946), No. 2, pp. 91-100, illus. 3).—When a selected white clover plant exhibiting a severe

mottling of its leaf blades—suggesting the symptoms of a virosis—was crossed with an unrelated healthy plant, the  $F_1$  segregated into 12 mottled and 33 healthy. A total population of 4,193 plants from various backcrosses ( $B$ ),  $F_2$ , and  $F_3$  families was classified in the greenhouse; all segregations were well defined, with no cases of intermediate injury. Ratios of 9:7, 3:1, 3:5, 1:3, and no segregation were obtained in different families, depending on the genotypes. Most of the ratios fitted the expected closely; in general, however, there was a deficiency of mottled plants—particularly in the families segregating 9:7 or 3:5. These findings are explainable by assuming two independent dominant factors, both of which must be present for development of the necrotic lesions. Evidence from  $B$ ,  $F_2$ , and  $F_3$  families suggested that the abnormal and healthy plants bearing the largest number of dominant factors tended to be lethal, but no significant differences in stand were obtained among the several segregating ratios. The number of leaves at the age of 6 weeks was used as a measure of vigor; the 1,673 healthy  $B$  and  $F_2$  individuals averaged 8.97 leaves per plant and the 605 abnormal plants 4.76, the difference between these averages being highly significant. The differences in average number of leaves were also highly significant between the different segregating ratios among both healthy and abnormal types. These averages were inversely correlated ( $r = -0.944$ ) with the number of dominant factors borne by the different classes, indicating a highly significant dosage effect caused by the same genes that conditioned the mottling but with the dosage effect superimposed on the sharply bilateral segregation observed with presence or absence of mottling. All attempts to transmit the mottling by inoculating or grafting were unsuccessful, giving further evidence that the agent was not a virus. This condition is of interest as another example of the fact that some heritable factors may induce types of morphological response similar to those induced by certain disease agents.

**Inheritance in *Begonia semperflorens*, W. D. HOLLEY.** (Univ. N. H.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 389-396, illus. 3).—In four separate crosses between double and single parents the progeny was all single flowered, indicating that doubleness is recessive. Crosses between doubles and semidoubles fitted for the most part into a 1:1 ratio. In only one instance did singles appear among the progeny. Genotypically, there are apparently several different semidoubles and the same may be true of doubles. Temperature, available plant food, season, and possibly other factors contribute to the degree of doubleness in the semidouble group. No evidence was obtained that doubleness is sex-linked. When seedlings from crosses between doubles and semidoubles were graded into large and small plants at the time of transplanting, there was found a higher percentage of doubles in the larger plots.

As to color inheritance, both parents must be pure reds to produce red hybrid. To produce white, both parents must be pure white. Pink varieties may be obtained by crossing a pure red and a pure white. To obtain 100 percent of dark foliage hybrids, one of the parents must be pure for the factor governing dark foliage. The possibilities in the production of hybrid seed are discussed.

**Inheritance in the carnation.—V, Tetraploid carnations from interspecific hybridization, G. A. L. MEHLQUIST.** (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 397-406, illus. 3).—In nearly 700 first-generation hybrids obtained from crosses between the tetraploid *Dianthus chinensis*,  $2n = 60$ , and diploid carnations,  $2n = 30$ , there occurred one fertile tetraploid with all others triploid and sterile. The fertile tetraploid hybrid behaved as a relatively stable amphidiploid. Tetraploid backcross derivatives three generations removed from the  $F_1$  appeared like autotetraploid carnations. These are self- and inter-fertile but set very few seeds when pollinated by either the tetraploid *D. chinensis* or diploid carnations. The new tetraploids are believed to have commercial possibilities and may serve as the basis for many more combinations.

**Double fertilization in petunia**, D. C. COOPER. (Wis. Expt. Sta.). (*Amer. Jour. Bot.*, 33 (1946), No. 1, pp. 54-57, illus. 10).—"The mature embryo sac of the garden petunia is a seven-celled structure consisting of three shrunken antipodals, a three-celled egg apparatus, and a large endosperm mother cell. The two polar nuclei usually fuse prior to fertilization. Fertilization occurs in the apical ovules of the ovary approximately 24 hr. after the open flower stage and the basal ones are being fertilized at 32 hr. Double fertilization takes place in the usual manner, and the entire endosperm is triploid from its inception. Two 'x-bodies' remain in the tip of the pollen tube following discharge of the male gamete nuclei."

**Recent genetical experiments with yeasts**, E. R. SANSOME (*Nature [London]*, 157 (1946), No. 3976, pp. 52-53).—A brief review (eight references) of recent studies on life histories, segregation, cytoplasmic effects, and mutation.

**A new mutant of *Saccharomyces cerevisiae***, M. K. SUBRAMANIAM and B. RANGANATHAN (*Nature [London]*, 157 (1946), No. 3976, pp. 49-50, illus. 1).

**Peculiar cytological behaviour of a distillery yeast**, M. K. SUBRAMANIAM and B. RANGANATHAN (*Nature [London]*, 157 (1946), No. 3976, pp. 50-51, illus. 1).—An unusual chromosomal behavior.

**Inheritance of reaction to crown rust and stem rust and other characters in crosses between Bond (*Avena byzantina*) and varieties of *A. sativa***, S. Y. KO, J. H. TORRIE, and J. G. DICKSON. (Wis. Expt. Sta. coop. U. S. D. A.). (*Phytopathology*, 36 (1946), No. 3, pp. 226-235, illus. 1).—The mode of inheritance of reactions to crown rust (*Puccinia coronata avenae*) and stem rust (*P. graminis avenae*), several kernel characters, and earliness among crosses of several varieties of *A. sativa* with Bond (*A. byzantina*) was studied. The segregation found for crown rust reaction in all crosses except Bond  $\times$  S. D. 334 could be explained by either the hypothesis of two complementary factors carried by Bond or of two factor pairs—S for crown rust resistance and I which partly inhibits the expression of S. Plants heterozygous for both factor pairs were more susceptible in the field than in the greenhouse. A single factor pair with dominance of resistance governed stem rust reaction. In the cross Bond  $\times$  Hawkeye the characters of basal hair length and number, basal articulation, rachilla attachment, lemma color, awnedness, and twisted black base of awn were monogenic and linked; in the cross Bond  $\times$  S. D. 334 the same kernel characters were digenic and linked. A partial dominance of earliness of heading occurred in the cross Bond  $\times$  Hawkeye; in the cross Bond  $\times$  S. D. 334 lateness of heading was dominant over early heading.

**Animal cytology and evolution**, M. J. D. WHITE (*Cambridge, [Eng.]: Univ. Press*, 1945, pp. 375-411, illus. 121).—The elements of cytology are briefly, thoroughly, and clearly reviewed.

**[Genetic studies with livestock by the Bureau of Animal Industry]**. (Partly coop. Mont. Expt. Sta. et al.). (*U. S. Dept. Agr., Bur. Anim. Indus. Rpt.*, 1945, pp. 5-6, 10-11, 16-18, 19, 20-21; also in *U. S. Dept. Agr., Agr. Res. Admin. Rpt.*, 1945, pp. 53-54, 58-59, 64-66, 67, 68-69).—Brief results are given of genetic studies, largely in continuation of those previously noted (E. S. R., 92, p. 777), on differences in meat quality of steers of different parentage, differences in efficiency and desirability of beef production by steers produced by different parents, heritability of mutton and wool characters of Rambouillet sheep, breeding skin folds out of Rambouillet sheep, effect of various conditions on traits of Rambouillet sheep, avoidance of overshot jaws in breeding sheep, increasing egg production of Rhode Island Red and White Leghorn hens by crossing inbred lines, increasing egg production of Beltsville Small White turkeys by individual and family selection, increasing consumer preferences by improving percentage of thick white and eggshell quality by reducing blood spots in eggs through heredity, developing inbred lines

of chickens resistant to lymphomatosis, and laboratory tests which simulate conditions of air travel for hatching eggs.

**[Genetics studies with dairy cattle by the Bureau of Dairy Industry]** (*U. S. Dept. Agr., Bur. Dairy Indus. Rpt., 1945, pp. 7-9, 11-12, 15-17; also in U. S. Dept. Agr., Agr. Res. Admin. Rpt., 1945, pp. 105-107, 109-110, 113-115*).—Studies along this line were conducted with dairy cattle, especially on use of proved sires for building a higher level of inheritance, the level of production in farm herds raised by the sons of proved sires, linebreeding and outbreeding equally effective in developing high-producing herds, selecting calves on the basis of mammary development, low-producing cows have smaller thyroid glands, dairy herd improvement progresses with more supervisors available, high-producing herds produce butterfat cheaper, sires proved with association records, and outstanding sires proved by cooperative breeding associations.

**Artificial breeding of dairy cattle as a practical procedure for the general practitioner.** E. L. SHUFORD (*North Amer. Vet., 27 (1946), No. 1, pp. 17-21, illus. 5*).—Methods are outlined which may be followed by the veterinarian in carrying out artificial insemination and the avoidance of many cases of failure to breed.

**Artificial insemination of cows,** W. L. HINDMARSH and R. FARKAS (*Austral. Vet. Jour., 21 (1945), No. 4, pp. 95-99*).—A description of the conduct of artificial insemination in cows, with details of carrying out an artificial insemination ring.

**The multinipple trait in sheep,** R. W. PHILLIPS, R. G. SCHOTT, and D. A. SPENCER. (U. S. D. A.). (*Jour. Hered., 37 (1946), No. 1, pp. 19-26, illus. 4*).—In a study of Bell's multinipple flock (E. S. R., 50, p. 331), the incidence of the multinipple trait in sheep was shown to be readily increased or decreased by selection of sires and dams. There is little indication that either high fertility or increased milk production is associated with the trait, and in most flocks this condition can be safely disregarded. If the incidence of multinipple individuals becomes high enough to be objectionable, it should be possible to bring it under control quickly by the use of rams with only two rudimentary nipples. In Bell's flock from about 1895 to 1925, the average number of multinipples increased from about two to six.

**Heritability of type and condition in range Rambouillet lambs as evaluated by scoring,** L. N. HAZEL and C. E. TERRILL. (U. S. D. A.). (*Jour. Anim. Sci., 5 (1946), No. 1, pp. 55-61*).—The heritability of mutton conformation and degree of fatness were estimated from the half-sib correlations and intrasire regressions of offspring on dam from data on 2,183 range lambs and 892 dam-offspring pairs. The averages of eight estimates indicated that type was about  $13 \pm 4$  percent and condition about  $4 \pm 3$  percent heritable. It seems with the low heritability of these traits that more emphasis should be placed on other more highly heritable traits and relatively less on type and condition in the development of a sound breeding program of improvement of sheep.

**Heritability of growth and efficiency in beef cattle,** B. KNAPP, JR., and A. W. NORDSKOG. (U. S. D. A. and Mont. Expt. Sta.). (*Jour. Anim. Sci., 5 (1946), No. 1, pp. 62-70*).—Study was made of the records of 177 steers produced by 23 sires at the U. S. Range Livestock Experiment Station, Miles City, Mont. The relative effects of heredity on weights, gains, and efficiency of production were estimated from the intrasire correlations obtained by an analysis of variance and the sire progeny regression obtained by covariance analysis. The heritabilities obtained from intrasire correlations for the various weights and gains were birth weight 23 percent, weaning weight 12, final feed lot weight 81, gain in feed lot 99, and efficiency of gain 75 percent. The sire : progeny would indicate heritability obtained from the sire to be birth weight 42 percent, weaning weight 0, final weight 69, daily gain 46, and efficiency of gain 54 percent. After adjusting for differences in feeding for sires each year, the heritability was found to be birth weight 34

percent, weaning weight 30, final weight 94, daily gain 97, and efficiency of gain 48 percent. These estimates of heritability seem higher than is reasonably possible, the causes for which are not known. Meanwhile, the breeder and feeder of beef cattle may take encouragement for selection of cattle for rate of gain and efficiency of feed utilization.

**Effectiveness of selecting for rapid and for slow growth rate in Hampshire swine,** J. L. KRIDER, B. W. FAIRBANKS, W. E. CARROLL, and E. ROBERTS. (Univ. Ill. coop. U. S. D. A.). (*Jour. Anim. Sci.*, 5 (1946), No. 1, pp. 3-15, illus. 1).—The mean weights at birth, 21, 56, 150, and 180 days are presented for 749 Hampshire pigs from 98 spring litters sired by 41 boars during four generations of selection for rapid and slow growth in two lines. The effectiveness of selection or heritability of growth rate was estimated (1) directly from the line differences resulting from the selection practiced and (2) indirectly from the portion of the variance within line and year due to heritable differences between sires.

Selection for rapid or slow growth rate at 5 or 6 mo. of age was one-sixth to one-fifth as large as would have been expected if the differences in growth rate were completely heritable. This estimate is less than indicated by the results of the first generation and corresponds to the lower limits of heritability estimates reported in the literature based on studies of the association between relatives. Variance analyses within lines and years indicated that heritable differences in weight increased steadily from 5 percent at birth to 24 percent at 180 days, whereas the percentage of variance due to nonheritable differences between litters decreased from 40 percent at birth to 14 percent at 180 days. From 46 to 62 percent of the variance in weight at all ages was accounted for by nonheritable variation among litter mates. The results support the findings of Nordskog et al. (E. S. R., 92, p. 35) that the heritability of weight for age increases steadily with age, while the influence of litter environment (maternal) decreases. Heritability estimates are higher for 180-day than for 150-day weight, both from line differences resulting from selection and from the analysis of variance similar to the results reported by Nordskog et al. Growth rate up to market weight is represented more by 180-day weight than by 150-day weight. Therefore, the 180-day weight is preferred to the 150-day weight as a measure of growth rate in the selection of breeding stock. However, because of the ranting in boars and certain other conditions, it may be desirable to use weight at an earlier age. Many of the statistical formulas and treatments were supplied by G. E. Dickerson of the Regional Swine Breeding Laboratory.

**Hybrid vigor in single crosses between inbred lines of Poland China swine,** G. E. DICKERSON, J. L. LUSH, and C. C. CULBERTSON. (Iowa Expt. Sta. coop. U. S. D. A.). (*Jour. Anim. Sci.*, 5 (1946), No. 1, pp. 16-24, illus. 1).—The carcass quality and dimensions of single crosses between inbred lines of Poland Chinas were compared with those of inbreds produced by the same boars.

The 28 intrasire comparisons included 56 inbred litters from 11 lines and 60 single-cross litters representing 43 different combinations of fall litters from 1942 and 1943. The inbreeding averaged 42 percent for inbreds and 6 percent for single crosses. The corresponding averages for inbreeding of the dams were 34 and 28 percent, and for the age of the dams 18 and 17 mo., respectively. Hybrid vigor or its converse (inbreeding) had a greater effect on viability than on rate of growth. However, faster growing pigs were more likely to survive. Mortality before and after birth was lower in crosses than in inbreds. At 5 mo. of age crosses exceeded inbreds by 1.4 live pigs per litter. Although both groups were suckling inbred sows, the crosses were a little heavier than inbreds at birth and at 21 days, and at 56 days the crosses averaged 3.4 lb. heavier and by 25 lb. at 154 days of age. With the differences in litter size the total litter weights of crosses at this age exceeded

inbreds by 290 lb. Although the crosses grew more rapidly, both crosses and inbreds required as much feed per 100 lb. of gain from 84 days to 225 lb. Crosses seemed to have a lower dressing percentage and less fat, but plumper hams, than inbreds. More careful selection must be practiced to maintain litter size and viability than to hold rate of growth. The performance of single crosses with dams inbred 28 percent averaged about the same as other outbred Poland China station herds. This fact suggests that the selection practiced in the development of these lines has effected considerable improvement, and using the best of such improved lines in top crossing on outbred sows or in the triple crosses offers opportunity for spacing the performance of outbreds.

**The United States Morgan Horse Farm: Its work and its objectives**, R. W. PHILLIPS. (U. S. D. A.). (*Morgan Horse Mag.*, 5 (1946), No. 2, pp. 29, 40-45, illus. 8).—The breeding program is reviewed, including descriptions of the pedigree and breeding of outstanding stallions, training devices and pasture investigations, and work with other types of livestock at the farm.

**On the bicolor gene in dog**, Ö. WINGE (*Compt. Rend. Lab. Carlsberg, Sér. Physiol.*, 24 (1946), No. 11, pp. 125-132).—The results in 10 English Setter studbooks showed that in matings of black-and-whites with their own type there were produced 147 black-and-white, 37 tricolor, 22 red-and-white, 6 liver-and-white, and 5 yellow-and-white dogs. Here tricolor seems recessive to  $c^b c^b$ , segregated by the dominant  $Cc^b$ . Pairing tricolored setters produced 17 black-and-white, 84 tricolor, 18 red-and-white, 1 liver-and-white, and 8 yellow-and-white. There were produced in matings of tricolors with black-and-white, 188 black-and-white, 151 tricolor, 25 red-and-white, 5 liver-and-white, and 7 yellow-and-white. Gordon Setter  $\times$  English Setter was black  $BEECc^b Th(i?)$ . Obviously there are several alleles of  $C$  besides  $c^b$ , namely,  $c^{**}$ , which limits black to a saddle-formed or blanketlike area on the trunk, whereas the rest of the animal is tan. Designations of other supposedly new alleles are presented.

**A blueprint of the Collie**, M. G. DENLINGER (*Washington, D. C.: Denlinger's*, 1945, pp. 96, illus. 16).—A brief description of points of differences between breeds of Collies.

**The "snowy belly" mouse: A dominant allele of the agouti series in the house mouse**, O. N. EATON and E. SCHWARZ (*Jour. Hered.*, 37 (1946), No. 1, pp. 31-32).—Another double allele in the agouti series of mice, as described by Keeler (E. S. R., 65, p. 650), is noted. It is designated as "snowy belly," for which the symbol  $A'$  is suggested. The color of this individual is ochraceous suffused with black. The back is much lighter agouti than that of  $A^w$  or  $A$ . The underside is pure white. The  $F_1$  and  $F_2$  progeny from this mouse, mated to light-bellied ( $A^w$ ), gray-bellied ( $A$ ), and black ( $aa$ )  $\varnothing \varnothing$ , suggest that snowy belly is dominant to  $A^w$  and lower alleles in the agouti series. The conclusions obtained are based on 758 individuals produced in the crosses and backcrosses.

**Value of the sisters' performance in selecting breeding cockerels**, A. B. GODFREY. (U. S. D. A.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 148-156).—A study of 652 sires on farms of U. S. R. O. P. (Record of Performance) breeders of White Leghorn, Rhode Island Red, White Plymouth Rock, Barred Plymouth Rock, and New Hampshire breeds, where the sires had at least 20 sisters and daughters as U. S. R. O. P. candidates, and 21 Beltsville sires having an average of 48 unselected daughters trapnested indicated that a minimum of 20 daughters will predict the sire's daughters' performance. Neither the production of a cockerel's full sisters nor the production of his dam is as reliable a basis for predicting the production of his daughters as the production of his full and half sisters. In most cases the families of the full sisters entered as candidates for U. S. R. O. P. are too small and the individuals too highly selective to be used in predicting the breeding per-

formance of their brothers. Representative daughters should be trapnested for selecting cockerels. Differences in breeds, strains, and environmental conditions affect egg production of the pullets more than that of their sire's sisters. Many breeders of low-producing flocks should replace their entire flocks with high-producing birds. The rate and persistence of production of a male's sisters are significantly related to the performance of his daughters. A sib-test record on a hen-housed basis is at least as reliable as one on a hen-survival basis.

**Inheritance of sexual maturity in male chickens and turkeys**, F. W. LORENZ and I. M. LERNER. (Univ. Calif.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 188-189).—As Jones and Lamoreux (E. S. R., 87, p. 364) found differences as to the age of sexual maturity in two strains of fowls, tests were conducted on the hereditary nature of the age of sexual maturity in chickens and turkeys. Limitations of material on chickens were threefold, (1) the males were culled at 6 weeks, greatly reducing the number of full brothers per family, (2) culling was largely based on physical development and appearance, so that the sample was by no means random although it must be recognized that this type of culling would operate to minimize genetic differences, and (3) the first trials were operated at an age when a considerable portion of the cockerels had already attained sexual maturity. By correcting for hatching date and age, arbitrary ages were assigned to cockerels from 1 to 4, and the rest of the birds in the study were subjected to trials once a week until the 255 cockerels of the original 260 yielded semen at 30 weeks of age. A total of 237 cockerels originating from 17 sires and 79 dams resulted. The complete analysis of variance does not make it evident that any heritability is operated because of the limitations of the data. However, the ratio of variance between cockerels by different sires to that within sires definitely indicates that the character studied has a hereditary basis. The only alternative explanation to this distribution of variance would be that a maternal effect combined with a high degree of uniformity in the mates of each sire exists. This seems unlikely. A similar series was conducted on 67 toms with ages from the first appearance of semen of 137 to 293 days. The small number limited the analysis, but there seems little doubt of the hereditary nature. Age at first semen production is inherited in both chickens and turkeys.

**Sex identification in baby chicks of "red" varieties**, R. G. JAAP. (Okla. Expt. Sta.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 185-186).—The accuracy of correct sex identification at hatching was 92.5 percent when the web area of the dorsal wing surface was used in sexing 103 chicks. The sex of 216 chicks was identified with an accuracy of 92.6 percent. Male chicks were required to have a relatively large white spot in the web region of the dorsal wing surface. The accuracy of sex identification was increased to 94.9 percent in 315 chicks by mating those whose dorsal surface color was uniform over the entire area. In a very light strain of New Hampshires the sex of 80.5 percent was correctly identified. It is suggested, for those who wish to improve sex identification in these two red-colored strains, that only those chicks having larger white areas on the dorsal surface of the wing web be saved. The general color tone does not need to be dark, but should be distinctly pigmented and uniform in both sexes. The head should be as deeply pigmented as the back. Chick sexors using the cloacal method and immediately changing to the color method for sex identification in Rhode Island Reds obtained an accuracy above 90 percent.

**Color sexing of day-old Brown Leghorns**, J. W. MACARTHUR and J. J. MACILRAITH (*Poultry Sci.*, 25 (1946), No. 2, pp. 180-183, illus. 2).—Sexing by color of 120 Brown Leghorn chicks at hatching showed that successful color sexing in this breed is based on marked sexual differences in the characteristic wild type down pattern of stripes on the crown, neck, back, face and also upon the down color

along the edge and below the wing front. In day-old chicks and throughout the down period the series of stripes is better developed, more deeply pigmented, and more sharply defined in pullets than in cockerels. The pullets are usually darker shades, while the cockerels are lighter in color and have narrower stripes.

**Induction of estrus in lactating sows with equine gonadotropin**, I. H. COLE and E. H. HUGHES. (Univ. Calif.). (*Jour. Anim. Sci.*, 5 (1946), No. 1, pp. 25-29).—A total of 42 sows of the Poland China, Berkshire, and Duroc Jersey breeds were injected with about 1,000 International Units of equine gonadotropin during lactation to induce estrus. The sows injected early in lactation (1 to 38 days) did not manifest estrus regularly, but 26 of 27 sows injected in the thirty-ninth to sixty-eighth days came into heat 3 to 7 days later. Twenty of 23 of the sows on which information is available became pregnant.

**Effects of thiouracil on the mammary gland**, J. F. SMITHCOORS. (Cornell Univ.). (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 2, pp. 197-200, illus. 2).—In studies with 85 ♂ and ♀ rats, part of which were castrated or thyroidectomized, thiouracil treatment produced no differences in the mammary glands. The thiouracil was administered for 18 to 35 days in aqueous suspensions in daily doses of 10 mg. per 100 gm. of body weight or in the drinking water as a 0.1-percent solution. When thyroxin was given with thiouracil and estrogen for 10 days the mammary glands resembled those from rats receiving estrogen alone.

**Influence of thiouracil on growth and fattening in broilers**, F. N. ANDREWS and E. E. SCHNETZLER. (Ind. Expt. Sta.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 124-129, illus. 1).—Thiouracil at levels of 0.025, 0.05, 0.10, and 0.20 percent had a progressively increasing effect on the weight and microscopic anatomy of the thyroid gland of the chicken when it was fed between the sixth and fourteenth weeks of age. The average thyroid weight increase at the 0.20-percent level, approximated 20 times normal, and in one case was 70 times normal, but no toxic effects were observed grossly or by histopathologic study of the liver and kidney. The body temperature was slightly raised. Growth was retarded but not significantly except in ♂♂ when artificial light was used during the night. Market grade and fat deposition were improved by thiouracil, although the treated birds made less gain and efficiency of feed utilization was greater when adjusted for gain by the analysis of covariance.

**Effect of rape seed on the thyroid of the chick**, C. W. TURNER. (Mo. Expt. Sta.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 186-187).—Since Kempster and Turner (E. S. R., 92, p. 825) reported that the addition of 0.2 percent thiouracil to rations of New Hampshire broilers greatly improved the market grade during 16- to 36-day fattening periods, it was of interest to compare the goitrogenic effects of varying amounts of ground rape seed in comparison with thiouracil in fattening rations of broilers. Groups of 10 to 11 chicks each received additions of 5, 10, 20, and 40 percent ground rape seed or 0.1 percent thiouracil to chick starter rations for a 3-week period, at the end of which the thyroids were weighed. It was only at the 40-percent level that rape seed caused thyroid hyperplasia. With 1 percent thiouracil, enlargement of the thyroid was almost twice that produced by 40 percent rape seed and five times that on the lower levels. Even at the 40-percent level rape seed would probably be a poor substitute for thiouracil for fattening broilers.

**Rapid assays to determine the fattening potency of orally administered estrogens in birds**, R. G. JAAP. (Okla. Expt. Sta.). (*Okla. Acad. Sci. Proc.*, 25 (1945), pp. 37-38).—In the chick oviduct test, ♀♀ baby chicks were fed estrogenized feed for 16 days after hatching and were killed on the seventeenth day, after which the oviducts were weighed and found to correlate closely with actual fattening trials. The feather color test was made with a mature Brown Leghorn cockerel or capon. The black breast feathers were plucked and the estrogen administered during

growth of the new feathers. The growing part of these feathers became salmon colored. The width of the salmon bar demonstrated the length of time the body had been under the influence of the estrogen. The weight was determined on young chicks after feeding estrogen, and the androgen stimulation on comb size was suppressed in carrying out the comb test.

**Effect of roentgen rays on bone growth in pigeons**, L. J. COLE. (Wis. Expt. Sta.). (*Jour. Expt. Zool.*, 100 (1945), No. 3, pp. 487-495, illus. 1).—The growth of bones in the wings of pigeons was definitely retarded by irradiations with X-rays at 1 to 15 days of age. There was no effect on the bones of birds irradiated 5 mo. or older. At 1 to 3 days of age the bones were most sensitive to irradiation, but they were less so at 4 to 6 days, and there was little relative response in birds irradiated at ages older than 5 mo., as the bones had attained full growth at that time. Doses of 750 r. produced no observable effect, but those of 1,000 r., 1,500 r., and 2,000 r. were increasingly effective in this order.

## FIELD CROPS

**Correcting potash deficiency in growing corn**, J. B. WASHKO (*Tennessee Sta. Cir.* 93 (1945), pp. [4], illus. 5).—Corn grown on a K-poor Fullerton cherty silt loam showed definite K-deficiency symptoms. It responded to acre applications of 25, 50, and 1,000 lb. of potassium chloride, and that treated with 50 and 100 lb. 40 days after planting made greater yield increases. While applications 59 days after planting also corrected K deficiency, improvement was least when K was applied 79 days afterward. Corn of better quality was produced on plots receiving 50 and 100 lb. of potassium chloride.

**The water factor in transplanting guayule**, L. C. ERICKSON. (U. S. D. A.). (*Amer. Jour. Bot.*, 32 (1945), No. 10, pp. 634-643, illus. 10).—The main physiological benefit of topping guayule transplants came from reduction of transpiration, without which tap roots of leafy transplants with few or no lateral roots almost always became low in moisture content and failed to generate new roots within a reasonable period of time, as contrasted with the best results obtained for certain degrees of topping, under conditions of both water culture and soil. When relative humidity was high (95 to 100 percent) little or no defoliation was needed to obtain rooting of plants in water. In leafy transplants water evidently is often severely limiting in the formation of new roots.

**The potato in health and disease**, T. WHITEHEAD, T. P. MCINTOSH, and W. M. FINDLAY (*Edinburgh: Oliver & Boyd*, 1945, 2. ed., rev. and enl., pp. 400+, illus. 32).—This general treatise considers the international position of the potato; its country of origin; intervarietal differences in the foliage, flowers, roots, tubers, sprouts, and stolons; variations and correlations; maintenance of pure stocks; cultivation; manuring; surplus potatoes on the farm; and the chief diseases of the crop. Appendixes take up fungicides, descriptive observations on some varieties in Britain, and descriptions of potato sprouts. There are 185 pages of references.

**The effect of shearing sugar-beet seed on stand of beets, on labor requirements at the time of blocking and thinning, and on yield of roots**, R. W. BELL, L. S. ROBERTSON, and R. L. COOK (*Michigan Sta. Quart. Bul.*, 28 (1945), No. 2, pp. 157-164, illus. 2).—A field study of sugar beets grown from sheared v. unsheared seed was conducted under weather and soil conditions unfavorable for seed germination and seedling growth. Compared with the amount of time required to block and thin beets grown from unsheared seed planted at the rate of 15.0 lb. per acre, the use of high-grade sheared seed at an average rate of 4.2 lb. per acre reduced the amount of time required to block and thin the beets 30.3 percent. The greatest saving of labor was effected where sheared seed was planted at the relatively low rate of 2.6

lb. per acre. However, the use of sheared seed at a high rate, 6.3 lb. per acre, also resulted in a marked saving. Post-thinning stand counts were lowest where sheared seed was planted at the rate of 2.6 lb. per acre; highest where unsheared seed was planted at the rate of 15.0 lb. per acre.

The study indicates that where the beet seedlings are unevenly distributed in the row a germination stand count of nearly 30 is necessary if a post-thinning stand of 90 beets per 100 ft. of row is to be attained. More nearly uniform distribution of sheared seed in the row would make possible lowered planting rates, lowered germination stands, and post-thinning stands of 100. Beets grown from sheared seed outyielded significantly those grown from unsheared seed, although the number of marketable beets on the sheared-seed plots at harvest time was less. Apparently with sheared seed the seedlings were disturbed less in the thinning process than with unsheared seed.

**The relation of test weight and protein content to the milling and baking quality of hard red spring wheat hybrids, R. H. HARRIS and L. R. WALDRON.** (N. Dak. Expt. Sta.). (*Jour. Agr. Res. [U. S.]*, 72 (1946), No. 3, pp. 131-136).—Very significant differences between crop years were found in test weight, wheat protein content, flour yield, and flour loaf volume for 659 samples of hard red spring wheat produced in the Fargo nursery over a 4-yr. period. These differences were ascribed principally to yearly variation in weather conditions, variations in the genetic composition of the wheats being less important.

Correlation coefficients for each of the four crop years between test weight and flour yield were so low as to be of no practical significance, while the coefficients between wheat protein content and loaf volume, though generally higher, were of little practical value for predicting loaf volume from wheat protein content. The relationships between the different pairs of variables were essentially linear in character.

The results secured in these investigations are thought to show the danger of relying solely upon test weight and wheat protein content data to predict accurately milling and baking quality in nursery rod-row samples of hard red spring wheat.

**Herbicidal use of carbon disulfide, H. A. HANNESSON, R. N. RAYNOR, and A. S. CRAFTS** (*California Sta. Bul.* 693 (1945), pp. 57, illus. 34).—Toxicity studies with  $CS_2$  and experiments to determine effects of dosage, spacing, and depth of injection, under varying soil conditions such as high and low soil moisture, presence and absence of plow sole, and variations in profile character are reported, together with a historical review of research with  $CS_2$  as a herbicide and directions for and discussion of its practical use.

$CS_2$  is a volatile liquid, and when injected into the soil forms a toxic gas which permeates the pore spaces and renders the soil atmosphere poisonous to plant roots. Different weed species respond differently to  $CS_2$ , primarily because of their soil requirements and root distributions. The standard treatment evolved is injection of 2 fluid oz. of liquid in holes 18 in. apart each way to a depth of 6 to 8 in. Effectiveness of  $CS_2$  is determined by many factors, mostly related to the soil. Rapid diffusion of the gas is favored by high soil temperature, low moisture content, and loose, open structure. Structure predominates under most field conditions. Since prevention of losses of the vapor from the surface is as essential as uniform distribution through the soil, the surface soil is sealed after an injection. Compaction by rolling and tamping is part of the standard procedure, and treatment followed by sprinkling or made after early fall rains is also common. Shallow injection is used where the surface soil is moist and can be effectively sealed, and deep injection where the topsoil is dry. Effective mulching is necessary in dry soil. Wide spacing of injection points is economical, but only under favorable conditions

of soil temperature can the distance exceed 18 in. Spacing may be as close as 12 in. where conditions are adverse.

Warm, coarse-textured, pervious soils that can be sealed effectively may require only 10 lb. per square rod, or 1,600 lb. per acre, i. e., half the standard amount. In moist, fine-textured soils and under adverse conditions, dosage may be increased to 25 or 30 lb. per square rod. Plow sole is the commonest soil structure interfering with  $CS_2$  treatment, and if dense and wet may be almost completely impervious to the vapor. Where the plow sole cannot be broken up before application, soil moisture should be reduced by growing a vigorous annual crop, and injection should place the liquid on top of the dry sole beneath at least 10 in. of well-pulverized dust mulch. Hardpan, because of its position, does not interfere with weed control by  $CS_2$ .

Summer is the most favorable time to use  $CS_2$  as to soil temperature and moisture.  $CS_2$  should not be applied during heavy wind, but light wind does not interfere if the surface sealing is adequate.

**Notes on some variations in field bindweed (*Convolvulus arvensis* L.),** E. O. BROWN. (Iowa Expt. Sta. coop. U. S. D. A.). (*Iowa State Col. Jour. Sci.*, 20 (1946), No. 2, pp. 269-276, illus. 4).

## HORTICULTURE

**Rooting of cuttings from plants sprayed with growth-regulating substances,** V. T. STOUTMYER and F. L. O'ROURKE. (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 407-411).—Cuttings taken after a certain interval from plants sprayed with 2,4,5-trichlorophenoxyacetic acid or its sodium salt in a suitable concentration showed essentially the same rooting response as did cuttings treated with growth substances according to accepted methods. The most desirable time interval between spraying and taking the cuttings was not fully established. That the effect diminishes gradually with time was indicated in experiments with privet.

There is a need of adjusting the concentration of the spray to different species in order to obtain optimum results. Noticeable effects were noted on the foliage of the sprayed plants, with epinasty of the leaves and the terminal portions of the growing shoots being common. Some plants showed discoloration of the foliage. Whether or not these external effects would persist and cause abnormalities in the succeeding growing season is yet to be determined.

**The field snapping method of harvesting asparagus,** K. C. BARRONS (*Michigan Sta. Quart. Bul.*, 28 (1945), No. 2, pp. 111-114, illus. 1).—During the acute labor shortage caused by the war, a test was made of a simple method of harvesting asparagus spears by breaking them in the field rather than cutting below the soil, which is the usual practice. Labor costs were reduced by snapping and the yields of cannable asparagus were slightly larger than in cutting operations. In addition less labor was needed in the cannery.

**The control of weeds in canning peas with chemical sprays,** K. C. BARRONS and B. H. GRIGSBY (*Michigan Sta. Quart. Bul.*, 28 (1945), No. 2, pp. 145-156, illus. 4).—This article consists of a report of experiments on the use of selective sprays of the "dinitro" compounds for the control of annual weeds, some results of tests on the value of 2,4-D for the eradication of perennials, and a summary of recommendations for the use of the various herbicides. Temperature was an important factor in the success of various sprays for annual weeds. Best results were obtained when the air temperature remained above 70° F. for several hours after application. Practically no weed kill occurred when the temperature was below 60°. In general the best results were obtained when the vines were dry and no rainfall occurred for several hours after spraying. Pressures between 40 and 125 lb. gave the best results.

In the case of the 2,4-D spray, found very promising for controlling Canada thistle, it is suggested that the spray be used to clean the fields the year before they are planted to peas. The best success was obtained when the thistles were in an actively growing condition, no later than the full bloom stage. Spot treatments could be employed in pea fields for eradicating patches of thistle.

**Growing tree fruits for home use**, W. P. JUDKINS (*Ohio Sta. Bimo. Bul.* 238 (1946), pp. 3-18, illus. 9)—Information is presented on varieties of apple, cherry, peach, pear, and plum; pollination requirements; planting; culture; fertilization; training and pruning; fruit thinning; disease and insect control; harvesting; etc.

**Blossom structure and setting of Delicious and other apple varieties**, R. H. ROBERTS. (Wis. Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 87-90, illus. 3).—In pollination experiments in 1943 the varieties Dudley, Jonathan, McIntosh, Fameuse, Wealthy, and Wolf River, were found self-unfruitful but interfertile. Red Rome was self-fruitful. Duchess (Oldenburg), Cortland, Jonathan, McIntosh, McMahon, Northwestern Greening, and Red Rome gave good sets of fruit when applied to Delicious flowers.

Studies of the flower structure of Delicious showed the pistils to be so short that honeybees in the act of collecting nectar do not always touch the stigmas. In only about 20 percent of the visits did the bees crawl over the anthers and stigmas. Bumblebees on the other hand crawl over the tops of the flowers and effect satisfactory pollination of Delicious. Delicious orchards with a good bumblebee population set satisfactorily.

Observations on the honeybee pollination relationship in several varieties showed that varieties with flower structure like Delicious are also poor fruit setters.

Distance from a pollen source was shown to be an important factor in successful pollination of Delicious flowers by honeybees. Favorable pollination of the Delicious resulted from a good population of bumblebees, a very nearby pollen source, or a very high honeybee population.

**Effect of naphthaleneacetic acid spray on maturity of apples**, L. P. BATJER and H. H. MOON. (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 113-117).—A number of apple varieties, representing a seasonal distribution in maturity from midsummer to late autumn, were treated before harvest with naphthaleneacetic acid to determine if the growth substance had any stimulatory effect on maturity. There was observed a direct stimulatory effect of the acid on summer varieties such as Close, Williams, and Duchess (Oldenburg). In the case of Summer Rambo there was no positive evidence of stimulation although there was a slight suggestion that apples from the check trees were somewhat firmer at harvest. Jonathan and Rome Beauty apples showed no effects. The naphthaleneacetic acid appeared to have a slight stimulatory effect on the maturity of Delicious. The stimulatory effect of naphthaleneacetic acid on the summer varieties may have been due to the softer flesh and limited storage life of these varieties, and the relatively high temperatures prevailing generally when the fruits attain picking maturity may also have been a contributory factor.

**Retardation of pre-harvest drop of apples through aerosol application of growth-regulating substances**, H. B. TUKEY and C. L. HAMNER. (N. Y. State Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 102-108, illus. 2).—Working with dwarf and semidwarf trees of the McIntosh, Macoun, and Kendall varieties, all of which tend to drop their fruit prematurely, comparisons were made of the effect of naphthaleneacetic acid applied in aerosol form and in water sprays.

Timing was found very important, as shown in a poor response by McIntosh trees treated 7 days before commercial harvest. Applications made at 4 weekly intervals beginning 1 day before the date of commercial harvest proved highly effective. At the relatively high concentration of 40 mg. of growth-regulating substance per

bushel of fruit, 1 lb. of aerosol containing 0.25 percent of the growth substance was equivalent to 28.25 gal. of water spray containing 10 p. p. m. of the same material.

Treatments were particularly effective on the Kendall apple. At a time when only 2 percent of the fruit of untreated trees remained on the trees, there was 87 percent on the treated. By this time many of the remaining Kendall fruits were cracked and split and long past their optimum picking condition. In a single test of 2,4-dichlorophenoxyacetic acid on a Kendall tree, there was a strong retention of the fruits.

The aerosol method appears very promising for relatively small trees, and may be a good method for applying other types of materials commonly used in spraying fruit trees.

**Relative effectiveness of sprays, dusts, and aerosols of naphthalene-acetic acid on harvest drop of apples,** P. C. MARTH, L. P. BATJER, and H. H. MOON. (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 109-112, illus. 1).—Operating with 13-year-old Stayman Winesap trees in the Kearneysville, W. Va., experimental orchard, comparisons were made of aerosol, dusting, and spraying methods of applying naphthaleneacetic acid to reduce the preharvest fall of fruit. All treatments were significantly effective, the dusts as a whole being somewhat more potent than the sprays. The dusts were applied in early morning to take advantage of the dews. The high degree of effectiveness obtained with naphthaleneacetic acid in aerosol form was of particular interest. In the application there was no visible indication that all the fruits were being contacted with the fog, yet the results were comparable to those obtained with the other methods. Light rains occurring soon after applications may have had some influence on results.

**Use of growth-promoting substances in the prevention of apple drop following frost,** T. SWARBRICK (*Nature [London]*, 156 (1945), No. 3971, pp. 691-692).—In a preliminary trial, two apple varieties—following a severe spring frost—were sprayed with a wash containing  $\beta$ -indolebutyric,  $\alpha$ -naphthaleneacetic, 2,4-dichlorophenoxyacetic, and  $\beta$ -naphoxyacetic acids, making a total hormone concentration of 75 p. p. m. The extraordinary effect in keeping the fruit on the trees was shown by the fact that unthinned trees averaged 9,486 fruits per tree.

**Differences in after-ripening requirements of several sources and varieties of peach seed,** R. F. CARLSON and H. B. TUKEY. (N. Y. State Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 199-202).—Peach pits collected from nine varieties in the station orchard and Lovell pits obtained from California were opened to obtain the seeds, which were then after-ripened in moist peat moss at 34° to 37° F. Five to 10 seeds were removed at weekly intervals from each lot and germinated in petri dishes held at 60° to 75°. Of the 10 lots, 7 germinated to some degree after 3 weeks of after-ripening. The maximum percentage of germination was reached earlier by some varieties than others. One variety, Muir, showed no germination until after 11 weeks of after-ripening. Check observations on four lots of Lovell seed planted in a field on September 26 and sampled on December 5 showed results comparable to those obtained with Lovell seeds after-ripened in the laboratory. Each variety and source of seed had specific after-ripening requirements, with most lots showing a steady increase in percentage germination and in development of strong seedlings up to about the tenth week of after-ripening treatment.

**The effect of cultivation, sod, and sod plus straw mulch on the growth and yield of peach trees,** W. P. JUDKINS and I. W. WANDER. (Ohio Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 183-186, illus. 1).—Six soil treatments were compared in a South Haven peach orchard planted in 1935 on Wooster silt loam soil. One treatment cultivation-soybean-rye, had to be discarded because of

location in a poorly drained area. During the first 10 yr. none of the remaining five systems, (1) sod; (2) sod plus straw mulch; (3) cultivation plus cover crops; (4) cultivation, cover crops, and stover; and (5) cultivation, cover crops, and manure, had any significant effect on blooming date, ripening date, quality or color of fruit, or winter injury to wood or buds. Measurement of leaves in 1941, 1943, and 1944 showed no definite correlation between the different soil treatments and leaf area. Yields were found to be proportional to the size of trees. The average trunk circumference of trees in the sod plots was smaller than in the other plots. Growth and yield were not proportional to total soil organic matter, undecomposed organic matter, or soil moisture. The principal factor limiting tree growth in the sod plots appeared to be the lack of available nitrogen.

**Fruitfulness in peaches and its relationship to morphology and physiology of pollen grains**, L. R. DETJEN (*Delaware Sta. Bul.* 257 (1945), pp. 24, illus. 5).—Of 37 varieties of peach examined over a period of 4 yr., all were self-fruitful except 4, Candoka, Chinese Cling, J. H. Hale, and June Elberta. Hand pollination resulted in larger sets of fruit than were obtained by simple bagging of the branches, but the latter method gave an adequate set and is more preferable because of less labor required. Differences in set of cross-pollinated flowers were observed among trees of the same and different varieties, among branches on a single tree, and among different varieties of pollen applied on a single tree.

Chinese Cling in 1941 produced an abundance of normal viable pollen grains which however proved incompatible with related pistils. Non-emasculated flowers of pollen-sterile varieties yielded usually a heavy set of fruit upon cross pollination. Elberta, Golden Jubilee, Halehaven, and Rio-Oso-Gem proved effective pollinizers for Candoka and June Elberta. Pollen-sterile varieties produced a small percentage of viable pollen which induced a small set of fruit on bagged branches.

A study of the pollen of peach varieties showed differences in gross morphology and physiology. Certain varieties, like Cumberland, Early Elberta, Golden Globe, and Kalhaven, produced mostly large, oval pollen grains. Fireglow and Rio-Oso-Gem produced mostly large irregular but viable pollen grains. The majority of the varieties under study produced a mixture of large oval, large irregular, and small irregular grains in various proportions. Rio-Oso-Gem was the only peach to produce exclusively large, irregular pollen grains. Fireglow produced about 62 percent of these grains. In all the varieties, except Rio-Oso-Gem and Fireglow, the relative number of large oval grains present in the pollen was a good index to viability. Variability in size of pollen grains might be used as a means of identification of varieties.

**Some effects of irrigation on the interrelations of growth, yields, and drying ratios of French prunes**, A. H. HENDRICKSON and F. J. VEHMEYER. (Univ. Calif.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 187-190).—Although at the beginning of the experiment in 1932 the average cross-section areas of the trunks of trees that were to receive no irrigation water during the growing season were slightly larger than those of the trees that were to be irrigated, at the end of 12 yr. the irrigated trees were larger in trunk cross section and in size of top. The irrigated trees produced usually more fruit per unit of cross-section area than did the unirrigated. The lack of readily available moisture in the soil after July 1 had an apparently harmful effect on fruit setting. Inasmuch as the unirrigated trees had rather consistently a lower drying ratio and a small ratio of yields to cross-section area, it may be argued that correlations between drying ratios of prunes and the ratio of yields or numbers to cross-section areas of trunks would necessarily follow when the two groups were used in the same calculation. If the trunk cross-section area may be used as a measure of leaf area, the fruits on the unirrigated trees had a larger leaf area per prune than did the irrigated trees. If this is true,

the increased leaf area may help explain the slightly lower drying ratio found frequently with prunes from the unirrigated plots.

**Ripening of the Italian prune as related to maturity and storage**, F. GERHARDT and H. ENGLISH. (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 205-209, illus. 1).—The variation in maturity of Italian prunes from different orchards and grown under different cultural conditions was great enough to preclude the use of firmness, total acids, or soluble solids as reliable indexes of harvesting maturity. Color of flesh together with the solids-acid ratio was the most satisfactory guide to proper time to harvest. Fruits with flesh of a medium to dark amber color and a solids-acid ratio of 13 to 15 were judged to be acceptable for long distance shipment.

Immediate storage of prunes at 31° F. was followed by a low temperature injury characterized by mealiness of the fruit and discoloration and breakdown of the flesh, usually evident at about the time the fruit had attained its best dessert quality. Partial ripening before storing at 31° or holding fruit at 40° to 45° prevented this storage breakdown.

**The Lamida, Ebony, and Spalding sweet cherries**, L. VERNER (*Idaho Sta. Cir.* 109 (1946), pp. 4, illus. 1).—Descriptive information is presented on three new cherries developed by the station from open-pollinated seed. The ovule parent is thus known and the pollen parent unknown, although presumed to be nearby trees of compatible varieties. The Lamida is said to resemble closely the Lambert cherry and to be far superior to Lambert in resistance to fruit cracking. All three of the new varieties are described as very good or better in quality. Spalding, because of its exceptionally firm flesh, appears promising for long shipment.

**The effect of varying the reaction of organic soil on the growth and production of the domesticated blueberry**, P. M. HARMER (*Soil Sci. Soc. Amer. Proc.*, 9 (1944), pp. 133-141, illus. 6).—Variation of the soil reaction was accomplished in three different ways: (1) By the use of mixtures of alkaline and very acid soil without the introduction of any foreign material, (2) by addition of sulfur at different rates to alkaline soil in greenhouse and to slightly acid soil in field, and (3) by addition of ground limestone at different rates to soil so intensely acid that lime might be a limiting factor on growth and production. Results showed satisfactory pH between 4.0 and 5.2, with optimum from 4.5 to 4.8. Sulfur proved very satisfactory in correcting pH which was too high for satisfactory growth, but from a practical standpoint its use is not advisable with soil pH above 6.5. With soil pH below 4.0, a light application of ground limestone is likely to be beneficial. Reaction of soil just below the plowed layer should be considered in applying sulfur or limestone. Explanation for the unsatisfactory growth of blueberries in soil with high pH may lie in the soil content of available calcium, magnesium, and possibly nitrate and in the effect of the first two on availability of the soil's manganese and possibly boron.

**The cultivated blueberry industry in New Jersey, 1944**, D. T. PITT (*N. J. Dept. Agr. Cir.* 356 (1945), pp. 7-42, illus. 7).—The results of a survey made in cooperation with the New Jersey Experiment Stations. For notes on insect pests, see p. 84.

**Surface and volume determinations of citrus fruits**, F. M. TURREL, J. P. CARLSON, and L. J. KLOTZ. (Calif. Citrus Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 46 (1945), pp. 159-165, illus. 3).—Surface and volume tables for oblate and prolate spheroids and spheres were found of value in estimating surfaces and volumes of citrus fruits such as Marsh grapefruit, Washington Navel orange, Valencia orange, and Eureka lemon. The average percentages of difference between actual measurements of the fruits and the values determined by surface and volume tables ranged from 2.23 to 5.59 percent for surface area and 1.95 to 8.35 percent for volume.

**Changes in lemons during storage as affected by air circulation and ventilation,** E. M. HARVEY (*U. S. Dept. Agr., Tech. Bul. 908 (1946), pp. 32, illus. 9*).—This study showed in general (1) that air circulation cannot be substituted for ventilation as ordinarily provided in commercial storage, (2) that sufficient carbon dioxide does not accumulate in commercial storage to injure lemons, but it did not eliminate the probability that certain other emanations (particularly ethylene) of molds and of the lemons themselves can easily become injurious to lemons held in long storage; and (3) that the percentage of buttons that are green and their rate of change from one color class to another affords a practical means of predicting the maximum safe period for holding a given lot of lemons in storage.

Weekly loss of weight was greater in a commercial storage room than in either a still-air chamber or a chamber which had air circulation. Lemons of different stages of maturity lost weight in the following order: Tree-ripe, silver, light-green, and dark-green. For all practical purposes differences in rate of loss of weight were negligible because of differences in the relative length of the storage period for fruit of different maturities. The first external sign of *alternaria* decay in a lot was seldom found to indicate decay in more than 1 percent of the other lemons of the lot. When at least 2 percent of the lemons showed externally visible symptoms of decay the lot was considered to have reached decay break (beginning of definite susceptibility to *Alternaria*). This stage was later fixed arbitrarily at 3 percent. The length of time lemons could be held in storage before decay break occurred depended upon their stage of maturity at storage, the time of picking, the year, and the storage conditions; the rate of subsequent decay was rapid and rather uniform regardless of the original storage quality. At or near decay break lemons changed from almost complete immunity to *Alternaria* to extreme susceptibility. Lemons picked in midwinter had the best storage quality; after February their keeping quality diminished until late spring and early summer. Light-green lemons picked in February did not reach their decay break until 6 weeks after those picked from the same grove in May. Lemons keep much longer in storage in some years than in others.

**The organic acids of lemon fruits,** W. B. SINCLAIR and D. M. ENY. (Calif. Citrus Expt. Sta.). (*Bot. Gaz.*, 107 (1945), No. 2, pp. 231-242, illus. 3).—The acidity of lemon juice is due chiefly to citric and malic acids; others, if present, are in very small amounts. The citric acid determined on the pure juice did not differ significantly from the amount precipitated by lead acetate; the total acid content thus precipitated from lemon juice was equal—within experimental error—to the sum of the citric and malic acids. The difference between the free-acid fraction and the total organic-acid radical (citric and malic) was relatively much greater than the combined acids determined from the alkalinity of the ash. Since this difference was not reflected in the titratable acidity or pH values, it is believed to represent the quantity of organic acid in the ester form. The alkalinity of the ash represented the organic acid combined in salt form with the excess inorganic cations. The titration curve of lemon juice was very similar to that of a pure citric acid solution provided a correction was made for the combined acid naturally occurring in the juice. A definite relation existed between the pH and the amount of acid in the salt or combined form. The small fluctuations in pH of mature lemon juice were correlated with the large ratio of free acid: combined acid. The free acids (mg. per cc.) increased and the pH of the juice decreased as the fruit grew larger. The great reduction in pH (5.2 to 2.6) occurring in fruits 2 to 4 cm. in diameter was due to a correspondingly large increase in free acid. Further increase in fruit size (up to 6 cm. diameter) resulted in a slight decrease of about 0.3 pH, while the free acids continued to increase gradually in the juice.

**Plantas medicinales de posible cultivo en Puerto Rico** [Medicinal plants for possible cultivation in Puerto Rico], E. NÚÑEZ MELÉNDEZ (*Puerto Rico Univ. Sta. Bul.* 67 (1945), *Span. ed.*, pp. 47+, *illus.* 6).—Prior to the war, the majority of the vegetable drugs were obtained from the Old World. During the war, a large variety of plants were tested in the botanical garden of the University of Puerto Rico as to their possible culture. In this bulletin about 40 are described with notes as to the extraction and use of the essential ingredient.

**Cinchona investigations in Puerto Rico**, R. E. HARPER and H. F. WINTERS. (P. R. Fed. Expt. Sta.). (*U. S. Dept. Agr., Agr. in Americas*, 6 (1946), No. 2, pp. 30–32, 37, *illus.* 3).—This is an account of experiments in progress to determine environmental and cultural factors essential to the growth and development of strains of cinchona which may be used to provide supplies of planting stock for various locations in the Western Hemisphere. A stem canker and two root diseases, responsible for large losses in the nursery and field, are closely associated with adverse soil conditions such as poor drainage and inadequate aeration. Thrips of various kinds are the worst insect enemies. There is a need of selecting strains of cinchona that are adapted to American conditions.

**Cinchona officinalis in the Colombian Andes**, A. L. McCOMB. (Iowa State Col.). (*Jour. Forestry*, 44 (1946), No. 2, pp. 92–97, *illus.* 3).—This paper presents a description of *C. officinalis*, its site requirements, its yield of bark, and the alkaloid content of bark in the eastern cordillera of the Colombian Andes. The species grows in dense, temperate or cool temperate, wet forests as a subdominant in high forest stands, or frequently as a dominant on high ridges. With tree diameters of 3 to 6 in., some 150 to 600 trees are required to yield a ton of dry bark, and it was necessary usually to cover some 375 acres to obtain this amount. Great variation was found in the alkaloid content of the bark.

## FORESTRY

**Effects of plant-growth regulators on shoot development and field survival of forest-tree seedlings**, C. E. OSTROM. (U. S. D. A.). (*Bot. Gaz.*, 107 (1945), No. 2, pp. 139–183, *illus.* 12).—A series of seven experiments (October 1942–October 1943)—involving about 25,000 trees and several hundred feet of nursery bed—was carried out on seedlings of red, loblolly, shortleaf, pitch, and table-mountain pines, red spruce, tuliptree, and white ash treated in the nursery bed before storage or planting with naphthalenecetic acid, naphthalenemethylacetate, naphthaleneacetamide, and mixtures of naphthalene compounds with or without indolebutyric acid applied in various ways. The normal surge of leader growth of pine seedlings was not delayed or substantially lessened by 200 or 600 mg./l. sprayed on expanding buds or old foliage. Once started, needle development could be completely arrested shortly after treatment and “frozen” for the remainder of the season on red and table-mountain pines; undesirable curving of the new leaders resulted, however, on the latter. At the end of the growing season, red pine seedlings sprayed in May with 600 mg./l. naphthaleneacetamide had somewhat lower top : root ratios and much lower average dry weights than the untreated. Inhibiting treatments were close to the lethal concentration. Red pine seedlings with only one-third to one-half the normal quantity of new foliage from inhibition by growth regulators were no more resistant to artificial drought than the untreated. Top pruning of loblolly pine during early spring resulted in decreased resistance to artificial drought and to transplanting during the same summer.

Vapors and sprays of naphthalenemethylacetate and a mixture of growth regulators effectively prevented or restricted the development of etiolated shoots of white ash seedlings held in unrefrigerated storage until June; initiation of new roots was

also stimulated, particularly on the stem. Inhibition of shoots and stimulation of roots were much less distinct in treated trees heeled-in outdoors. Prestorage treatments with growth regulators failed to affect the survival of white ash seedlings planted in May when controls were still largely dormant, but resulted in higher initial survival and greater root growth of trees planted in June; naphthalene-methylacetate applied as vapor (0.3 or 0.5 mg./cu. ft. of space for 18 hr. at 70° F.) or spray (100 mg./l. in dilute commercial wax emulsion) was successful for 2-yr. seedlings. Similar prestorage treatments failed to improve survival of loblolly or shortleaf pine seedlings. Preplanting treatments were given to tops of seedlings of red, shortleaf, and loblolly pines and to roots, tops, and whole plants of red spruce and tuliptree. Various treatments with 80-1,000 mg./l. naphthaleneacetic acid and other compounds failed to improve the field survival of conifers and usually lowered it. Seedlings of tuliptree dipped in emulsions of 200 or 400 mg./l. of mixture of growth regulators just before spring planting leafed out more slowly than controls; survival was, however, so uniformly high for all treatment groups (May planting) that no advantage resulted from the prolonged dormancy. Treated tuliptree seedlings showed a slight stimulation of root growth in the heeling-in bed and excelled controls in the total dry weight by the end of the first season in the plantation. Application of emulsions of lanolin or commercial wax to conifer foliage immediately before planting resulted in higher survival during the spring months; after a long severe drought (1943), their survival exceeded that in controls in some but not all plantations. There are 17 references.

**Effects of soaking with indolebutyric acid on root development and survival of tree seedlings,** T. E. MAKI and H. MARSHALL. (U. S. D. A. et al.). (*Bot. Gaz.*, 107 (1945), No. 2, pp. 268-276, illus. 3).—Eastern red oak and loblolly pine seedlings were treated just before planting by soaking the roots for 24 hr. (also a 6-hr. series for pine) in aqueous solutions of indolebutyric acid at 2.5 to 160 mg. per liter; root volumes were measured before planting and again when the seedlings were lifted at the end of the first growing season. Consistent increases in root volume of red oak followed soaking in all concentrations; they were statistically significant at 40 mg./l. or more. A barely significant increase in survival followed treatment of red oak with 5 mg./l.; on the other hand, a marked increase in mortality followed treatment with 80 mg./l. or more. The largest increases in root volume of red oak were associated with the greatest mortality. Treatments usually increased the root volume of loblolly pine, though there was no consistent relationship between root volume and concentration. A marked increase in mortality of the pine followed treatment with concentrations above 20 mg./l.

**Analysis of fire spread in light forest fuels,** W. L. FONS. (U. S. D. A. coop. Univ. Calif.). (*Jour. Agr. Res.* [U. S.], 72 (1946), No. 3, pp. 93-121, illus. 12).—The analysis of rate of fire spread in light forest fuels reported in this paper is based on the theory that the spread of a fire can be expressed as successive ignitions of adjacent fuel particles, and that its rate is therefore governed by the time required to raise successive fuel particles to ignition temperature. Equations have been derived for rate of fire spread in homogeneous and heterogeneous fuel beds, taking into account the physical characteristics of the fuel particles, the arrangement of the bed, and the pertinent attributes of the atmosphere. The spread equations are expressed in terms of the following fundamental variables: (1) Film conductance, (2) heat transfer factor for radiation, (3) ignition temperature, (4) fuel particle spacing, (5) surface volume ratio of fuel, (6) specific heat, (7) density of fuel, and (8) fuel temperature. It has been shown that the variables ordinarily recognized in the field practice—wind velocity, fuel moisture, fuel density, fuel size, fuel bed compactness, slope, and time—influence fire spread only as they produce changes in the fundamental variables.

The results of field and laboratory experiments were used to check the theory and analysis, as well as to provide quantitative information for determining the magnitude of the effects of variables measurable in field practice on the rate of spread.

**Prescribed burning in relation to grazing in longleaf-slash pine type,** P. C. LEMON. (U. S. D. A. coop. Ga. Coastal Plain Expt. Sta.). (*Jour. Forestry*, 44 (1946), No. 2, pp. 115-117).—Studies conducted on the Alapaha Experimental Range in Georgia showed that planned moderate burning in the longleaf-slash pine type improves the forage for grazing and results in better cattle gains. Such burning may be also beneficial with respect to fire hazard reduction, seedbed preparation, and brown spot control.

Planned burning to improve grazing can be done successfully without excessive tree damage, if the area selected for burning has an adequate stand of trees capable of withstanding light fires, if the area is divided into small units by natural or prepared firebreaks, if conditions for burning are considered carefully, and if the job is done by personnel trained in the skillful handling of fires.

**Christmas tree production,** J. C. MOORE. (Coop. U. S. D. A.). (*Alabama Sta. Cir.* 92 (1945), pp. 15, illus. 7).—In 1940 a total of 15 species of evergreens were planted in a test of their potential value as Christmas tree material. Four types of culture were compared, (1) native vegetation, (2) partridge peas, (3) lespedeza sericea, and (4) a combination of crimson clover and rescue grass. Trees were planted in contour rows 4 ft. wide and spaced 4 ft. in the rows, thus providing approximately 2,700 trees per acre. All four systems of culture were effective in controlling erosion, but because the cover crops in three of the systems made their growth in summer there was serious competition between the covers and the trees for water. The crimson clover-rescue grass combination made its growth during winter and early spring and furthermore the mature vegetation fell to the ground and formed a heavy mulch which eliminated most of the weed growth during the summer.

Of the 15 species Arizona cypress, red cedar, scrub pine, and white pine, in the order given, were most promising for Christmas tree production. Arizona cypress grew rapidly, had good form, and held its needles and rich aroma for a long period after cutting, and while it had one minor disqualification, that of a disease which attacked the tender growing points giving them a brownish color, it proved to be the most desirable from the consumer's standpoint, commanding a ready sale at good prices. There was also evidence that desirable new trees would grow from its cut stump, indicating that several trees might be harvested ultimately from the original plant.

**Studies of Chinese gallnuts,** P. C. YEH and C. S. CHENG (*Jour. Forestry*, 44 (1946), No. 2, pp. 121-124).—This paper discusses the kinds, distribution, formation, development, constituents, and yield of gallnuts, a forest byproduct of importance in southwestern China. The trees that produce gallnuts all belong to the cashew family, Anacardiaceae, and include species of *Rhus* and *Pistacia*. The insects causing the galls are aphids.

## DISEASES OF PLANTS

**The Plant Disease Reporter** [February 15 and March 15, 1946] (*U. S. Dept. Agr., Plant Disease Rptr.*, 30 (1946), Nos. 2, pp. 35-64, illus. 2; 3, pp. 65-92).—The above issues contain the following:

No. 2.—Host-parasite check list revision—*Medicago-Petalostemon* (Leguminosae), by F. Weiss; legume diseases previously unreported from Oklahoma, by D. A. Preston (Okla. A. and M. Col.); seasonal variations in the incidence of the loose

smuts of wheat and barley in West Virginia, by C. F. Taylor and J. G. Leach (W. Va. Univ.); notes on diseases of garden crops in Georgia in 1945, by J. H. Miller (Univ. Ga.); late blight on tomatoes on the west coast of Florida, by A. L. Harrison; diseases of vegetable crops during December in Palm Beach County, Fla., by G. R. Townsend, R. C. Cassell, E. L. Felix, and R. Desrosiers (Fla. Everglades Expt. Sta.); a nomenclatorial discussion of *Ustilago striiformis*, by J. A. Stevenson; notes on visual differentiation of white pine blister rust from pinyon rust in the telial stage, by J. W. Kimmey; plant diseases recorded from new locations in Arkansas by V. H. Young (Univ. Ark.) and in Louisiana and Oklahoma by D. A. Preston (Okla. A. and M. Col.); and brief notes on cornstalk rots in Virginia in 1945 by S. B. Fenne (Va. A. and M. Col.) and virus disease on avocado—a correction by R. C. Baines.

*No. 3.*—Host-parasite check list revision—*Phaseolus* (Leguminosae), by F. Weiss, and note regarding distribution of separates of revised check list; some psychological aspects involved in conducting plant disease surveys—personal bias a factor to be reckoned with in estimating and evaluating plant disease losses, by P. R. Miller; observations on blasting of onion seed heads in Idaho, by E. C. Blodgett (Idaho Sta.); observations on Mississippi tomato diseases during 1945, by L. P. McColloch, H. H. Foster, and J. M. Lutz (coop. Miss. Sta.); nut diseases in Oregon in 1945, by P. W. Miller; a note on the distribution of black rot of orchids, by D. P. Limber; and diseases of vegetable crops during January in Palm Beach and Broward Counties, Fla., by G. R. Townsend, R. C. Cassell, E. L. Felix, and R. Desrosiers (Fla. Everglades Sta.).

**Preventing plant disease introduction**, W. A. McCUBBIN. (U. S. D. A.). (*Bot. Rev.*, 12 (1946), No. 2, pp. 101-139).—In this analytic review (89 references) the author summarizes the problem of plant disease introduction from the restricted viewpoint of the United States, "in the hope of bringing out certain values and relations most likely to be useful in national thinking and planning." The points brought out are the reality of disease introduction and the fact that it involves effective establishment, the past and present cost of foreign diseases to the country and the potential danger from further entries, special relations of contiguous lands, natural channels of introduction including human agencies, relation of pathogen groups to entry channels and of biological races to disease introduction, natural barriers to entry, factors influencing national efforts to prevent disease introduction, programs and procedures of disease exclusion, value of the foreign certificate, and viewpoints—pessimistic and optimistic—with respect to disease-exclusion possibilities.

**Determination of factors injurious to plants in acid soils**, T. WALLACE, E. J. HEWITT, and D. J. D. NICHOLAS (*Nature* [London], 156 (1945), No. 3974, pp. 778-779, illus. 2).—A preliminary report on experiments emphasizing the importance of the visual method in diagnosing causes of crop failures due to defective nutrition, and of the sand-culture technic in analyzing complex soil problems of plant nutrition.

**Chlorosis of plants in Idaho**, E. C. BLODGETT (*Idaho Sta. Cir.* 110 (1946), pp. 7).—In southern Idaho and other arid regions of the western United States, chlorosis usually refers to the lime-induced type; this disease has been known to the station since 1894, but has increased noticeably in the recent past and is now regarded as the most important single disease affecting orchard and small fruit production in certain irrigated sections of the State. This circular briefly summarizes the information developed by the station, including suggested control measures.

**Infection by viruses**, M. A. LAUFFER and W. C. PRICE (*Arch. Biochem.*, 8 (1945), No. 3, pp. 449-468, illus. 6).—The development of an equation involving the Poisson series—applicable to the study of virus infectivity at various concentrations—is reviewed (20 references) and discussed. The fundamental assumption underlying this development is that virus infection depends on the chance occurrence of the

required minimum number of virus units in the dose actually coming into contact with a susceptible region of the host. When the inoculation method is such that many foci of infection must be judged by gross symptoms, the results might deviate from the equations because of possible variability in the number of foci per entity showing gross symptoms. The development of an alternative hypothesis is also reviewed; according to it the distribution of the number of positive responses to varying dose levels is due solely to the variability of host susceptibility. It is shown that under special circumstances this theory could lead to a final result resembling fairly closely that obtained for the other theory. All the large amount of data examined from the literature tended to be consistent with the theory that the quantitative response at various dosage levels is due primarily to the chance occurrence of at least one infectious unit per dose; excluded entirely was the possibility that the response at various levels is due to the chance occurrence of a minimum of two or more units. These data also appeared to fit the alternative hypothesis when suitable restrictions were applied; independent evidence is presented, however, to show that this theory is untenable. The findings led to the conclusion that the only tenable theory at present available for explaining the character of the quantitative response of hosts to various doses of viruses is that the probability of infection is related to the probability of finding the minimum requisite number of infectious units in an element of volume which comes into intimate contact with a susceptible focus in the host. If this theory is correct, the data prove conclusively that for the viruses thus far studied, one infectious unit is sufficient to cause an infection. On the basis of present knowledge, therefore, the proposition that one infectious unit can cause virus infection is the most reasonable starting point for speculation concerning the nature of virus reproduction.

**Determination of the isoelectric point of virus proteins by the staining technique,** L. M. TARASSEVICH (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 47 (1945), No. 9, pp. 666-668, illus. 1.*)—It has been reported by many authors that the staining of live and dead tissues depends on the pH of the staining solution, the basis of this dependence being the difference between the electric charge of the staining solution and the substance which adsorbs the stain. The elaboration of a technic based on this dependence would enable determination of the isoelectric point of the virus proteins accumulating in plant tissues in crystalline form, purified preparations of which have not yet been obtained. The author tested this technic with three plant viruses and with the polyhedra of silkworm jaundice and found a close coincidence in results with those obtained by other methods. The proposed technic is distinguished by its simplicity and speed; the chief disadvantage lies in its relatively low precision, due to individual difference in evaluating the intensity of the staining reaction.

**On the growth hormones in a diseased plant,** K. SUKHORUKOV and B. STROGONOV (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 47 (1945), No. 8, pp. 593-596.*)—The authors review the work of others (11 references) and present the results of their own studies on growth hormones in diseased plants and in the secretions of parasites and saprophytes (oats with crown rust, potato with late blight, crown gall bacteria, and *Aspergillus niger*) and on the post-mortem formation of auxins. They conclude, in general, that the auxins of diseased plants are destroyed in protective necroses and that no auxins are formed in dead cells. Parasitic organisms which disturb correlations among the growth processes (e. g., crown gall bacteria) are found capable of producing and secreting the "auxins and hormones of cell division."

**Some comparisons of bacterial plant galls and of their causal agents,** A. J. RIKER, F. SPOERL, and A. E. GUTSCHE. (*Wis. Expt. Sta. (Bot. Rev., 12 (1946), No. 2, pp. 57-82.*)—In this comprehensive review (101 references), comparisons are

made of nine bacterial plant gall diseases—beet pocket rot, cane gall, crown gall, Douglas fir gall, gypsophila gall, hairy root, oleander knot, olive knot, and pea fasciation, as well as some similar nonparasitic galls. The text considers the different kinds of bacterial galls, comparison of bacteriological characters, comparative life histories in relation to pathogenesis, locations of bacteria within the host plants and their movements within the tissues, and nonparasitic growths caused, e. g., by wounds, grafts, accumulated food materials, genetic characteristics, and certain chemicals including "plant hormones."

**Physiologic specialization of the parasitic fungi, II,** G. M. REED (*Bot. Rev.*, 12 (1946), No. 3, pp. 141-164).—As shown in this supplementary review (E. S. R., 74, p. 48), the investigations of the past 10 yr. have resulted in the differentiation of many new races among a wide range of host plants. The author discusses and/or tabulates (with authority, year, and country) the number of races in cereal and other rusts, cereal and other smuts, powdery mildews, and other pathogens recorded during this period; there are 177 references.

**Danish species of *Alternaria* and *Stemphylium*: Taxonomy, parasitism, economical significance,** P. NEERGAARD (*Köbenhavn (Copenhagen): Einar Munksgaard*, 1945, pp. 560, illus. 159; *Dan. abs.*, pp. 417-430; *Esperanto abs.*, pp. 431-437).—The general part of this monograph on these two phytopathological fungus genera takes up material and methods, nomenclature, terminology, and taxonomy in the aspects applying to the study as a whole; the special part deals with the individual species; and a concluding section includes remarks on the life cycles, pathogenesis, and control of the fungi studied. Included also are 67 tables, 33.5 pages of references, and indexes to fungi and host plants.

**Inhibition of the development of *Fusarium oxysporum cubense* by a growth substance produced by Meredith's actinomycetes,** A. C. THAYSEN and K. R. BUTLIN (*Nature [London]*, 156 (1945), No. 3974, pp. 781-782).—In the tests reported, Meredith's organism (E. S. R., 91, p. 163)—after 5 weeks' growth in food yeast waste liquor—had developed a sufficient concentration of inhibitory substance so that 1 cc. of the liquor prevented growth of *F. oxysporum cubense*. Though the active substance has not yet been isolated, it was found to be thermolabile and not to pass through a porcelain filter.

**Observations on chytridiaceous parasites of phanerogams.—I, *Physoderma menyanthidis* de Bary,** F. K. SPARROW (*Amer. Jour. Bot.*, 33 (1946), No. 2, pp. 112-118, illus. 41).—The author describes certain phases in the life history of this chytrid parasite of a bog-inhabiting flowering plant—*Menyanthes trifoliata*. The fungus, *P. menyanthidis*, overwinters in the resting spore stage; at germination, it cracks open and a thin-walled fingerlike structure is produced within which zoospores are formed. These swimmers may eventually settle down on the surface of a living host, penetrate its tissues, and form a monophagous bushy rhizoidal system within. The epibiotic body of the spore steadily enlarges and forms at maturity a thin-walled "ephemeral" sporangium; this produces zoospores somewhat smaller than those developed at the germination of the resting spores. These now apparently form only new ephemeral sporangia, which may also be formed by internal proliferation of discharged ones. About 5 days after the swarming of the zoospores from germinated resting spores, the first evidences are observed of the thallus on which the dark resting spores will be borne. Contrasted with the epibiotic thallus this one is polycentric—bearing numerous turbinate organs—and produces visible hypertrophy of the host plant.

**Further observations on the mechanism of germination of the conidia of various species of powdery mildew at low humidity,** H. J. BRODIE (*Canad. Jour. Res.*, 23 (1945), No. 6, Sect. C, pp. 198-211, illus. 7).—Collected data from observations by the author and others indicate that nine species of powdery mildew fungi

from 21 different host plants have been examined as to conidial germination at various humidities. Of these species, *Erysiphe graminis*, *E. polygoni*, *Uncinula salicis*, and *Microsphaera alni* seem beyond doubt to produce conidia capable of germinating at low humidity; according to published data, five species fail to tolerate low humidity. Conidia of *E. graminis* detached from the conidiophore but adhering in chains do not germinate as well as separate conidia from the same sample; the longer the chain, the lower the germination. In chains, it is usually the end conidia that germinate. These observations are discussed in the light of the author's theory (E. S. R., 87, p. 70) explaining the germination of powdery mildew conidia at low humidity. The apparent osmotic pressures of the cell sap of two powdery mildews were determined by plasmolysis with  $\text{KNO}_3$ —for *E. polygoni* the figure obtained was 63 atmospheres; for *E. graminis hordei*, 68 atm. The significance of this high osmotic pressure is discussed. • Study of the papillae regularly appearing on the end of the conidia of *E. graminis* indicated them to be special structures with a particular function; they should not be considered as germ pores. It is suggested that the conidium wall is two-layered, at least in the region between adjacent conidia; rupture of the outer part of the wall in a ring at the septum may serve to disjoin the conidia and form the papilla.

**A comparative study of *Torulopsis pulcherrima* and *Taphrina deformans* in culture.** C. ROBERTS. (Univ. Calif.). (*Farlowia*, 2 (1946), No. 3, pp. 345-383, illus. 32).—Both fungi presented a similar yeastlike appearance when grown at room temperature on potato dextrose agar and produced a reddish or pinkish noncarotinoid pigment—that of *Torulopsis pulcherrima* being diffusible and that of *Taphrina deformans* not. In *Torulopsis pulcherrima* a predictable mutationlike change involving the production of white sectors occurred with great regularity in pigmented colonies; in the other species unpredictable sectors involving a color change from pink to yellow occurred frequently but sporadically. These variants of both species were transmissible but failed to have complete stability. Cellular morphology and a mycelial tendency were essentially similar in cultures of both species; in old cultures cellular structures indicative of sporulation were noted and interpreted as ascogenous cells, asci, and ascospores. In *T. pulcherrima* a tendency for differentiation of the red and white cultural types on the basis of cellular morphology was noted and found correlated with the sporulation phenomenon; in *Taphrina deformans* no such morphological differentiation among the three types was evident. A constant uninucleate condition occurred in the young vegetative cells of both fungi. *Torulopsis pulcherrima* fermented glucose; *Taphrina deformans* did not. No evidence was obtained of physiological differences among the various cultural types of either species. On the basis of these findings the interrelationship of the two fungi is discussed with special reference to a recent proposal to remove *Torulopsis pulcherrima* from the imperfect yeasts to the Taphrinales.

**Soil disinfection.—IV, Chemical treatment of glasshouse soil.** H. JACKS (*New Zeal. Jour. Sci. and Technol.*, 27 (1945), No. 3, Sect. A, pp. 250-255, illus. 1).—In these further studies (E. S. R., 93, p. 723), chloropicrin, formalin (40 percent formaldehyde), Shell D-D, and  $\text{CS}_2$  were used in treating greenhouse soil infested with root knot nematode and verticillium wilt of tomato; all but the formalin gave satisfactory control but at the dosages used did not eradicate the nematode when the soil contained undecayed infested roots. All treatments gave increased yields, chloropicrin proving best from this standpoint. Chloropicrin and formalin gave complete control of the wilt, but Shell D-D allowed a small percentage of infection. Results suggested that chloropicrin had also improved the soil fertility.

**Fungicides and their action.** J. G. HORSFALL (*Waltham, Mass.: Chron. Bot. Co.*, 1945, pp. 239+, illus. 24).—This textbook, which "has constituted for the author a postgraduate course on fungicidal action," is designed to consider two basic problems,

viz, "(1) to procure the proper materials for killing the enemy and (2) to deliver them to him in sufficient quantity when and where he is vulnerable." These two problems are discussed in the light of the chemistry and physiology of toxic action and of the mechanics of application. The illustrative examples, in general, are drawn from plant pathology, but in many cases reference is made to wood and fabric preservation, human pathology, bacteriology, and entomology. This is, however, "no cook book;" rather, it attempts to develop the underlying theory on which a practice is based and by which it may be improved. Following a historical introduction, the author deals with some general concepts, laboratory assay, some problems of data assessment, principles of chemical protection, deposition, coverage of single and of multiple surfaces, tenacity, artificial immunization and chemotherapy, the actions of copper, sulfur, organic nitrogen compounds, and of other organics, antagonism and synergism, and phytotoxicity. A bibliography of 22.5 pages and author and subject indexes are provided. A foreword is by D. Fairchild.

**The fungicidal action of copper**, R. L. WAIN (*Chem. and Indus. [weekly]*, No. 7 (1946), pp. 70-73, illus. 1).—This address reviews (36 references) the mechanism of the fungicidal action of Cu fungicides and the factors influencing it, including recent work by the author and his associates.

**Progress in testing the relative effectiveness of new organic fungicides in the control of plant diseases—a summation of nation-wide data in 1945**, H. P. BARSS ET AL. (Washington, D. C.: *Amer. Phytopathol. Soc., Potomac Div.*, 1946, pp. 21+).—This report, prepared by the Fungicide Committee, Potomac Division, American Phytopathological Society, contains lists of the cooperators and of the fungicides tested and presents the results of trials with diseases of fruits, vegetables, ornamentals, and miscellaneous crops and with treatments for seeds and planting stock. A summary of results for promising newer fungicides is included.

**Parasitism of *Xanthomonas translucens* (J. J. and R.) Dowson on grasses and cereals**, J. R. WALLIN. (Iowa Expt. Sta.). (*Iowa State Col. Jour. Sci.*, 20 (1946), No. 2, pp. 171-193, illus. 12).—*X. translucens* was studied on grasses and cereals over a 4-yr. period (1941-44); it causes small water-soaked translucent areas enlarging into yellowish, brownish, or blackish somewhat irregular streaks on the leaves, culms, and young seedlings. The most characteristic symptom on all the hosts was a brown or blackish streaking of the foliage. "Xanthomonas streak" is proposed for the diseases induced by this organism on all grasses and cereals, replacing "bacterial blight" on barley and rye and "black chaff" on wheat. The organisms from brome grass and timothy were established as a new variety and race, respectively, of *X. translucens*. In morphological, cultural, and biochemical characters these two forms were like the barley, rye, and wheat strains; they survived the winter on foliage in the field and infected new leaves in the spring. In comparative inoculation trials infection proved more consistent over a wider host range by the hypodermic than by the spray method. Six isolates of the brome race were found by cross-inoculation tests to be alike in reactions on the different hosts but distinct from *X. translucens cerealis*. Hagborg's *X. translucens* f. sp. *cerealis* is redescribed on the basis of the reactions of strains from barley, brome grass, rye, and wheat on six host plant genera. Six pathogenic races of *X. translucens cerealis* were separated by cross-inoculation trials. These races all parasitized barley, *Bromus* spp., *Agropyron repens*, oats, rye, and wheat, but were separated by their reactions on 7 oats varieties and 13 *Bromus* spp., including 2 varieties of *B. inermis*; detailed results are given. There are 19 references.

**The prevalence and control of seed-borne diseases of cereals in Manitoba**, F. J. GREANEY and J. E. MACHACEK (*Sci. Agr.*, 26 (1946), No. 2, pp. 59-78, illus. 1).—In the interest of further information on the health of the seed of wheat, oats, and barley being grown in Manitoba, over 3,000 farm samples from the 1937-42

crops from all over the province were examined, and the results are presented in detail. *Helminthosporium* spp. were the predominating pathogens; pathogenic *Fusaria* were by no means commonly isolated. Seed treatment, particularly of oats and barley, was found inadequately carried out. The amount of infection of seed grain by smut, seedling blight, and leaf spot fungi varied appreciably from district to district and year to year, depending largely on the environmental factors where the seed was produced. Climatic conditions favoring early ripening and harvesting were followed by a low incidence of seed infection; warm humid weather during ripening and harvesting favored a high incidence of infection. Greenhouse tests of a large number of infected samples of wheat, oats, and barley seed with an organic mercury dust gave almost complete control of seed-borne *Helminthosporium* and *Isararium* and favored germination of such samples; treatment of healthy seed proved of little value except where the seed was sown in heavily infested soil. The survey indicated that the health condition of the wheat, oats, and barley seed being produced and used annually in Manitoba is by no means satisfactory. The most important seed-borne diseases of cereals in the Province were the surface-borne smuts of oats and barley. In the absence of adequate facilities for determining the presence of smut or other pathogens on oats and barley seed, it is strongly recommended that all seed of these crops produced in Manitoba be treated with an approved disinfectant before being sown.

**Tyrosinase enzyme in the causative agent of the black bacteriosis of cereals,** A. P. KLYKOV (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 47 (1945), No. 8, p. 597*)—The author evolved the hypothesis that the dark pigment in black chaff of wheat caused by *Bacterium translucens* is due to the action of tyrosinase. In a medium containing tyrosin, some 20 strains of *B. translucens* were grown to test the theory; after several days the culture assumed various shades from deepest black to yellow. The different strains contained varying amounts of the enzyme and in some cases none at all.

**Étude biométrique de *Puccinia graminis* Persoon (rouille noire des Graminées),** L. GUYOT (*Compt. Rend. Acad. Sci. [Paris], 220 (1945), No. 19, pp. 700-701*).—A biometrical study, comparing the uredio- and teliospores of *P. graminis* on various host plants spontaneously attacked, and revealing appreciable morphological differences.

**Detection of the loose smut fungi in embryos of barley and wheat,** P. M. SIMMONDS (*Sci. Agr., 26 (1946), No. 2, pp. 51-58, illus. 2*).—The problem of internally borne loose smut of barley and wheat is briefly reviewed, with special reference to two methods for detection in seed samples. The embryos are first removed by treatment with KOH or NaOH solutions: (1) In the whole embryo method they are dehydrated, cleared in cedar oil, and examined without staining; (2) in the sectioned method the embryos are embedded, sectioned en masse, and stained. Both procedures are said to give reasonably good results.

**Destroy the rust-spreading barberry—protect small grains,** M. A. CAMPBELL, R. W. BILLS, and B. KOEHLER. (Coop. U. S. D. A. and Ill. Expt. Sta.). (*Ill. Agr. Col. Ext. Cir. 598 (1946), pp. 16, illus. 9*).—An informative circular telling how the rust spreads and how to identify and destroy the barberry, and discussing the increase in rust during warm muggy weather, resistant grain varieties, and the threat of new races of the rust fungus.

**The effect of leaf rust of barley on the yield and quality of barley varieties,** M. NEWTON, B. PETURSON, and W. O. S. MEREDITH (*Canad. Jour. Res., 23 (1945), No. 6, Sect. C, pp. 212-218*).—In tests of the effects of *Puccinia anomala* on the yield, grade, and malting quality of the barley varieties O. A. C. 21, Mensury, Chevron, Peatland, Regal, and Plush, the authors found that it reduced the first two by one commercial grade and caused significant reductions in yield and in bushel and

kernel weights of all the varieties except Mensury. It adversely affected the value of all varieties for malting by reductions in the proportion of heavy-grade kernels. The nitrogen content and wort N were reduced by leaf rust, but the malt extract and diastatic powers were not greatly influenced. Differential responses of the varieties to rust infection were observed in yield, kernel and bushel weights, and malt properties.

**Effect of leaf and stem rust on the phosphorus metabolism of hard red spring wheat,** A. HOFFER, W. F. GEDDES, and M. N. LEVINE. (UNIV. MINN. COOP. U. S. D. A.). (*Cereal Chem.*, 23 (1946), No. 1, pp. 52-64).—Total P determinations were made on the grain, chaff (glumes and rachides), and straw (stems and leaves) prepared from tillers harvested during kernel filling from plots of Thatcher and Marquis wheats variously infected with leaf and stem rusts. The rust epidemics were induced by inoculation and the intensity of spontaneous rust infection was controlled by periodic sulfur dustings. Average kernel weights and moisture contents of entire tillers were determined as indexes of progressive maturity. The average kernel weight was adversely influenced by severe rust infections—particularly from stem rust. Transpiration was accelerated more by stem rust than by leaf rust, even though the average maximum stem rust infection was 48.6 percent as compared with 89.5 percent for leaf rust. The percentage of P in the dry matter of the kernels remained more or less constant with progressive maturity; in the chaff its percentage tended to decrease appreciably as the plants approached maturity, whereas in the straw a very consistent and more pronounced decrease occurred. The total P in the entire tiller remained relatively constant during maturation, but it was translocated from the straw and chaff into the developing kernel; its translocation exceeded that of the other ash elements. Severely rusted plants contained somewhat more P in the grain than more lightly infected ones during the early stages of kernel development, but the differences were reduced as the maturity of the plant approached. Intensity of rust infection was without apparent influence on the percentage of P in the chaff, but caused a definite increase in its concentration in the straw during the final stages of maturation. The effects were similar for both leaf and stem rusts. Severe leaf rust infection, as for stem rust, lowered the total P content of the entire tiller and markedly interfered with its translocation into the kernels.

**Four new recommended wheats which combine stem rust resistance with yield and quality** (*Agr. Gaz. N. S. Wales*, 57 (1946), No. 1, pp. 3-6, illus. 4).—The outstanding feature of the current recommendation of varieties of wheat for sowing in the various wheat zones of New South Wales is said to be the inclusion of the four new varieties Gabo, Kendee, Yalta, and Celebration—all local developments which are described.

**The effect of eyespot (*Cercospora herpotrichoides* Fron.) on wheat and the influence of nitrogen on the disease,** M. D. GLYNNE, W. M. DION, and J. W. WEIL (*Ann. Appl. Biol.*, 32 (1945), No. 4, pp. 297-303, illus. 8).—The seasonal effects of eyespot on wheat receiving different amounts of N were studied in pot experiments. Plants inoculated in December exhibited chlorosis on the outer leaves in February. Among those with high N, eyespot killed 11 percent and caused straggling in 31 percent and whiteheads in 14 percent of the surviving ear-bearing straws; the straw yield was reduced by 8 percent and that of grain by 16 percent. Loss in straw was from reduction in number of plants; that in grain was due about equally to fewer ears and lighter grains. Among plants with low N, the disease killed 23 percent; it also caused straggling in 86 percent and whiteheads in 18 percent of the surviving ear-bearing straws and reduced the straw yield by 23 percent and that of grain by 44 percent. The loss in straw was due to death of the plants; that of grain, about two-thirds to fewer ears and one-third to lighter

grains. In the high-N series the number of shoots at maximum tillering was reduced by 29 percent; in the low-N series the height of the plants was reduced, the crop was very uneven, ear and anther emergence was delayed, and "tail corn" increased from 4 percent in controls to 30 percent in inoculated plants. All of the last became infected, but those receiving high N had only 49 percent of the ear-bearing straws with severe lesions at harvest; those on low N, 86 percent. The larger number of tillers produced with N applications may have enabled the less severely diseased shoots to survive and bear ears, while the most severely infected died.

**An undescribed ear rot of corn caused by *Physalospora zeae*, A. J. ULLSTRUP.** (Ind. Expt. Sta. and U. S. D. A.). (*Phytopathology*, 36 (1946), No. 3, pp. 201-212, illus. 3).—For several years an unidentified ear rot of corn was observed in Indiana. Isolates of *P. zeae* (*Macrophoma zeae*) from diseased corn leaves proved strikingly similar in cultural behavior, growth rate, and loss of viability to the fungus causing the ear rot. After a number of trials to induce sporulation in a wide variety of media held under different environments, the ear rot fungus finally produced pycnospores after 4 months' incubation in pure cultures on sterilized corn-stalks. Pycnospores produced by *P. zeae* and *M. zeae* on the same substrate were identical with those of the ear rot fungus. A third type of fruiting body was produced in pure culture by *P. zeae*, *M. zeae*, and the ear rot pathogen; this was a pycnidiumlike body bearing minute hyaline 1-celled oblong spores that did not germinate. Symptoms on ears inoculated with single-spore isolates of *P. zeae* and *M. zeae* and mass isolates of the ear rot fungus were indistinguishable from each other or from ears infected spontaneously. On the basis of similarity in morphology, cultural behavior, growth rate, and ear rot symptoms, it is concluded that *P. zeae* and *M. zeae* are the sexual and asexual phases of the same fungus, and that the heretofore undescribed ear rot pathogen is *P. zeae*.

**Some factors in the production and germination of spores of *Diplodia zeae* in culture, G. C. KENT.** (Iowa Expt. Sta.). (*Iowa State Col. Jour. Sci.*, 20 (1946), No. 2, pp. 259-263).—Production of pycnidia and formation of germinable conidia were found greatest when this fungus was grown on a thin layer of oatmeal-extract agar on the sides and bottom of an Erlenmeyer flask. Incubation in the light at 20° C. proved most favorable for developing a large number of germinable conidia. Spores washed in sterile distilled water germinated better than those not washed. Carrot extract was the most favorable for spore germination. Washed spores incubated in carrot extract germinated 90 percent after a 12-hr. incubation at 28°-30°. Uncovered ground glass slides were the most satisfactory for incubating spore suspensions.

**Influence of carbohydrate levels and root-surface microfloras on phymatotrichum root rot in cotton and maize plants, F. M. EATON and N. E. RIGLER.** (U. S. D. A. coop. Tex. Expt. Sta.). (*Jour. Agr. Res* [U. S.], 72 (1946), No. 4, pp. 137-161, illus. 5).—In both pot and field experiments the resistance of cotton plants of fruiting age to phymatotrichum root rot proved directly related to the carbohydrate content of the root bark; when the levels were increased sufficiently by the removal of bolls and branches and withholding N, *Phymatotrichum omnivorum* disappeared from previously infected parts of the root system. With increased carbohydrate levels, marked changes occurred in the root surface microflora, the total numbers of bacteria and spores of aerobic bacilli decreasing and the blue-green fluorescent bacteria increasing greatly. This type of resistance in cotton is attributed to an increased antibiotic activity of the saprophytic microflora of the root surfaces. The resistance of young cotton plants to *Phymatotrichum* is evidently chemical, since it was not altered by changes in carbohydrate levels or when the plants were grown in sterile sand-bentonite. The significance of the

antibiotic factor in disease resistance is illustrated by experiments with corn—a plant long regarded as immune to root rot: The roots of corn growing in sterile sand-bentonite were rapidly destroyed and the plants killed when *P. omnivorum* was introduced; in soil-inoculated cultures, on the other hand, the roots remained bright even though paralleled for long distances by strands of the fungus. There are 35 references.

**Zinc deficiency in flax**, C. R. MILLIKAN (*Jour. Dept. Agr. Victoria*, 44 (1946), No. 2, pp. 69-73, 88, illus. 5).—Zinc deficiency has occurred in flax crops in certain parts of Victoria, Austral. Its alleviation by  $\text{ZnSO}_4$  applications was demonstrated in the field. The symptoms may involve dieback, bronzing, or rosetting. Characteristically, the affected plants "recover" in spring and make prolific and healthy second growth; in water cultures no such "recovery" has been observed. Time of sowing was found to have a very significant effect on the incidence of the deficiency symptoms. Superphosphate dressings in themselves had no effect on incidence, but when applied in conjunction with 30 lb. of  $\text{ZnSO}_4$  per acre the superphosphate at 10 cwt. per acre induced a significant increase in the percentages of both dieback and total Zn-deficiency symptoms.

**Breeding potatoes resistant to disease**, F. J. STEVENSON. (U. S. D. A.). (*Natl. Hort. Mag.*, 25 (1946), No. 1, pp. 18-28, illus. 6).—Following introductory remarks on the origin of the potato and its introduction into North America and Europe, the author discusses early improvement efforts and the results of more recent breeding and selection work, with information on some of the newer varieties and a listing of characters now available to plant breeders in the United States. Varieties are now available that are resistant to the following diseases and insects: Mild mosaic, latent mosaic, rugose mosaic, net necrosis in the tubers caused by current-season infection with the leaf roll virus, yellow dwarf, late blight of the vines, tuber rot initiated by the fungus that causes late blight, common scab, potato wart, rot, ring rot, hopperburn, flea beetle injury, and aphid injury—a list that continues to grow as new varieties and species are now being introduced from many other countries.

**En del vanliga potatissorters reaktion mot vissa vira** [The reactions of some common potato varieties to certain viruses], H. ESBO (*K. Lantbr. Akad. Tidskr.*, 84 (1945), No. 4, pp. 299-313; *Ger. abs.*, pp. 309-310).—The foliage and tuber reactions of 12 varieties to the X plus Y virus combination were tested.

**Spray materials and the blooming of potatoes**, J. D. WILSON and J. P. SLEESMAN. (Ohio Expt. Sta.). (*Amer. Potato Jour.*, 23 (1946), No. 2, pp. 57-64).—Bordeaux caused the greatest decrease and DDT the greatest increase in bloom of the materials used in this study. All Cu-containing fungicides decreased the bloom when used with calcium arsenate, but some of the organic fungicides like Zerlate and Fermate caused a slight increase. Addition of DDT to the Cu fungicides decreased their depressing effects on bloom but did not entirely counteract it. Combinations of DDT with the organic fungicides all increased the bloom, Zerlate plus DDT nearly doubling it. Bloom was least persistent in plants treated with Cu plus calcium arsenate and lasted much longer with organic fungicides plus DDT. Persistence was most marked with DDT alone, being greatest at 1-100 (the highest concentration used) applied 200 gal. to the acre. The bloom increased with each increase in amount of DDT used from  $\frac{1}{8}$  to  $1\frac{1}{2}$  lb. per acre per application; DDT emulsions were somewhat less effective than wettable powders. The flower clusters were fewer on plants treated every 20 days than on those sprayed at 10-day intervals. There was little or no correlation between bloom and yield on plots treated with combinations of fungicide and either calcium arsenate or DDT. With DDT alone the plots exhibiting the heaviest flower production also produced the most tubers. The Cu formulas seemed to depress flowering by some unfavorable physiological

action, but they increased tuber production by giving the foliage continued protection from injury by diseases and pests after flowering had occurred. DDT, on the other hand, encouraged heavy vegetative growth throughout and maintained a considerable leaf area until early blight finally killed the plants at the very end of their normal growth period—which persisted in this instance for at least 15 days beyond the usual 90 days for Cobblers at Wooster, Ohio.

**Potato spray and dust experiments in 1945,** J. C. CAMPBELL and R. S. FILMER. (N. J. Expt. Stas.). (*N. J. State Potato Assoc., Hints to Potato Growers*, 26 (1946), No. 10, pp. [4]).—It was evident from a single spray test on Katahdin potatoes that DDT with either bordeaux or Microgel may be expected to increase yields substantially even in the absence of severe insect infestation; Dithane, though inferior in controlling flea beetles and late blight, produced a favorable yield; Microgel was almost equal to bordeaux against late blight and produced slightly higher yields; basic copper arsenate was inferior to all of the other materials. In the dust trials Microgel-talc was equal to or better than the copper-lime dusts; DDT with a neutral copper increased the yield appreciably, but with a copper-lime it did not; 666 failed to produce outstanding results but is considered worthy of further trial as an insecticide. None of the dusts except DDT-Microgel gave as high a yield or as good control of late blight as did bordeaux.

**The effect of disinfecting and bruising seed potatoes on the incidence of dry rot (*Fusarium caeruleum* (Lib.) Sacc.),** T. SMALL (*Ann. Appl. Biol.*, 32 (1945), No. 4, pp. 310–318).—The effect of bruising and disinfecting ("dipping") seed tubers with a proprietary organo-mercury preparation on the incidence of dry rot was tested in field trials over three seasons. If left undisturbed in their boxes, seed tubers not deliberately bruised—whether dipped or not at harvest—remained practically sound until planting time the following season. Those deliberately bruised—either at digging time or 1 to 2 weeks later but not dipped—with few exceptions developed severe dry rot; the disease had run its course by mid-October. When undipped sound tubers were bruised in October, they contracted severe dry rot, but dipping them immediately before bruising reduced the loss satisfactorily in five or six trials. In almost all cases, tubers bruised at digging time and immediately dipped suffered little from dry rot; delayed dipping checked the disease in some trials but not in others. Seed tubers severely bruised 1 to 2 weeks after dipping remained practically sound (one exception); those severely bruised about 3 mo. after dipping subsequently developed severe dry rot in four of six tests—unless they had been redipped immediately before they were bruised. Inoculation of healthy tubers with soil samples indicated the fungus to be widely distributed in Cheshire (England) potato fields; dipping killed all or nearly all of the fungus in soil adhering to the tubers. The findings are discussed, and suggestions are made for further investigations and practical control.

**A comparison of *Fusarium avenaceum* and *Fusarium caeruleum* as causes of wastage in stored potato tubers,** F. J. MOORE (*Ann. Appl. Biol.*, 32 (1945), No. 4, pp. 304–309, illus. 1).—*F. avenaceum* is reported for the first time as a cause of potato tuber rot in Britain; the progress of decay in infected tubers is compared with the dry rot due to *F. caeruleum* in the laboratory, clamp, and potato store. Of the varieties Majestic, King Edward, Arran Pilot, and Doon Star, the last was most susceptible to *F. caeruleum* and King Edward to *F. avenaceum*. Optimum growth temperatures on potato-dextrose agar were 20°–25° C. for *F. avenaceum* and 20° for *F. caeruleum*; maxima were >30° and 30°, respectively. For infection of wounded tubers, the cardinal temperatures for *F. avenaceum* were like those on agar; for *F. caeruleum* the optimum was 15° and the maximum 25°. With both, the optimum for rotting tended to be higher in the more susceptible varieties. At low temperatures *F. caeruleum* caused quicker rotting than *F. avenaceum*, even

though its growth rate on agar was scarcely more than half that of the latter. High humidity favored rotting, especially with *F. avenaceum*; the other fungus was more tolerant of relatively low humidity. Both species caused quicker rotting in the clamp than in storage, even though there was no appreciable difference in mean temperature; this was attributed to the higher atmospheric humidity in the clamp.

**Field trials of copper fungicides for the control of potato blight.—I, Foliage protection and yield, E. C. LARGE** (*Ann. Appl. Biol.*, 32 (1945), No. 4, pp. 319–329, illus. 4).—Recent technics of disease measurement on foliage were applied and developed and characteristic curves obtained defining the conditions of trial and the relations between spray timing and progress of late blight attack. The time interval between half-decay dates for sprayed and unsprayed foliage was taken as a numerical criterion of the direct protective effect of treatment. A linear relationship was found to hold between probit foliage decay and time, and this was accounted for by the close correspondence of the probit curve to that derived from a growth law,  $da = Ca(A-a)dt$ , where  $a$  denotes the percentage foliage area affected by blight at time  $t$  after the beginning of the attack. Methods were found for preparing dispersible mixtures of bentonite with active Cu compounds for use in spraying. With such admixture—to improve adhesion—both cuprous oxide and copper oxychloride preparations nearly equaled bordeaux at the same Cu dosage. Without sticker, and compounded with water-soluble dispersing agents, these materials were equaled by bordeaux at half their Cu dosage. Suspensions of metallic Cu had a pronounced fungicidal effect against *Phytophthora infestans*; a bearing of this result on the fungicidal mechanism of cuprous oxide is discussed. Results from 103 pairs of twice-sprayed and unsprayed plots of main-crop potatoes (1941–44) showed a mean prolongation of growth from spraying of 16.5 days and a mean gain in total yield of 2.75 tons per acre; the gain in yield from a given prolongation of growth, however, varied greatly according to the stage of the crop development at which this prolongation began. Spray retention data—for correlation with foliage protection and yields—were obtained for all 4 yr.

**Ensayos del caldo bordelés contra la *Phytophthora infestans* (Mont.) de Bary en *Solanum tuberosum*** [Trials with bordeaux against late blight of potato], J. A. BERTA and H. D. TOBLER BOTTINI (*Rev. Asoc. Ingen. Agrón. [Montevideo]*, 17 (1945), No. 4, pp. 3–11, illus. 6; *Eng. abs.*, p. 11).—At rates of 0.5, 1, and 2 percent  $\text{CuSO}_4$  and with neutral and slightly and highly alkaline reactions, it was found that the reaction of the bordeaux did not interfere with the yields, but neutral and slightly alkaline mixtures resulted in injury when applied on wet days. Best yields followed use of the 1 percent formula.

**Ring-rot-like symptoms produced by soft-rot bacteria in potato tubers, R. S. DAVIDSON.** (Minn. Expt. Sta.). (*Phytopathology*, 36 (1946), No. 3, pp. 237–239, illus. 1).—Symptoms resembling those from infection by *Corynebacterium sepe-donicum* were produced by *Erwinia carotovora* in mature potato tubers which had been subjected to flooded field conditions.

**Sclerotium rot of potato seed pieces, A. H. EDDINS and E. WEST.** (Fla. Expt. Sta.). (*Phytopathology*, 36 (1946), No. 3, pp. 239–240, illus. 1).—*S. rolfsii* attacked potato seed pieces in a Florida field planted to Sebago potatoes after a crop of cabbage had been harvested. This is believed to be the first report of the spontaneous occurrence of sclerotium rot of seed pieces in the field.

**Trials of potatoes for immunity from wart disease** (*Agriculture, Jour. Min. Agr. [Gt. Brit.]*, 52 (1946), No. 10, pp. 475–476).—The official trials of new varieties for immunity to wart disease were continued in 1945, and seven new varieties—here described—are added to approved list.

The life history of the golden nematode of potatoes, *Heterodera rostochiensis* Wollenweber, under Long Island, New York, conditions, B. G. CHITWOOD and E. M. BUHRER. (U. S. D. A., [N. Y.] Cornell Expt. Sta., et al.). (*Phytopathology*, 36 (1946), No. 3, pp. 180-189, illus. 4).—Eggs and larvae overwintered in the soil within the body of the dead female which acted as a cyst. When the mean weekly temperature reached about 59° F. in spring, the eggs hatched and the larvae emigrated from the cyst to attack potato roots. Thereafter they underwent various growth stages, reaching maturity and producing embryonated eggs within 38 to 48 days. Whether or not more than one generation may occur in a year is unknown. Evidence is presented that in seasons with a short spring there is more damage to potato yields than in those with a long spring. Potatoes may be capable of growth at 45° to 58°, at which temperatures there is little or no nematode activity.

Blind-seed disease of rye-grass (*Phiala temulenta* Prill. & Delacr.), E. L. CALVERT and A. E. MUSKETT (*Ann. Appl. Biol.*, 32 (1945), No. 4, pp. 329-343, illus. 13).—A brief review of the present status of knowledge on the disease is given, and methods for examination of the seed are described. *P. temulenta* was isolated by germinating macroconidia and ascospores as well as from mycelium within the seed, grown in culture, and the fungus and its life history are described. Inoculations (1940-41) proved its pathogenicity and the saprophytic nature of *Pullularia pullulans*. Italian ryegrass, commercial perennial ryegrass, and two strains of pedigree perennial ryegrass all proved susceptible when inoculated at flowering time with either macroconidia or ascospores. Tested on commercial perennial ryegrass, the amount of infection was much reduced on inoculation after flowering had ceased. The correlation coefficient between percentage infection and germination was calculated and in all cases proved highly significant—negative correlation indicating that infection results in reduced germination. *P. temulenta* has been isolated from *Festuca ovina*, *Agrostis canina*, *A. palustris*, *Poa pratensis*, *Holcus lanatus*, and *Cynosurus cristatus*, while *P. elatior* and *P. trivialis* were successfully inoculated in 1943 using macrospores of the fungus. Control by breeding resistant strains and by crop management are discussed. The fungus is probably nonviable in over-year seed samples. In field tests, hot-water treatment of the seed prevented the production of apothecia, but infection occurred because of the dispersal of ascospores from other plots. A later test indicated the fungus to be widespread in pastures, waste ground, and hedgerows, rendering treated seed no guarantee of a healthy seed crop. Use of organo-mercury disinfectants applied dry or by the short wet method proved only partially effective. Hot water for 15 min. at 50° C. following a 4-hr. preimmersion in tepid water, or for 30 min. at 50° without preimmersion, provided complete control, and germination was in no case impaired when the seed was thoroughly dried at once.

The fungus that causes sooty stripe of *Sorghum* spp., L. S. OLIVE, C. L. LEFEBVRE, and H. S. SHERWIN. (U. S. D. A.). (*Phytopathology*, 36 (1946), No. 3, pp. 190-200, illus. 4).—Since studies have shown the fruiting body of the sooty stripe fungus of sorghum to be a sporodochium, the fungus (*Septorella sorghi*) is transferred from the Melanconiales to the Tuberculariales as *Ramulispora sorghi* n. comb. The typical leaf spots produced begin as small oblong reddish-purple spots that develop into conspicuous elongate lesions with purplish borders and straw-colored centers of dead tissue. This dead tissue bears small black sclerotia which often impart a sooty appearance to the lesion. The fungus overwinters via these sclerotia. The conidia produced in spring appear to be largely responsible for initiating primary infections. Typical lesions with sclerotia, sporodochia, and conidia were readily produced by inoculating several varieties of sorghum, Johnson grass, and Sudan grass in the greenhouse.

**The transmission of beet mosaic and beet yellows viruses by aphides: A comparative study of a non-persistent and a persistent virus having host plants and vectors in common,** M. A. WATSON (*Roy. Soc. [London], Proc., Ser. B, 133 (1946), No. 871, pp. 200-219, illus. 1*)—The vector (green peach aphid) of beet mosaic becomes most infective when fed only a few minutes on diseased plants after a period of fasting. After such feeding, the infectivity is very rapidly lost when the vector feeds on healthy plants, but a single individual is capable of infecting several plants. Infectivity is lost much more slowly when the vector fasts after an infective feeding. In this behavior beet mosaic virus resembles Hy 3, potato Y, cucumber 1, and other aphid-transmitted viruses, which have been called the non-persistent group; it resembles these viruses also in physical properties. In some secondary characters beet mosaic differs from the other nonpersistent viruses more than they differ among themselves; it is retained longer by the fasting vectors and their infectivity may increase considerably with lengthening of the infective feeding time in the absence of the preliminary fasting, though it very rarely reaches the optimum level.

In the case of beet yellows virus, infectivity of the vector (also the green peach aphid) is not influenced by a preliminary fasting but always increases with lengthened feeding time on both infected and healthy plants. Infectivity increases with feeding time on healthy plants, whatever the infective feeding time; there is always a delay, therefore, in the production of optimum infectivity by the aphid after cessation of the infective feeding. Infectivity is more rapidly lost from fasting than from feeding vectors. Its properties indicate that this disease belongs to the persistent group of viruses, although its persistence in the fasting vector is only about the same as that of the nonpersistent beet mosaic virus. The main basis of distinction between the two types seems not to lie in the time they are retained by the vector but in the effect of preliminary fasting. Since the two diseases have the same vector and host plant, the differences in their behavior are properties of the viruses themselves and are not induced by the conditions under which they are transmitted.

**Epiphytology and control of sugar beet leaf spot caused by *Cercospora beticola* Sacc.,** C. M. NAGEL (*Iowa Sta. Res. Bul. 338 (1945), pp. 677-706, illus. 10*)—In eight different spacings on a loam soil, leaf spot development, sugar beet yield, and sucrose content were studied over a 5-yr. period (1933-37); in a similar way the number of plants per hill in three different spaces, for 4 yr. Wide spacing gave evidence of reducing the prevalence of leaf spot under moderate infection. The disease varied in prevalence and destructiveness with the weather conditions. In 1933, 1934, and 1937 it caused less injury to the leaves in the wider than in the narrower spacings. In 1935—a wet season—a serious epidemic occurred, infection being prevalent and destructive in all spacings. In 1936—a dry season—little or no leaf spot developed in any of the plots; the differences in yield appeared to be due partly to spacing and partly to leaf spot. With the possible exception of the 21- × 21-in. spacing in 1937, yields did not differ significantly in the spacings now commonly used, viz, 12 × 21, 18 × 18, and 21 × 21 in.; these spacings were used in 1935-37. The leaf spot severity tended to increase with the number of plants per hill. In each year wider spacings produced beets of greater size than in the closer spacings, although the acre yield was usually less. The acre yield was practically the same with one and two plants per hill; with more than two, the roots were reduced below marketable size. The sucrose percentage varied only slightly with difference in spacing and number of plants per hill.

**Soil populations of beet eelworm (*Heterodera schachtii* Schm.) in relation to cropping,** F. G. W. JONES (*Ann. Appl. Biol., 32 (1945), No. 4, pp. 351-380, illus. 19*).—The sampling technic used and investigation of the various steps of which it

is composed are first discussed; this is followed by the results of applying the method to 24 fields, 1937-42. There appeared to be a correlation of the general level of the nematode population with the frequency of preceding susceptible crops and the amount of crop damage. Marked increases followed the planting of susceptible crops on heavily infested land; smaller increases occurred in fields with low initial populations. Fields which are completely "beet-sick" require over 10 yr. before sugar beets can again be grown with safety. The general effect of non-susceptible crops was to lower the nematode populations; cereals had the same effect but to a lesser extent. "Claying" had a beneficial effect. Crucifers proved capable of increasing the beet eelworm population, although they did not as a rule show signs of distress when growing on land where sugar beet developed the signs of "sickness." A strong correlation was observed between the viable cyst and egg content of bulk samples, suggesting that viable cysts are a better measure of the general level of nematode population than might have been supposed. Cysts decay slowly and remain in the soil long after they are devoid of living contents. The best measure of populations yet devised is an estimate of the encysted egg population; it is not nearly so satisfactory, however, in forecasting damage to an ensuing crop. In examining cysts for viability, fungus hyphae and the fruiting bodies of other organisms were found inside; it is believed that at least some part of the microcyst population of soils is composed of fruiting bodies of fungi of the order Chytridiales. Another organism—probably a fungus—had a rather high incidence and might be important in reducing the egg populations. Experience suggests that the general level of the egg population above which it is unsafe to grow sugar beets or mangolds on Fen soils is about 10 eggs per gram of air-dried soil or approximately 0.1 viable cyst per gram.

**Tobacco rosette: A complex virus disease,** K. M. SMITH (*Parasitology*, 37 (1946), No. 1-2, pp. 21-24, illus. 10).—The name "tobacco rosette" is suggested for the composite disease studied. The two component viruses—named the "mottle" and "vein-distorting" viruses—were separated, and their symptomatology and methods of transmission are described. The former is both sap- and aphid-transmitted; the latter, aphid-borne only. The symptoms are of three main types: Intense rosetting, splitting of the tissues, and formation of enations on the lower leaf surface. Tissue splitting was examined microscopically and is illustrated. It is suggested that the virus concentration in the cambium prevents the formation of normal xylem. Abnormal tissue and giant cells are formed in the cortex and pith; this apparently sets up stresses which cause the splitting. The green peach aphid is the main vector; another species, *Myzus pseudosolani*, is a less efficient transmitter.

**Purification and crystallization of southern bean mosaic virus,** W. C. PRICE (*Amer. Jour. Bot.*, 33 (1946), No. 1, pp. 45-54, illus. 5).—This virus (*Marmor laciofaciens*) is distinguished from other plant viruses on the basis of its high degree of thermostability, the symptoms produced, and the host range. Cross protection tests indicated that it is not closely related to tobacco mosaic or necrosis or to the alfalfa mosaic viruses, though it resembles each in some respects. The virus was concentrated and purified either via alternating cycles of high and low speed centrifugation or by fractionation—with essentially identical end products. The purified virus appeared homogeneous on examination in an analytical centrifuge, an electrophoresis apparatus, a diffusion apparatus, and an electron microscope. Such preparations gave positive tests for protein and negative tests for carbohydrate and contained spherical particles having a mean diameter of about 33.6 m $\mu$ ; they remained active for months when held at 3° C. but soon became noninfectious when frozen. Crystallization was done by centrifuging purified preparations—brought to about 20 percent saturation with MgSO<sub>4</sub> or (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>—at 24,000

r. p. m. to obtain amber-colored pellets, draining off the supernatant fluid, adding only one or two drops of water, and allowing to stand for several hours at 3°. The crystals were either rhombic bipyramids joined by two pinacoids or rhombic prisms—both probably belonging to the orthorhombic system though neither showed birefringence under a polarizing microscope. Solutions of the crystals were highly active and produced typical symptoms of southern bean mosaic. There are 31 references.

**The effects of soil moisture and temperature on fusarium wilt of tomato,** M. C. STRONG. (Mich. Expt. Sta.). (*Phytopathology*, 36 (1946), No. 3, pp. 218–225, illus. 2).—During a 10-yr. study of the fusarium wilt disease of tomato in connection with a breeding program for wilt-resistant varieties, the author observed that John Baer (susceptible) and Marglobe (resistant) have opposite responses to soil moisture as far as it affects susceptibility to wilt. Marglobe had more wilt infection under less rainfall; John Baer, in seasons of greater rainfall. Tests with these varieties under controlled temperature and moisture substantiated the field observations. Their responses to wilt v. temperature were similar. There are 19 references.

**Root diseases of deciduous fruit trees,** J. S. COOLEY. (U. S. D. A.). (*Bot. Rev.*, 12 (1946), No. 2, pp. 83–100).—The object of this review (59 references) is to present briefly the current status of information on the subject, emphasis being placed on the diseases rather than on the mycological aspects of the pathogens—on the host and the effects of various environal factors on its resistance or susceptibility. The author has attempted “to make this discussion world-wide in its scope and application.” The main headings concern pome fruits, stone fruits, and nonparasitic diseases; a final section includes a general discussion, with remedial measures.

**Cost studies show airplane dusting is practical,** F. C. STRONG and E. J. RASMUSSEN. (Mich. State Col.). (*Food Packer*, 26 (1945), No. 13, pp. 63–64, 66, illus. 2).—This account of 1 year's tests on orchard trees shows the costs of airplane dusting in materials used and in distribution to be very reasonable and not likely to deter an orchardist from use of the method. A rate of 20 acres dusted per hour was maintained in some applications in the larger orchards used.

**Experiments with new organic fungicides for control of apple scab and Brooks' fruit spot (*Phoma pomii*),** R. H. DAINES and S. L. HOPPERSTEAD. (N. J. coop. Del. Expt. Stas.). (*Phytopathology*, 36 (1946), No. 3, pp. 236–237).—In Delaware tests during 1944, No. 604 (2,3-dichloro-1,4-naphthoquinone) and Puratized N5-X (phenyl mercuri triethanol ammonium lactate) equaled liquid lime-sulfur in apple scab control. Fermate alone and in combination with sulfur and Isothan Q-15 equaled the standard wettable sulfurs in providing protection against scab. He 175 (disodium ethylene bisdithiocarbamate) alone or in combination with zinc sulfate-lime failed to provide satisfactory control. The scab control in the New Jersey tests was in the same order except that 604 and Isothan Q-15 were somewhat less satisfactory. In Delaware, Puratized N5-X was shown to have eradicant value equal to lime-sulfur. In New Jersey, Thiosan, Fermate, and lead dimethyl dithiocarbamate gave excellent control of Brooks' fruit spot when used at the 17-, 27, and 37-day (after petal fall) applications; they proved compatible with summer oils, as was also Isothan Q-15; 604 and oil caused severe injury, while Puratized N5-X and oil produced mild fruit russetting. Lime in combination with Fermate increased fruit russetting somewhat during one year in three.

**Ground treatments as an aid in apple scab control,** D. H. PALMITER (*New York State Sta. Bul.* 714 (1946), pp. 27, illus. 6).—Control experiments indicated that the quantity of spores of *Venturia inaequalis* in overwintered apple leaves in a year favorable for disease development may determine the success or failure

of the scab control program. Orchards in which less than 5 percent of the old leaves contained spores were well protected from infection with five to seven ground applications of wettable sulfur. Similar orchards with more abundant inoculum required extra fungicidal applications and higher S concentrations for equal control. Nine yr. of laboratory and field tests showed the effectiveness of certain chemicals in killing or preventing ascospore discharge. Nitrogen fertilizers (e. g., nitrate of soda, sulfate of ammonia) used at 12 percent concentration were effective, but the 500 to 600 lb. required per acre for effective coverage increased the N supply available to the trees beyond the optimum for best fruit quality. Elgetol at 2 qt. to 100 gal. reduced the primary inoculum more than 95 percent when carefully applied and resulted in improved scab control. The ground treatments proved most effective in years of excessive rainfall; they reduced the amount of fruit infection on trees receiving a wettable sulfur program from 20 percent to 2 percent.

**Sur le mode de contamination du poirier par les conidies de *Venturia pirina* Aderhold** [The mode of contamination of pears with conidia of *V. pirina*], L. GUYOMARD (*Compt. Rend. Acad. Sci. [Paris]*, 220 (1945), No. 24, pp. 858-860).—The author's observations show that the first conidia of the pear scab fungus appear at the end of winter, even before the ascospores, in pustules on twigs of the preceding year. It seems probable that these pustules afford ports of entry for the *Nectria ditissima* of pear canker. A suggested spray program is given.

**Sur la catalase des feuilles de *Prunus persica* et ses variations dans les tissus atteints de chlorose spécifique des sols calcaires** [The catalase of peach leaves and its variations in tissues affected by the specific chlorosis of calcareous soils], G. DROUINEAU and P. GOUNY (*Compt. Rend. Acad. Sci. [Paris]*, 221 (1945), No. 23, pp. 709-710).—A brief report on the effects of temperature, pH, and HCN on the activity of the catalase and its content in the chlorotic leaves. The concentration of catalase at the beginning of the growing season was found to be the same in both healthy and affected leaves, but to decrease rapidly in the chlorotic leaves starting about mid-May and finally decreasing to about a fourth that in the normal leaves. This diminution of catalase had no relation to the respiratory intensity. A similar situation was observed in chlorotic leaves of quince and pear on calcareous soil.

**A new disease of Russian olive in the Pacific Northwest**, H. W. MILLER. (U. S. D. A. coop. Univ. Idaho and Wash. Expt. Sta.). (*Jour. Forestry*, 44 (1946), No. 2, pp. 118-120).—The author reports *Elaeagnus angustifolia* in the intermountain area of Washington, Idaho, and Oregon to be attacked by a previously unreported disease, the first and most characteristic symptom of which is arrested bud development. The following year affected portions of a branch are dead; the arrested bud development follows progressively down the branch until the root collar is reached and the whole plant is killed. Another symptom consists of small brown necrotic areas just outside the phloem and usually on the lower side of diseased stems. Preliminary studies have failed to reveal the cause and a survey of the literature showed no record of such a disease of this plant; these studies have given no evidence of a relationship to influences of site condition, soil type, rainfall or temperature extremes, or deficiencies of minor elements, nor have attempts to isolate a possible parasite or to find a disease-free strain been successful. No definite record has been found of its occurrence in irrigated plantings. The disease constitutes a threat to continued use of this shrub or small tree for shelter belt and other plantings in the Pacific Northwest.

**Phytohormones et court-noué de la vigne**, F. NYSTÉRAKIS (*Compt. Rend. Acad. Sci. [Paris]*, 221 (1945), No. 2, pp. 54-56).—In the author's experiments, treatment with heteroauxin was followed by the development of symptoms resembling those of court-noué. This result is believed to favor the theory that the malady results

from a hormonal disequilibrium—either in a parasite or in some other factor. The theory thus permits an explanation of the same general effect resulting from the most diverse causes, viz, that the ultimate origin of the trouble is hormonal.

**Coconut diseases in Jamaica.**—I, "Bronze leaf wilt" and other diseases affecting the bud of coconuts. II, Diseases affecting the leaves, crown, and stem of coconuts, E. B. MARTYN (*Trop. Agr. [Trinidad]*, 22 (1945), Nos 3, pp. 51-59, illus. 3; 4, pp. 69-70)—In part 1 the author considers diseases involving the rapid death of the bud and including bud rot, lightning strike, and bronze leaf wilt. The last is potentially the most serious disease of coconuts yet recorded in the West Indies. Although, pending the discovery of its exact nature, it is impossible to be certain that the varying symptoms recorded in different areas originate in identical causes, it is believed that they are closely allied, and that when the solution is found in one locality it will enable the problem of this puzzling disease to be solved elsewhere. According to the results of studies reported, the disease at first glance appears to be correlated with soil conditions, but the extremely varied soil types on which it occurs would seem to invalidate this hypothesis; on the other hand, no parasitic organism or virus has yet been proved responsible. The history of coconut cultivation in Jamaica is outlined, as well as the general methods at present practiced—often consisting of a combination of cattle pasture and coconuts.

In part 2 the author takes up the diseases affecting emerging leaves. These include two main types of the "bitten leaf" disease, the causes of which seem not to be fully agreed upon; and a condition variously known as St. Mary disease, wet weather disease, leaf disease, or leaf stalk rot—apparently attributable to environmental conditions but often involving secondary invaders. Another group comprises diseases of the whole crown and older leaves, including leaf spots, dieback, leaf blight or silver tip, drought wilt, leaf break, yellowing, pencil point or little leaf, and false wilt. A final group—diseases of the stem—includes stem bleeding associated with *Thielaviopsis* and a leaf scar trouble associated with *Cytospora*. A general key for identifying the diseases of coconut palms in Jamaica is provided. There are 25 references

**Azalea petal-blight can be controlled, [I], II, C. WESTCOTT** (*South Florist and Nurseryman*, 58 (1945), Nos. 23, pp. 5, 37-38, illus. 3; 24, pp. 6, 14-15, illus. 1).—Part 1 considers the history of the disease, how the fungus works, the weather relations, and control. In part 2, the author states that, though sanitary measures and use of mulches have failed in controlling this flower spot, properly timed protective spraying has proved successful. Of the many new wartime chemicals tested, Dithane and 604 are said to have given almost complete control with a minimum of injury or unsightly residue. Consistently good results were obtained in 2 years' testing in many different gardens.

**Het Botrytis-rot der gladiolen veroorzaakt door Botrytis gladiolorum nov. spec., A. S. TIMMERMANS** ([*Netherlands*] *Lab. Bloembollen Onderzoek, Lisse*, No. 67 (1941), pp. 32+, illus. 24; *Ger., Eng. abs.*, pp. 29-30).—This disease, known for several years in the Netherlands, is reported to have suddenly become serious. Infection spreads along the vascular bundles of the leaves and stem to the corm, which may show symptoms of rot at the center. From all infected parts a *Botrytis* differing from *B. gladioli* was isolated and is described as *B. gladiolorum*. Many of the newer varieties are more susceptible to the disease. Storage tests indicated the earlier harvested corms to be less frequently infested with the fungus; under storage at 25.5°-30° C. the corms dry rapidly and the disease scarcely spreads at all.

**Investigations on virus-diseases of narcissus, E. VAN SLOGTEREN and M. P. DE B. OUBOTER** ([*Netherlands*] *Lab. Bloembollen Onderzoek, Lisse*, No. 64 (1941), pp. 18, illus. 32).—This paper was written for the Daffodil Yearbook (1940); trans-

mission of the manuscript having been impossible on account of the war, it was published locally. Here the authors detail their experimental findings, including inoculation experiments, factors influencing the disease symptoms, mode of spread, and control.

**Onderzoekingen over virus-ziekten in bloembolgewassen, II, tulpen, I** [Investigations of the virus diseases of flowering bulbs, II, tulips, I], E. VAN SLOGTEREN and M. P. DE BRUYN OUBOTER ([Netherlands] *Lab. Bloembollen Onderzoek, Lisse, No. 65 (1941), pp. 54, illus. 62; Ger., Eng. abs., pp. 49-52*).—In a historical survey of the literature (35 references) it is pointed out that as far back as 1637 the Dutch bulb growers knew how to transmit the symptoms of breaking in tulips; this is the oldest virus disease of plants known to botanical literature. A description of the symptoms is given, and the confusion in terminology is criticized. The ways of transmission are discussed from the results of many experiments, and it is concluded that in the Netherlands the chief agent of spread is *Mycus persicae* and to a lesser degree *Macrosiphum euphorbiae* and *Doralis fabae*. The technic of inoculating tulips at an early stage to obtain current season symptoms is fully described. All factors favoring aphid development and exposure of tulips to their attack increase the danger of spreading the disease, which is also transmitted by the cutting of the blooms. It is believed that two closely related strains of one virus are involved rather than two distinct viruses. The use of serological methods of study is recommended. Roguing diseased and suspected plants before the aphids appear is advised. Stocks not entirely free from infection should not be grown near other crops frequented by the vectors.

**Resuscitation of the nematode *Tylenchus polyhypnus* n. sp. after almost 39 years' dormancy**, G. STEINER and F. E. ALBIN. (U. S. D. A.). (*Jour. Wash. Acad. Sci.*, 36 (1946), No. 3, pp. 97-99, illus. 1).—This new nematode—here described—was resuscitated in 1945 from an infested herbarium specimen of a rye leaf collected in 1906; this is believed to be the longest period of dormancy as yet observed for a nematode.

**A new hyphomycete parasitic on a species of nematode**, C. DRECHSLER. (U. S. D. A.). (*Phytopathology*, 36 (1946), No. 3, pp. 213-217, illus. 1).—In corn meal agar plate cultures planted with small quantities of partly decomposed stems and leaves of *Digitaria sanguinalis* collected from old weed piles in Virginia late in April, numerous specimens of the free-living nematode *Panagrolaimus subelongatus* were found parasitized and killed by a hyphomycete here described as *Acrostalagmus zeosporus* n. sp. Infection came about through germination of adhering conidia. The fungus is manifestly related to the entomogenous species of *Acrostalagmus*, *Beauveria*, and allied genera.

## ECONOMIC ZOOLOGY—ENTOMOLOGY

**Small mammal censuses near Prairie du Sac, Wisconsin**, H. C. HANSON. (Univ. Wis.). (*Wis. Acad. Sci., Arts, and Letters, Trans.*, 36 (1944), pp. 105-129).

**Increase of rat infestation on vessels coming to New York**, R. OLESEN (*Pests*, 14 (1946), No. 2, p. 32).—A note on the increased incidence as a potential danger to public health.

**Carriage of plague by the common brown rat (*Rattus norvegicus*)**, S. A. BARNETT (*Nature [London]*, 157 (1946), No. 3978, p. 105).—Data from a 1945 outbreak in Malta clearly indicate *R. norvegicus* to be a carrier of plague to man.

**Fall migration**, edited by M. B. HICKEY (*Audubon Mag.*, 48 (1946), No. 1, Sect. 2, pp. 14, illus. 12).—Notes on the fall (1945) migration of birds are presented by various individuals for the Boston, New York, Philadelphia, Carolina, Pensacola (Fla.), Ohio-Michigan, middle-western, Missouri, Minnesota, Utah, Texas coastal, San Francisco, and southern California regions.

A summary of [Indiana] bird-banding activities from April 1941, to November 1944, J. W. BAERCHLE (*Ind. Acad. Sci. Proc.*, 54 (1944), pp. 201-206, illus. 1).

Increasing valley quail in California, J. T. EMLEN, JR., and B. GLADING (*California Sta. Bul.* 695 (1945), pp. 56, illus. 30).—The valley quail (*Lophortyx californica*)—the California State bird—is said to be one of the most popular wild creatures on the farm lands, ranches, and waste areas where it is found. Quail have been driven from some areas formerly inhabited by them and are less common than desirable in many others. Existing knowledge on their management is still far from complete; enough information has been accumulated, however, to warrant publication of this practical guide for ranchers and others interested in building up quail populations. The discussion includes improving the quail habitat, cover, food, and water conditions; protecting against predators, diseases and parasites, accidents, and excessive hunting; and harvesting the quail crop. There are 24 references.

The quail in early Wisconsin, A. W. SCHORGER (*Wis. Acad. Sci., Arts, and Letters, Trans.*, 36 (1944), pp. 77-103, illus. 2).—The author considers the original range of quail in the State, their extension northward, the periods of abundance, the effects of commerce, the decline in populations of quail, their migration, the effects of agriculture, introductions, and weather relations.

La pesca y distribucion de pescado en Puerto Rico [Fishing and distribution of fish in Puerto Rico], M. VELEZ, S. DIAZ PACHECO, and P. B. VAZQUEZ CACCERRADA (*Puerto Rico Univ. Sta. Bul.* 66 (1945), *Span. ed.*, pp. 45+, illus. 8; *Eng. abs.*, pp. 39-44).—This is a study of the fishing and marketing activities of 281 fishermen owning boats and gear, 6 wholesalers, 11 fish store operators, 80 peddlers, and 63 grocery stores. The education of fishermen, wholesalers, fish store operators, and of fish peddlers was generally low. With the exception of wholesalers, all the groups studied had been engaged in their respective activities for a considerable number of years. The majority of the fishermen interviewed (88 percent) devoted practically all their working time to fishing activities, only 12 percent receiving additional income. The catch of fish was generally low. Monthly sales of fish per fisherman amounted to only 571 lb. with a value of \$60, and sales of other fishery products to \$2. After deducting expenses, an average net income of \$47 resulted. Of this amount \$24 was retained by the owner of the boat and gear, and the remaining \$23 went as pay to the auxiliary crew of 1.7 men, or \$13 per auxiliary fisherman. Monthly expenses incurred in fishing averaged \$15 per fisherman. Average monthly sales of fish by wholesalers amounted to 5,553 lb. valued at \$793. After deducting the cost of the fish purchased, the resulting gross profit was \$249. Six of the fish stores studied operated profitably while four operated at a loss. Fish stores had a gross margin of 27 ct. per dollar of fish sold, expenses amounting to 22 ct., and a net income of 15 ct. Monthly sales of fish by peddlers averaged 619 lb., with a value of \$100; other fishery products sold amounted to \$3, increasing the total to \$103. Peddlers had a gross income of \$32, expenses of \$6, and a net income of \$26. Peddlers who owned their business received \$28 net income, while those working on a commission basis received only \$18. Only 28 percent of the grocery stores sold fresh fish. The quantity sold ranged from 40 to 500 lb., the average being 170 lb.

The eastern coasts of Puerto Rico proved to be the best fishing area of the island.

Equipment used at present by fish peddlers lacks capacity and attractiveness. The functions of the peddlers in the distribution of fresh fish contribute an essential service; this points to the convenience of improving the equipment used by them, both in capacity and attractiveness. Such an improvement would lead to a larger volume of sales and to a greater demand and patronage.

The lake sturgeon (*Acipenser fulvescens Rafinesque*) in Lake Winnebago, Wisconsin, E. SCHNEBERGER and L. A. WOODBURY (*Wis. Acad. Sci., Arts, and Letters, Trans.*, 36 (1944), pp. 131-140, illus. 1).

**Parasites of northern Wisconsin fish**, R. V. BANGHAM (*IVis. Acad. Sci., Arts, and Letters, Trans.*, 36 (1944), pp. 291-325).

**Protozoology**, R. R. KUDO (*Springfield, Ill.: Charles C. Thomas, 1946, 3. ed., pp. 778+*, illus. 336).—This revision (E. S. R., 82, p. 506) contains numerous alterations and additions, including 69 new figures, more information on protozoa that parasitize man, and new chapters on major groups and phylogeny of protozoa and collection, cultivation, and observation of protozoa.

**[Notes on insects and insecticides]** (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 706-725, illus. 4).—Contributions presented (E. S. R., 94, p. 635) are *Platyptus compositus* Attacking Citrus, by J. T. Creighton (p. 706) (Univ. Fla.); The Alleghany Mound Ant [*Formica exsectoides* Forel] and Its Control, by W. A. Price (p. 706) (Univ. Ky.); Two Squash Root Aphids [*Triphidaphis phaseoli* (Passerini) and *Aphis middletonii* Thos. (det. M. A. Palmer)] (p. 707), *Labops* Damage to Range Grasses (pp. 707-708), and Elateridae Eaten by Utah Birds, all by G. F. Knowlton (p. 707) (Utah Expt. Sta.); Toxicity Tests of Certain N-Substituted 2,4-Dinitroanilines on Codling Moth Larvae, by E. H. Siegler and S. I. Gertler (pp. 708-709), and Improved Dispenser for Testing New Liquefied-Gas Aerosols, by L. D. Goodhue, W. R. Ballinger, and J. H. Fales (pp. 709-710) (both U. S. D. A.); Rate of Penetration of Nicotine Into the [American] Cockroach From Solutions of Various Hydrogen Ion Concentration, by C. H. Richardson (pp. 710-711) (Iowa Sta.); Coincident Infestations of *Aonidiella citrina* and *Coccus hesperidum*, a Result of Ant Activity, by S. E. Flanders (pp. 711-712) (Calif. Citrus Sta.); Chinch Bug Dust Barrier—Preliminary Tests, by R. R. Walton (pp. 713-714) (Okla. Sta.); Hessian Fly Infestation in Tennessee and Kentucky, by L. B. Scott and J. Milam (pp. 712-713), N-Substituted *p*-Toluenesulfonamides to Control Codling Moth Larvae, by E. H. Siegler and S. I. Gertler (p. 715), Ethyl Formate and Isopropyl Formate as Fumigants for Packages of Dried Fruits, by P. Simmons and C. K. Fisher (pp. 715-716), Alpha-Trichloromethyl-Substituted Benzenes to Control Codling Moth Larvae, by E. H. Siegler and E. E. Fleck (pp. 716-717), Ethylene Dibromide as a Fumigant for the Japanese Beetle, by A. C. Mason and R. D. Chisholm (pp. 717-718), and Toxicity of Benzene Hexachloride to Housefly Larvae, by E. R. McGovran and P. G. Piquett (p. 719) (all U. S. D. A.); Bacterial Infections of Potato Tuber Moth Larvae in an Insectary, by E. A. Steinhilber (pp. 718-719) (Calif. State Sta.); and Factors Affecting the Larvicidal Action of DDT on *Culex quinquefasciatus*, by H. S. Hurlbut and R. M. Bohart (p. 725).

**The future of entomology**, C. T. BRUES (*Amer. Nat.*, 80 (1946), No. 786, pp. 19-21).

**Incomplete block experimental designs in insect population problems**, F. M. WADLEY. (U. S. D. A.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 651-654).—It appeared from the preliminary trials reported that insect populations and their activities tend to vary locally, and that there is a chance for some improvement in

precision through use of incomplete block designs. The improvement has thus far been moderate; a gain in efficiency equivalent to that obtained by addition of another replication—in ordinary tests—is suggested as likely. Where crop yield is also a criterion, it may—on variable soil—show more improvement than this. These designs are believed to deserve consideration in insect problems when large numbers of treatments are to be tried in field plots.

**Correlations between flight and vision, and particularly between wings and ocelli, in insects.** H. KALMUS (*Roy. Ent. Soc. London, Proc., Ser. A*, 20 (1945), No. 7-9, pp. 84-96, *illus* 2).—This paper surveys some of the taxonomic, morphological, developmental, hereditary, and physiological relations between flight and wings on the one hand and vision and eyes on the other. "Correlative development of eyes and wings, as mainly demonstrated on ocelli and wings, exists in respect of insect orders, families, genera, species, sexes, phases, castes; it extends even to the body parts of some mosaics. Mutant genes affecting both eye and wing characters are known in *Drosophila*, but gene segregation cannot account for the distribution in polymorphic populations. Eye and wing development is probably controlled hormonally by the corpus allatum, and their suppression may be part of a neotenic development, affecting other organs at the same time. In bringing about this widely distributed eye-wing relationship natural selection appears to have acted in many ways and on greatly differing levels of development and organization. Thus the same end is achieved by very different means. The selective advantage of ocelli to flying insects probably consists in the production of muscular tonus by these organs and possibly in orientating the flying insect with its back to the sky." There are 35 references.

**Mode of entry of contact insecticides.** N. E. HICKIN (*Nature [London]*, 156 (1945), No. 3973, pp. 753-754).—In experiments with various types of animal lice, contact between the insecticide used and the insects was almost entirely through the medium of the tarsi.

**Leaf area and its relation to application of insecticides.** W. W. STANLEY. (Tenn. Expt. Sta.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 703-705, *illus*. 1).—Measurements of the rapid increase in leaf area of growing bunch beans and burley tobacco indicated that the beans grew at an average daily rate of 12.67 percent and tobacco at 6.77 percent. The bean plants averaged a maximum of 3,058 sq. cm. (3.30 sq. ft.) per plant and the tobacco 21,072 sq. cm. (22.68 sq. ft.), but on an acre basis the total leaf area was about the same—slightly over 5 acres—for each crop. Most instructions on how to apply insecticides to plants give statements in terms of pounds of insecticide per acre of land. Since the information obtained shows that the area of the leaves to be treated may be 5 to 10 times more than the ground acreage, the instructions should consider also the stage of development of the plants—the plant-surface area per acre of ground. Median lethal dose studies show that for effective results an insecticide in field use must be applied in doses approaching those used in laboratories.

**The evaluation of liquefied-gas aerosol formulations.** L. D. GOODHUE (*Soap and Sanit. Chem.*, 22 (1946), No. 2, pp. 133, 135, 165).

**Preliminary investigations on heat-generated aerosols for the control of agricultural pests.** R. LATTI. (U. S. D. A.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 668-670).—Since gases of the Freon or methyl chloride type are too expensive for covering large areas, studies of the "heat-generated" aerosols were undertaken; the present method of applying them is to mount a generator on a truck and move slowly across the direction of the wind so that the aerosol will drift over the area to be treated from a front approximately at right angles to the wind drift. In this way it is possible to treat up to several hundred acres in part of a day. With the present generators, aerosols can be produced which contain up to 16 percent or more

of DDT in the original mixture, at intake rates of 20 to 100 gal. per hour per generator. This preliminary report is presented to serve as a background in the further study of applying aerosols to the control of agricultural pests.

**Dispersion of DDT sprays from fast combat aircraft,** H. A. JONES, A. W. LINDQUIST, C. C. DEONIER, and C. N. HUSMAN. (U. S. D. A.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 691-693).—Good control of captive houseflies and anopheline mosquito larvae was obtained in preliminary tests by releasing DDT solutions from Chemical Warfare Service M-10 tanks attached to fast combat planes, effective swaths under favorable conditions ranging from 150 to 400 yd. A plane flying across the wind and releasing a 27.5-gal. tank of 5 percent DDT in these tests would have resulted in good control of insects over an area of about 30 acres, assuming a 200-yd. effective swath and a linear coverage of 700 to 800 yd. Better control of test insects was obtained with a 10 percent than with a 5 percent solution of DDT; it would seem desirable to use this higher concentration to compensate for the uneven character of the deposit obtained, even though this may result in some overdosing. Applied at the dosage used, DDT may have injurious effects on fish, birds, frogs, and other wildlife; such factors, however, would be of minimum importance in military operations. These tests were the first to demonstrate the feasibility of controlling insects by release of DDT from fast combat aircraft. They stimulated further investigations in this field and served to fill the need until more efficient equipment had been designed.

**DDT penetration prevented by adding aluminum stearate to DDT-kerosene solutions,** W. EBELING. (Calif. Citrus Expt. Sta.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 689-691, illus. 1).—These experiments were initiated to determine whether the DDT dissolved in kerosene might not be more efficiently deposited on the tree surface if the kerosene were prevented from penetrating, thus evaporating and leaving the DDT crystals on the surface. In one typical test three to four times as much DDT was retained on the surfaces of absorptive substrates when 4 percent DDT-kerosene solutions containing 2 percent aluminum stearate were applied than when the same solutions not containing the stearate were employed. Use of mutual solvents to increase the amount of DDT that may be added to the oil solution affected the manner of deposition of DDT on the surface; for example, Tetralin and Velsicol AR-60 in 10 percent solutions in kerosene had a considerable effect themselves in retarding penetration of the kerosene, but this action was small compared to that of 1 percent aluminum stearate. Further detailed results are given.

**First progress report of cooperative research project on DDT between Canadian Pest Control Operators Association and Division of Entomology, Canadian Department of Agriculture,** E. R. BELLEMERE ET AL. (*Pests*, 14 (1946), No. 1, pp. 11-12).—A brief report on results with some eight groups of insect pests.

**A new chlorinated hydrocarbon insecticide,** C. W. KEARNS, L. INGLE, and R. L. METCALF. (Univ. Ill et al.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 661-668).—A chlorinated hydrocarbon (empirical formula  $C_{10}H_6Cl_8$ , designated "1068") was found to be more toxic than DDT and to compare favorably in toxicity to the  $\gamma$  isomer of benzenehexachloride to a number of insect species; it is possibly a mixture of isomers not as yet resolved and evaluated individually. It was the purpose of this preliminary paper to report laboratory tests by standard entomological procedures on several species of insects which will serve to indicate a few of the possible fields of usefulness for 1068. These trials were made on aphids, the Colorado potato beetle, squash bug, anopheline mosquitoes (including residual toxicity and larvicidal tests), the American cockroach, and the differential grasshopper (as a stomach poison to the adults); detailed results are presented.

**Insect-repellent properties of 2-ethylhexanediol-1,3,** P. GRANETT and H. L. HAYNES. (N. J. Expt. Stas.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 671-675).—

Extensive field and laboratory trials of this material—known during the war as Insect Repellent No. 612—indicated it to possess highly effective repellent properties against a variety of arthropod pests. Equally extensive toxicological studies and large-scale use by the military forces have proved its safety and lack of irritant properties. Finally its physical and chemical properties are such as to make it easy and pleasant to apply and stable in storage or use. This brief paper considers its physical, chemical, and repellent properties; its use in protecting against mosquitoes, including the effect of varying the amount employed; application to clothing; arthropod pests other than mosquitoes (stablefly, blackfly, sand flies, fleas, chiggers, bedbugs); and its toxicological properties.

**Insecticidal properties of Euphorbia extracts**, F. L. VANDERPLANK (*Nature [London]*, 156 (1945), No. 3974, p. 782).—Preliminary experiments indicated extracts of *E. tirucalli* to possess insecticidal properties. African tribes are reported to use this species and *E. calycina* as insecticides.

**New German insecticides**, L. B. KILGORE (*Soap and Sanit. Chem*, 21 (1945), No. 12, pp. 138-139, 169, 171; 22 (1946), No. 2, pp. 122-124).—This "resume of new synthetic chemicals and insect repellents developed in Germany has been compiled from the reports of specialists sent to Germany at the request of the Joint Chiefs of Staff and now released by declassification. . . ."

**Compatibility of cryolite and copper fungicides**, G. WENE and W. A. RAWLINS. (Cornell Univ.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 655-657).—Combining a number of commercial fixed Cu compounds with natural cryolite (Kryocide) failed to affect adversely the toxicity of the latter to third- and fourth-instar Mexican bean beetle larvae. Bordeaux delayed and decreased the toxic action but did not render the cryolite impotent. Considerably more feeding was observed on bean leaves sprayed with cryolite-bordeaux than with the cryolite-fixed copper combinations. The evidence thus suggests a change in the cryolite when combined with bordeaux—a change not evident in the fixed Cu mixtures. In a single field test against the Colorado potato beetle, bordeaux delayed the toxic action of the cryolite, but did not materially reduce the final mortality in comparison with kills obtained by two fixed Cu combinations.

**The distribution and relative seasonal abundance of the Indiana species of Cordulidae and Libellulidae (Odonata)**, B. E. MONTGOMERY. (Purdue Univ.). (*Ind. Acad. Sci. Proc.*, 54 (1944), pp. 217-224, illus. 2).—A summary of the Indiana records for members of these two families.

**Note préliminaire sur les récentes pullulations d'acridiens, du criquet migrateur (Locusta migratoria) en particulier** [Preliminary note on the recent swarms of acridians and of the migratory locust in particular], P. VAYSSIERE (*Compt. Rend. Acad. Sci. [Paris]*, 221 (1945), No. 2, pp. 62-64).

**A new genus and species of locust of the group Euthymiae (Orthoptera: Acrididae: Cyrtacanthacridinae) from South Africa**, J. A. G. REHN (*Phila. Acad. Nat. Sci., Notulae Naturae*, No. 155 (1945), pp. 7, illus. 7).—*Karruia paradoxa* n. gen. and sp. is described.

**A first list of Indiana stoneflies (Plecoptera)**, W. E. RICKER (*Ind. Acad. Sci. Proc.*, 54 (1944), pp. 225-230).

**Two species of Colias migrating in central U. S. A. (Lep.: Rhopalocera)**, K. J. FISHER (*Roy. Ent. Soc. London, Proc., Ser. A*, 20 (1945), No. 10-12, pp. 107-109, illus. 4).—Refers to butterflies of the al'alfa caterpillar and the clouded sulphur.

**The position of Epione mollicularia (Lep.: Geometridae)**, W. T. M. FORBES. (Cornell Univ.). (*Ent. News*, 56 (1945), No. 10, pp. 272-276, illus. 1).—Descriptive and taxonomic notes on this geometrid moth.

**The effects of rotenone-bearing dusts on the diamond-back moth (Plutella maculipennis Curt.)**, W. COTTIER and H. JACKS (*New Zeal. Jour. Sci. and Technol.*,

27 (1945), No. 3, Sect. A, pp. 244-249).—"Experiments were carried out to determine whether percentage rotenone or ether extract content would indicate insecticidal value of rotenone-bearing dusts against diamondback moth. Dusts were made up from four powdered roots imported from overseas manufacturers; three were derris root and one cube. When each of these was diluted with filler to give 0.25 percent, 0.5 percent, 0.75 percent, and 1.0 percent, rotenone-increasing concentration gave improved performance for dusts made up from the same powdered root. When, however, dusts of the same rotenone content but made up from different powdered roots were compared, considerable differences in performance occurred. Nor could these differences be explained by percentage ether extract content. Twenty-five lb. of a dust containing a certain percentage of rotenone gave better results than 50 lb. of one containing half that percentage of rotenone."

**A seedling method for testing aphid resistance and its application to breeding and inheritance studies in cucurbits and other plants, S. S. IVANOFF.** (Tex. Expt. Sta.). (*Jour. Hered.*, 36 (1945), No. 12, pp. 357-361, illus. 2).—A practical method is described for testing resistance to aphids (melon aphid used) in cucurbits by artificial infestation in the seedling stage. The advantages of the technic over the field method—which depends on spontaneous infestation—are speed, economy, high accuracy, dependability, and simplicity. The procedure is also useful for isolating lines resistant to downy mildew (*Peronoplasmopara cubensis*) in certain cantaloups where aphid resistance is closely associated genetically with resistance to this disease. The method is applicable to cotton and okra and may also be adaptable to other plant species.

**Monograph of the family Mordellidae (Coleoptera) of North America, north of Mexico, E. LILJEBLAD** (*Mich. Univ., Mus. Zool. Misc. Pub.* 62 (1945), pp. 229, illus. 125).

**Modification of the geraniol and eugenol content of Japanese beetle bait, M. H. MUMA, G. S. LANGFORD, and E. N. CORY** (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 658-660).—Studies directed toward modification of the present Japanese beetle bait formula in the interest of conserving or replacing the current limited and costly supplies of eugenol and geraniol—particularly the latter—indicated that this may be accomplished in three ways: (1) The present bait—composed of geraniol and eugenol—may be diluted 50 percent with equal parts of Deobase oil and light white mineral oil; this did not materially affect the attractive qualities of the bait. (2) The present 10 : 1 ratio of geraniol and eugenol may be shifted to a 1 : 1 mixture which may be diluted 30 percent with mineral oils without causing reduction in attractive value. (3) Substitute materials may be used to replace all or nearly all of the geraniol in the mixture; of those tested, caproic acid and anethol proved quite effective, with citral somewhat less desirable. Two esters, viz, ethyl caproate and phenyl ethyl butyrate, showed possibilities and may prove effective.

**The synergistic action of N,N-diethylpiperonylamide with pyrethrum marc in control of the Mexican bean beetle, C. A. WEIGEL and S. I. GERTLER** (U. S. D. A.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 683-686).—The tests reported show N,N-diethylpiperonylamide to be a synergist for pyrethrum marc when used against the Mexican bean beetle; it appears to act as a paralytic agent rather than a stomach poison. Since the affected insects drop to the ground, any factor such as extreme heat or direct sun would tend to kill them more readily. Further tests should be made on a large scale not only against this pest but also against other insects that may be controlled with pyrethrum.

**Disodium ethylene bisdithiocarbamate for control of Mexican bean beetle, D. O. WOLFENBARGER and J. W. HEUBERGER.** (Del. Expt. Sta.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 675-678, illus. 3).—Disodium ethylene bisdithiocarbamate (Dithane) applied to the soil around bean plants and as a foliage spray was found

to control the Mexican bean beetle. Dosages of 100 and 400 lb. applied as soil treatments effectively reduced the infestations but lowered the yields as well. Further work should be performed before Dithane can be recommended for this purpose.

**Influence of food plants on fecundity, larval development, and abundance of the tuber flea beetle in Nebraska.** R. E. HILL (*Nebraska Sta. Res. Bul.* 143 (1946), pp. 16, illus. 2).—All food plants tested were those on which overwintered *Epitrix tuberis* Gent. commonly fed in spring. The type of plant consumed by caged beetles markedly influenced oviposition and length of adult life. Egg production was highest and mortality lowest on potato foliage; on the same basis, tomato and wild tomato (*Solanum triflorum*) also proved favorable adult foods, but buffalo bur (*S. rostratum*)—although equally adequate for adult subsistence—proved inferior for egg production. Measured in terms of both oviposition and longevity, prairie ground cherry (*Physalis lanceolata*), field beans, marsh elder (*Iva xanthifolia*), and *Kochia scoparia* were less satisfactory. Substitution of potato foliage for less nutritious diets was followed by increased egg production; change from potato to foliage of other food plants, by decreased egg production. In one 60-day test significant fluctuations in egg deposition were recorded when—at 10-day intervals—diets of potato foliage were alternated with either marsh elder or buffalo bur. In the field, larvae developed most readily and in largest numbers on potato roots and tubers; considerably less development occurred on roots of tomato, and relatively few individuals matured on ground cherry, black nightshade (*S. nigrum*), buffalo bur, and bean. No larval development was recorded from wild tomato, marsh elder, and kochia. Egg viability was unaffected by type of food, but there was some indication that the frequency of copulation was influenced by the quality consumed.

The findings indicated that elimination of all early plantings of potatoes would lower the general population level by reducing the reproductive capacity and longevity of the overwintered beetles. Without potatoes the overwintered insects would be forced to feed, live, and reproduce on less nutritious hosts, thus greatly decreasing the numbers of the first generation available to infest late-planted potatoes. Since western Nebraska is essentially a late-potato area, elimination of the relatively few early-planted acres would be practical and should involve only minor adjustments in the general farming program of a few individual growers. There are 24 references.

**Crop rotations and cultural practices as related to wireworm control in Idaho.** F. H. SHIRCK. (U. S. D. A. coop. Idaho Expt. Sta.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 627–633, illus. 3).—Under normal conditions changes in wireworm populations were found to be gradual from year to year, but excessive increases occurred in red clover fields. High populations in alfalfa decreased from year to year, and the decrease was accelerated by soil dryness in fields where the alfalfa was allowed to go an entire season without irrigation. A survey of 52 fields showed that, in general, wireworm populations increased in the first crop following alfalfa; this increase was mathematically significant for potatoes and corn. There was no significant population change in sugar beets grown for 2 yr. following alfalfa. The increase of adults in crops following alfalfa was more rapid than the general increase of wireworm populations. A relatively long crop rotation—with the land in alfalfa at least half the time—appears to offer the best opportunity for cultural control of wireworms.

**Ethylene dibromide and dichloropropane-dichloropropene mixture for wireworm control.** W. H. LANGE, JR. (Calif. Expt. Sta.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 643–645).—The comparative tests of D-D mixture and ethylene dibromide at three California stations (1944–45) indicated these fumigants to offer

good possibilities for economical control of wireworms when applied in continuous streams at depths of 6 to 8 in. and 12- to 15-in. spacings. With D-D mixture, 40 gal. (400 lb.) per acre gave satisfactory control and increased the yields of lettuce and beans. The simultaneous applications of 35 lb. of anhydrous ammonia with 40 gal. of D-D mixture in the fall gave the greatest increases in yields of lettuce the following spring. Ethylene dibromide at both 30 and 40 gal. of 10 percent strength by volume in a naphtha-200 thinner per acre gave good kills of wireworms and increased both stands and yields. This dosage compared in most cases with 40 to 60 gal. of D-D mixture from the standpoint of actual kill of wireworms, though the increased yields from treatment may depend on what crop is to be planted, as well as on other factors such as the time interval between fumigation and planting date.

**The use of lead arsenate as a control for the grass-grub *Odontia zealandica* White, W. COTTIER** (*New Zeal. Jour. Sci. and Technol.*, 27 (1945), No. 3, Sect. A, pp. 239-243).—A significant reduction in the grub population was observed at 18 weeks after applications of 10 and 20 lb. of lead arsenate per 1,000 sq. ft. of turf; after 24 weeks, dosages of 2.5 and 5 lb. also became effective. Turf treated in April at 2.5, 5, and 10 lb. per 1,000 sq. ft. was protected from reinfestation the following season. A vigorously growing turf could be treated with up to 10 lb. per 1,000 sq. ft. without permanent injury; on less vigorous turf it sometimes caused serious damage, though 5 lb. did not. A top dressing of sulfate of ammonia at 2 cwt. per acre assisted grass to recover from the yellowing caused by the arsenate. Preliminary (10 mo.) tests showed that nitrate of soda and sulfate of ammonia at 0.5, 1, and 2 cwt. per acre and superphosphate at 2, 3, and 4 cwt. did not impair the efficiency of the lead arsenate. Observations indicated that application of lead arsenate at 2 lb. per 100 sq. ft. to strips of ground 6 in. wide and 2 to 3 in. deep—in which rows of strawberries were later planted—appeared to prevent reinfestation for at least three seasons and caused no injury to the plants.

***Aplomya caesar* (Aldrich), a tachinid parasite of the European corn borer, G. WISHART** (*Canad. Ent.*, 77 (1945), No. 9, pp. 157-167, illus. 14).—*A. caesar* is said to be the most abundant native parasite of the European corn borer, laying its eggs on cut or fed-upon surfaces of the host food. Its various life history stages are described. The parasite has as many generations per year as the borer, which means that in Ontario it is usually single brooded; it winters as a first-stage larva in the head of the host. Adults mate well and oviposit freely in laboratory cages, the ♀ producing about 1,000 eggs. The egg is eaten by the host, hatches in the digestive tract, and the larva bores through to the body cavity, finally taking a position in the head. After hibernation the larva moves forward and with its buccal armature cuts a respiratory opening at an antennal sclerite; a respiratory funnel is formed at this point. After hibernation is over, 6 to 8 days are required until the puparium is formed and a further 8 days to the emergence of the adult fly. The distribution and other hosts of the parasite are given.

**Corn rootworms, H. D. TATE and O. S. BARE** (*Nebraska Sta. Bul.* 381 (1946), pp. 12, illus. 7).—Corn rootworms are reported to be major pests of corn in Nebraska and to have become more and more menacing in recent years due to the favorable rainfall, an increase in irrigation, and the spread of the Colorado corn rootworm into commercial corn-growing areas. The northern and southern species are also common in the State, though the last is much less important than the other two. Information is presented on the history of the Colorado and northern corn rootworms, their local distribution, host plants, type of injury, economic importance, appearance, seasonal history, conditions favoring their abundance, and control; the southern species is discussed in less detail.

**The pea weevil and methods for its control, T. A. BRINDLEY, J. C. CHAMBERLIN, F. G. HINMAN, and K. W. GRAY.** (Coop. Idaho, Oreg., and Wash. Expt. Stas.).

(U. S. Dept. Agr., *Farmers' Bul.* 1971 (1946), pp. 24+, illus. 14).—The pea weevil is one of the most important insect pests attacking all varieties of edible and field peas in the United States; it does not attack other legumes. This publication presents information on the principal sources of infestation and on its life history, habits, natural enemies, and control.

**Field trials of insecticides for the control of the sugar-cane frog hopper,** A. PICKLES (*Trop. Agr. [Trinidad]*, 23 (1946), No. 1, pp. 9–11, illus. 8).—It is believed on the basis of these tests that DDT and sabadilla show promise for frog hopper control via drift dusting; the residual effect of DDT is likely to make it a most valuable ingredient of insecticidal mixtures for this purpose.

**Experiments with insecticides to control the strawberry weevil in North Carolina and Maryland,** W. A. THOMAS. (U. S. D. A.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 678–682).—The best results were obtained with arsenical and fluorine compounds, but none of them proved very satisfactory; control of relatively light infestations did not result in appreciable increases in yield. The strawberry plants produced a large percentage of surplus buds that failed to make marketable berries. Apparently a small amount of pruning by the weevil did not adversely affect the yield. Derris, sulfur, and pyrethrum were less effective than were calcium arsenate and cryolite. Nicotine bentonite was not satisfactory.

**The insects of the cultivated blueberry,** C. S. BECKWITH. (N. J. Expt. Stas.). (*N. J. Dept. Agr. Cir.* 356 (1945), pp. 43–51).

**Mortality of the Mexican fruitfly in mangoes treated by the vapor-heat process,** J. W. BALOCK and D. F. STARR. (U. S. D. A.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 646–651, illus. 3).—The vapor-heat tests were conducted in a conditioning cabinet equipped with a turntable of 16-tray capacity, designed to permit removal of random lots of fruit during treatment. The data submitted covered 23 tests with 25,300 mangoes and an estimated population of 205,343 larvae. Treatment periods were 8 to 13 hr., the first 8 hr. of which represented the approach period needed to reach temperature equilibrium at 110° F. Regression lines calculated by the method of probits from these data gave an exposure security at probit 9 (99.9968 percent kill) of 5.7 hr. based on the number of survivors attaining the pupal stage and 3.9 hr. based on the number attaining the adult stage. These periods were in addition to the 8 hr. used in the approach. The experiments were designed so that errors due to differences in position in the vapor-heat cabinet might be studied. The data were subjected to analysis of variance, and the error due to position was found not to be significant.

**The bronzed birch borer problem in Maine,** H. B. PEIRSON and A. D. NUTTING (*Maine Forest Serv. Cir.* 6 (1945), pp. 10, illus. 4).—An informative circular on this pest. Attention is called to the thousands of cords of birch allowed to fall over and rot during the past few years. It is recommended that a close watch on birch be kept and that infested or mature stands be cut while they are still usable. Young stands should be allowed to grow for future use.

**Southern pine bark beetles,** D. A. ANDERSON (*Tex. Forest Serv. Bul.* 33 [n. d.], pp. 8, illus. 9).—An informative leaflet.

**The southern pine sawyer,** D. A. ANDERSON (*Tex. Forest Serv. Bul.* 34 [n. d.], pp. 4, illus. 4).—An informative leaflet.

**Pine tip moth [*Rhyacionia frustrana*],** D. A. ANDERSON (*Tex. Forest Serv. Bul.* 35 [n. d.], pp. 4, illus. 4).—An informative leaflet.

**Food preferences of the cockroach *Blatta orientalis* Linn.,** P. RAU (*Ent. News*, 56 (1945), No. 10, pp. 276–278).—From results with seven baited traps it is concluded that starchy foods are practically the only choice of the oriental cockroach. In a further test it was evident that re-used odorous traps would give the same results in testing food preferences as did the new traps.

**Concentration-survival time relationship for roaches injected with arsenicals,** S. C. MUNSON and J. F. YEAGER. (U. S. D. A.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 634-642, illus. 3).—When injected into American cockroaches, sodium monohydrogen orthoarsenate and sodium metarsenite yielded hyperbolic concentration-survival time curves characterized by a region of inflection and a critical zone. Lead arsenate yielded a curve showing no inflection but having a critical zone. Sodium arsenate and sodium metarsenite were equally toxic except in the higher molar concentrations, where the arsenite was the more toxic; lead arsenate was less toxic than either. These findings are given a rational explanation on the basis of a dissociation hypothesis previously noted (E. S. R., 94, p. 793), according to which in these experiments the arsenical ions formed by the sodium metarsenite and the sodium arsenate (and probably by lead arsenate) are equally toxic and their differences in toxicity due largely if not entirely to the differences in their dissociation. Survival times agreeing well with the observed times were calculated with equations based on this dissociation hypothesis. Methods are suggested for estimating the blood volume of an insect and for comparing toxicity symptoms caused by different poisons. Evidence is presented that the yellow mealworm is more resistant than the American cockroach to poisoning by sodium metarsenite as applied in the tests here reported.

**Applied entomology in the cereal industries,** B. N. SMALLMAN (*Wallerstein Labs. Commun.*, 8 (1945), No. 25, pp. 156-168, illus. 5).—This paper reviews recent important advances in applied entomology for the brewing industry and presents illustrations—some of them in color—of several of the worst pests.

**A monograph of the beetles associated with stored products,** I. H. E. HINTON (*London: Brit. Mus. (Nat. Hist.)*, 1945, vol. 1, pp. 443+, illus. 505).—The preface by N. D. Riley states that "most of the beetles with which this work is concerned are small or very small. Their accurate identification is often a matter of difficulty even to the experienced entomologist. It is therefore not surprising that much confusion reigns in the literature on stored product beetles, and that the few works that profess to facilitate identification sometimes achieve only the opposite result. About one-third of the beetles known to be associated with stored products are described in the present volume, but it is hoped that the identification of these has now been placed on a thoroughly secure basis. The author has supplemented his descriptions of the species and their immature stages by summarizing the published information on their biology and in some cases by adding to it from personal observations. References are given to papers on control measures, but no attempt has been made to discuss them." A subject index and over 26 pages of references—listed alphabetically by authors—are included.

**Use of DDT as an insect control in the canning industry,** F. C. BISHOPP. (U. S. D. A.). (*Canner*, 102 (1946), No. 10, pp. 13-14, 18).—This account is from an address summarizing the current status of DDT, including control of insects in packing plants and present recommendations for its use, with a brief note on benzene hexachloride ("666").

**Preliminary report on the use of DDT as an insecticide in the fishery industries,** L. A. SANDHOLZER and A. W. LINDQUIST. (U. S. D. A. et al.). (*Pests*, 14 (1946), No. 1, pp. 22, 24, 26).

**The action on certain insects of fabrics impregnated with D. D. T.,** H. HAYHURST (*Jour. Soc. Chem. Indus., Trans. and Commun.*, 64 (1945), No. 10, p. 296).—The results of this investigation showed that insect infestation can be controlled by use of sacks impregnated with DDT. The tests were made on the rice weevil, confused flour beetle, and *Ptinus tectus* Bo.

**Summary of DDT experiments on insects that affect man and animals,** W. E. DOVE. (U. S. D. A.). (*Pests*, 14 (1946), No. 2, pp. 8-12, 14).

**Toxicity of DDT for laboratory and domestic animals**, P. J. G. PLUMMER (*Pests*, 14 (1946), No. 2, p. 28).—A brief note on the results of toxicological studies.

**Biological notes on *Chrysopa dorsalis* Burm. (Neuroptera)**, F. C. FRASER (*Roy. Ent. Soc. London, Proc., Ser. A*, 20 (1945), No. 10-12, pp. 116-121, illus. 2).—Notes on the life history and habits of this deer fly.

**[Brief contributions on mosquito and malaria control]** (*Mosquito News*, 5 (1945), No. 4, pp. 121-152, illus. 45).—The following are included: *Anopheles* and Malaria in the Northwestern States, by C. M. Gjullin and W. W. Yates (pp. 121-127) (U. S. D. A.); Some Inter-county Mosquito Control Operations Showing Equipment Used in Improvement of the Upper Passaic River Channel in Essex and Morris Counties, New Jersey, by R. L. Vannote and G. W. Eager (pp. 128-131); The Occurrence of *Orthopodomyia alba* Baker at New Orleans, Louisiana, by P. H. Harden (p. 131); Labor Vs. Mechanized Equipment in Mosquito Control Work—Shifting Emphasis in Alameda County (California) Mosquito Abatement District, by H. F. Gray (pp. 132-134); Notes on Mosquito Migration in Salt Lake City in 1945, by D. M. Rees (p. 134); Equipment Developed by Delaware State Highway Department for Mosquito Control Work, by E. E. Lynch (p. 135); Some Mosquito Control Operations in Bergen County, New Jersey, by V. Conant (pp. 136-137); Mobile Dredge Pump for Mosquito Control, by J. V. Osmun (pp. 138-139); The Disk Harrow—a Valuable Addition to Malaria Control Equipment, by W. J. Perry (pp. 140-141); Some Mosquito Control Operations in Monmouth County, New Jersey, by H. G. Vannote (pp. 142-143); DDT Emulsion for the Control of Culicine Mosquitoes in Cisterns, by R. P. Holdsworth, Jr., C. C. Deonier, and Z. D. Harrison (pp. 144-145) (U. S. D. A.); The Finding of *Anopheles albimanus* Wied. at West Palm Beach, Florida (Diptera: Culicidae), by E. V. Welch (p. 145); A Pump Installation to Drain a 300-Acre Salt Marsh, by O. W. Lafferty (pp. 146-147); and Mosquito Control in Suffolk County, New York, by C. T. Williamson (pp. 148-152).

**Occurrence of malaria mosquitoes in southern Michigan**, C. W. SABROSKY (*Michigan Sta. Tech. Bul.* 202 (1946), pp. 50, illus. 2).—In pioneer days, Michigan was regarded as highly malarial; in the recent past the average has been about 70 scattered cases per year. Four species of *Anopheles* are known to occur in the State, viz, the common malaria mosquito, and *A. punctipennis*, *A. walkeri*, and *A. maculipennis*; the last is a northern species, and this 1943 survey recorded only a few adults. In all, 660 stations were sampled (624 of them for larvae) and anophelines were observed to be common, abundant, and widely distributed; either larvae or adults of malaria mosquitoes were found in over 69 percent of these locations. Of the 624 breeding places sampled for larvae, anophelines were found in 419; the total field count averaged over 17 per positive station. The principal species in the southern part of the State is the common malaria mosquito—the chief vector for eastern North America; of the 4,907 identified larvae and pupae, 75 percent were this species. It was found breeding in a great variety of situations; the averages for standing-water types of breeding sites were somewhat higher than for running waters, though the latter habitats were surprisingly productive. *A. punctipennis* was second in importance, and showed a greater preference for running waters. *A. walkeri* appeared to be a minor factor in the anopheline fauna but—since its larvae may be scattered singly here and there over a large area of marsh or swamp—the samples probably failed to give a true picture of its abundance. On a number of occasions, two or rarely three species were found breeding at the same station; this has considerable significance in relation to control programs. The roles of various types of breeding places and of different areas of the State in the production of anophelines are discussed in some detail, and recommended control measures and suggestions are presented. Keys to the adults, larvae, and

pupae and a brief summary of the literature (12 references) on Michigan anophelines as malaria vectors are included.

**Contribuição para o estudo dos vetores de malaria no Brasil—*Anopheles (Nyssorhynchus) darlingi* Root, em Campos, no Estado do Rio [Malaria vectors in Brazil]**, J. O. COUTINHO and VAN RICCIARDI (*Mem. Inst. Oswaldo Cruz*, 42 (1945), No. 1, pp. 263–280; *Eng. abs.*, p. 278).—The author reports the occurrence outdoors in Campos City, Rio de Janeiro State, of *A. albitarsis*, *A. darlingi*, *A. triannulatus*, *A. oswaldoi*, *A. noroestensis*, *A. pessoai*, and *A. intermedius*—the first three also indoors; the first two were shown to be malaria vectors. Data are also presented on the breeding places; *A. darlingi* was found to breed in large bodies of water as well as in small pools and drainage ditches under the open sky. A review of the literature (17 references) on *A. darlingi* as a vector and on the ecology of its larvae is included.

**Comparisons of mating behavior, growth rate, and factors influencing egg-hatching in South American *Haemagogus* mosquitoes**, W. HOVANITZ (*Physiol. Zool.*, 19 (1946), No. 1, pp. 35–53, *illus.* 5).—Laboratory observations on the mating behavior, egg hatching, and developmental rate of the yellow fever mosquito and of seven species of *Haemagogus* are described. Comparisons are also made with similar data on *Anopheles* and *Culex*. The type and frequency of egg hatching in *Haemagogus* indicated a quality imposed through the ♀ which may be hereditary or environal. Seasonal or environal influences on the ♀ seemed to alter the hatching of the eggs; genetic selection of strains within the species for egg-hatching differences also appears highly possible. There was apparently no correlation between the number of eggs laid and the frequency of eggs which hatch in the progeny. A distinction is drawn between two phenomena which must be considered in these problems: One covers the factors influencing the capacity of eggs to hatch under the influence of a stimulus; the other covers the physiological mechanism by which eggs are enabled to remain in the quiescent stage. The normal hatching phenomena are discussed, followed by the ways in which a breeder can take advantage of them for increasing generation turn-over and number.

**A transmissão de *Plasmodium gallinaceum* pelo *Aedes (Ochlerotatus) lepidus***, W. L. PARAENSE (*Mem. Inst. Oswaldo Cruz*, 42 (1945), No. 1, pp. 81–84; *Eng. abs.*, p. 83).—This mosquito is reported to be a good vector of *P. gallinaceum*, transmitting this malarial infection to chicks of various ages.

**Four new species of mosquitoes from Okinawa (Diptera: Culicidae)**, R. M. BOHART and R. L. INGRAM (*Jour. Wash. Acad. Sci.*, 36 (1946), No. 2, pp. 46–52, *illus.* 24).—Two new species of *Aedes* and one each of *Anopheles* and *Uranotaenia* are described.

**Airplane spraying of rice fields with DDT to kill mosquito larvae**, C. B. WISECUP, W. C. BROTHERS, and P. M. EIDE. (U. S. D. A.). (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 686–688).—In these tests, a water emulsion of 5 or 10 percent DDT was prepared from a concentrate containing 25 percent DDT, 68 percent xylene, and 7 percent Triton X-100; applications were via liaison-type airplanes to more than 700 acres of growing rice in Arkansas. The emulsion was sprayed satisfactorily from the planes. *Anopheles* larvae were readily killed by 0.1 to 0.2 lb. DDT per acre, but preflooding treatments at these dosages were of doubtful value against the larvae; larvae of *Psorophora* spp. were killed by direct applications, and similar light dosages gave good control when applied before the fields were flooded. Dosages greater than 0.5 lb. DDT per acre tended to control all mosquito larvae for about a month. No damage to rice was observed. Liaison-type airplanes of Army designations L-2, L-3, and L-4 proved equally satisfactory for spraying. No special training was needed for service pilots to make these applications in open country.

**The Physaloptera (Nematoda) of carnivores**, B. B. MORGAN. (Univ. Wis.). (*Wis. Acad. Sci., Arts, and Letters, Trans.*, 36 (1944), pp. 375-388, illus. 14).—Includes an annotated list.

**The tail mite and its control**, F. L. JOYCE (*Amer. Fur Breeder*, 18 (1946), No. 8, pp. 22-27).—On promising results against the tail mite on minks by use of a dip made up with Hy-Kresol, said to be on the market as a general purpose disinfectant.

**Os tricoectideos dos roedores (Mallophaga) [Bird lice of the order Trichodectidae on rodents]**, F. L. WERNECK (*Mem. Inst. Oswaldo Cruz*, 42 (1945), No. 1, pp. 85-150, illus. 68).—Members of the genera *Geomydoecus* and *Eutrichophilus*—including new species—are described and discussed. Many of the species are illustrated.

**DDT as a chicken louse control**, H. S. TELFORD (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 700-703).—When 1 gm. DDT was administered orally to each of 4 louse-infested birds averaging in weight 2,333 gm. each, no significant reduction of body or shaft lice resulted. Dipping birds grossly infested with these lice in a 0.03-percent emulsion gave almost complete control within 4 hr. and full control within 2 days. These birds were then placed with an infested flock of 100; on the forty-fourth day 1 bird—which died soon after examination—harbored seven shaft lice. The surviving 3 were free of lice; in 67 days, 1 was still free, 1 harbored five body lice, and 1 harbored incipient infestations of both species. Dipping 12 infested birds in low concentrations of wetting agents either with or without solvents gave poor control of both forms of lice. Spraying 12 birds individually with 2.5 percent DDT emulsion at 32.8 to 39.1 cc. per bird gave complete control of body, shaft, and fluff lice within 40 to 48 hr.; released into an infested flock, these birds remained free of lice up to 15 to 19 days. Sodium fluoride (0.7 percent) sprayed individually on 8 birds at 31.1 to 32.2 cc. per bird gave no control of body or shaft lice. In six flock-spraying trials of 2 to 5 percent DDT emulsions or suspensions applied at 22 to 280 cc. per bird, all three species of lice were controlled for 36 hr. to 7 days; one trial with 2.5 percent DDT emulsion at 47 cc. per bird failed to control body lice at the end of 6 days. Spraying of floors, roosts, and nests with a 2.5 percent DDT emulsion at 6.3 to 20 cc. per square foot gave full control within 26 days; 2 to 5 percent dusts similarly applied at 0.8 to 3.9 gm. per square foot were generally unsatisfactory against all three species of lice. Shaft and fluff lice were more susceptible to control by spraying and dusting than were body lice.

**DDT as a larvicide against *Simulium***, G. B. FAIRCHILD and E. A. BARREDA (*Jour. Econ. Ent.*, 38 (1945), No. 6, pp. 694-699).—In these tests against *Simulium* (several species of blackflies or buffalo gnats) breeding in swift mountain streams in Guatemala, use was made of an emulsion containing 4 percent DDT made from a stock concentrate containing 20 percent DDT, 20 percent Triton X-100, and 60 percent xylene; complete eradication of the larvae from streams for distances up to 10 km. was effected at concentrations of 1 part DDT to 10 million parts water. Efforts to prolong larvicidal action by absorbing emulsions and solutions of DDT on porous substances proved unsuccessful, but the method offers possibilities for treatment of small streams. Trials of turpentine and crude saponin from soap berries indicate them to be moderately effective as solvent and emulsifying agents, respectively; they might economically replace xylene and Triton in Guatemala. In further tests, DDT powder made into a suspension in water with a wetting agent gave kills as satisfactory as those obtained with emulsions.

**The rabbit tick (*Haemaphysalis leporis-palustris* Pack.) as an ectoparasite of man**, J. H. BROWN (*Canad. Ent.*, 77 (1945), No. 9, p. 176).—Note on a case.

**Honeybees and legume seed production**, C. M. HARRISON, R. H. KELTY, and C. BLUMER (*Michigan Sta. Quart. Bul.*, 28 (1945), No. 2, pp. 85-89).—As a result of

records kept during 1943-44, together with certain unpublished data from the station, it is concluded that honeybees have relatively little effect on the setting of alfalfa seed. In the production of alsike and white clovers, on the other hand, bees are essential to seed setting and, for good yields, seed fields should not be over 2 miles from a bee yard and preferably under a mile. Harvesting technics should be improved to obtain full benefits of the increased bee activity.

**Winter cluster temperature**, V. G. MILUM. (Univ. Ill.). (*Gleanings Bee Cult.*, 72 (1944), No. 11, pp. 473-475).—The importance of having adequate stores of honey above the central portion of the cluster is stressed; stores in contact only with the lateral edge of the cluster may be of little value to the general cluster since during prolonged cold the chilled bees of the lateral edges and bottom of the cluster cannot produce heat or pass the stores on to the main body of the cluster.

**Movement of bees in edge of cluster**, V. G. MILUM (*Gleanings Bee Cult.*, 72 (1944), No. 12, pp. 516-518).—A continuation of the preceding. "The oft-expressed idea of the interchange of bees from the outside edge to the inside of the cluster is one that should be tempered with an additional qualifying phrase stating at what outside temperatures the colony is exposed but better still, what is the temperature surrounding the cluster. . . . Since . . . motionless bees are chilled at a point near 42° F., we suspect that at cluster-surrounding temperatures (not outside-of-hive temperatures) even a little higher, there will be no interchange of bees from inside to outside the cluster." Top ventilation prevents condensation, but possibly top insulation sufficient to prevent condensation of moisture and heat loss and a larger entrance for more ventilation with some provision against snow clogging would be the answer to overchilling of bees.

**Investigations on materials suggested as bee repellents**, F. R. SHAW and A. I. BOURNE. (Mass State Col.). (*Gleanings Bee Cult.*, 74 (1946), No. 2, pp. 77-79, 115).—For years beekeepers have hoped for some material which—added to insecticidal and fungicidal sprays or dusts—would repel bees from poisoned foliage. In this study, creosote, carbolic acid, and Milkol were tested for this purpose. Addition of such substances did reduce the life span of the bees; whether this was due to starvation because of the repellent action or to actual poisoning remains undetermined. Creosote mixtures also caused varying degrees of blossom injury to apple, though the importance of this damage might conceivably vary with the time of application. Before the use of any repellent material is recommended it should be thoroughly tested to determine its effects on both plants and bees. A brief review of previous investigations is given.

**The incidence and distribution of some diseases of the adult honeybee (*Apis mellifera* L.) in England and Wales**, C. G. BUTLER (*Ann. Appl. Biol.*, 32 (1945), No. 4, pp. 344-351, illus. 4).

**The acidity of honey**, H. A. SCHUETTE and F. J. SCHUBERT. (Univ. Wis.). (*Wis. Acad. Sci., Arts, and Letters, Trans.*, 36 (1944), pp. 427-433).—The pH of all samples studied lay between 3.16 and 4.52; geographical origins appeared to exert little influence. The comb honeys had a lower pH (3.52) than the extracted honeys packaged in glass or tin containers; there was practically no difference as to type of container here. The percentage of ash varied over a wide range; in general, it went up with increases in both pH and color.

## ANIMAL PRODUCTION

**Principles of animal production**, C. P. McMEEKAN ET AL. (*Christchurch, N. Z.: Whitcombe & Tombs*, [1943], pp. 243+, illus. 56).—The general principles of the production of various classes of livestock, with special emphasis on reproduction and breeding, particularly as practiced in New Zealand.

**Index to the Proceedings of the American Society of Animal Production** (*Jour. Anim. Sci.*, 5 (1946), No. 1, pp. 87-138).—In an attempt to index the early papers of this society, those published by the American Society of Animal Nutrition from 1908 and later combined with the American Society of Animal Production through 1940 have been grouped and listed by subject and author.

**[Experiments in livestock production by the Bureau of Animal Industry].** (Partly coop. Ga. Coastal Plain, Tex., and Okla. Expt. Stas., et al.). (*U. S. Dept. Agr., Bur. Anim. Indus. Rpt.*, 1945, pp. 5, 6, 7-10, 11-15, 19-20; also in *U. S. Dept. Agr., Agr. Res. Admin. Rpt.*, 1945, pp. 53, 54, 55-58, 59-61, 63, 67-68).—Largely in continuation of previous studies (E. S. R., 92, p. 819), brief results are given of thickness of fat as an index of hog carcass quality, a histological study of tenderness of different cuts of beef, the effects of different ways of feeding phosphorus supplements including bone meal (in self-feeders, in drinking water, and for fertilization of pastures), use of defluorinated fused phosphate, surplus sweetpotato products for beef and milk production, milo heads less satisfactory than threshed milo for beef production, cottonseed meal useful for wintering cattle, crop lands grazed to advantage by beef cattle, defluorinated phosphate satisfactory for lambs, improvement of sheep forage by range research, studies of wool and mohair properties, investigation of vitamin A deficiency in growing and fattening pigs, need of protein supplements shown by feeding records of 2,324 pigs, a uremic condition in young pigs, necrotic enteritis in swine usually caused by nicotinic acid deficiency symptoms, satisfactory horse rations from roughages and concentrates compressed into pellets, soybean meal a less desirable protein in mashes for breeding stock than in other feeds, loss of yellow pigment from chicks promoted by vitamin A, and growth of chicks in hot weather improved by artificial light.

**Composition and feeding values of green maize, millet, and bulrush millet cut for soiling purposes**, M. H. FRENCH (*East African Agr. Jour.*, 11 (1946), No. 3, pp. 159-161).—Corn, millet, or bulrush millet grown under irrigation in the dry seasons would form a valuable green supplement to rations of high-producing stock, but these green feeds should be supplied with adequate amounts of protein.

**Rations for fattening cattle in Arizona**, E. B. STANLEY (*Arizona Sta. Bul.* 198 (1945), pp. 16).—In several tests miscellaneous feeds for fattening cattle were tried. In five tests of about 120 days in duration, an average daily gain of 2.15 lb. was made by 49 steers receiving hegari silage with barley, cottonseed meal, and alfalfa hay, as contrasted with 1.80 lb. by 49 steers receiving similar feeds but no silage but otherwise similar feeds and more alfalfa hay. It was calculated that hegari silage had slightly less than 60 percent the value of alfalfa hay. In six further experiments of about 120 days' duration, steers with hegari silage made an average daily gain of 2.30 lb. as contrasted with 2.18 lb. by steers with Manko (a new grain sorghum) silage, which had a little more than 80 percent the value of hegari silage when fed with alfalfa hay, cottonseed meal, and grain. Grapefruit cannery refuse silage fed with these feeds was 82 percent as valuable as hegari silage, but because of the slimy compacted state of this material and extensive shrinkage and spoilage in ensiling and handling it this feed cannot be considered an economical substitute for hegari silage. Whole cottonseed had a replacement value of 88 percent for cottonseed meal when fed in a ration including silage, and 97 percent of the value of cottonseed meal when fed without silage. Additions of molasses to a ration of barley, cottonseed meal, hegari, silage, and alfalfa hay did not improve it. The most effective use of molasses was in rations without silage and of relatively poor palatability for fattening. A few tests showed that rolled barley was preferred to ground barley. The usual superiority of wheat over barley was not evident, but wheat may be substituted for barley if the market price favors the change, although wheat must be carefully fed, especially to calves. In over 6 years' experi-

ments with wheat, 547 cattle showed that top grade Arizona weaner calves may be finished into baby beeves following 60 days on alfalfa hay, hegari silage, and cottonseed meal. Dehydrated potato meal seemed equal to barley as a partial replacement.

**Dried molasses-beet pulp and beet molasses for fattening cattle,** H. P. SINGLETON, M. E. ENSMINGER, and W. W. HEINEMANN (*Washington Sta. Bul.* 469 (1945), pp. 31, illus. 10).—Feeding trials were conducted in three 120-day feeding periods to ascertain the replacement value of dried molasses-beet pulp for all or part of the corn, wheat, or barley in rations with chopped alfalfa hay, steamed bone meal, and salt. The cereals were fed alone or supplemented with one-third, one-half, or one-sixth part of dried molasses-beet pulp, replacing either corn, barley, or wheat or combinations of these. With mature steers, high quality hay, and a feeding period of 120 days, dried molasses-beet pulp may be fed satisfactorily up to 50 percent of the ration of corn, barley, or wheat during years of favorable price relationships. About 75 lb. of the grain was replaced by 100 lb. of the dried molasses-beet pulp. There was a slight decrease in hay consumption and gain. Comparative feed prices, rather than feed efficiency, determined costs. Dried molasses-beet pulp was a good appetizer.

**A statistical comparison of the influence of crude fibre on the digestibility of roughage by *Bos indicus* (Zebu) and *Bos taurus* cattle,** J. DUCKWORTH (*Trop. Agr. [Trinidad]*, 23 (1946), No. 1, pp. 4-8, illus. 3).—"A statistical study was made of the influence of crude fiber on the digestibility of organic matter in roughage, using American and Indian data. The correlation between crude fiber and organic matter digestibility was highly significant and negative for both *B. taurus* consuming temperate zone fodders and *B. indicus* consuming tropical fodders. The association between crude fiber and organic matter digestibility was, however, less in the Indian data than the American. Each increase of 1 percent in crude fiber content depressed the digestibility of the organic matter by 0.9 percent in the American studies but only by 0.5 percent in the Indian studies. Tropical roughage of low fiber content showed lower digestibility coefficients when fed to Zebu stock than did temperate zone roughage fed to *B. taurus* stock. Because of the lower regression of digestibility on crude fiber in tropical roughage fed to Zebu, there was little difference in comparison of high fiber roughage."

**Chemical composition and digestibility of flat pea forage in three stages of maturity,** T. W. DANIEL, F. B. WOLBERG, V. L. MILLER, J. H. ALSWAGER, M. E. ENSMINGER, and A. A. SPIELMAN. (Wash. Expt. Sta.). (*Jour. Anim. Sci.*, 5 (1946), No. 1, pp. 80-86).—The apparent digestibility of flat pea forage (*Lathyrus sylvestris wagneri*) at three stages of maturity was ascertained in fresh and dry form with sheep. The fresh and artificially dried materials were palatable and highly nutritious. However, the losses of several sheep during the first weeks of feeding indicated the need for caution until more is known about the possible toxicity of flat peas. The fresh green forage contained an average of 29.6 percent digestible protein and 69.8 percent total digestible nutrients as compared with 26.0 and 67.3 percent, respectively, in the artificially dried forage. The fresh green flat peas in the preblossom stage contained 34.26 percent digestible protein, the early bloom stage 30.17 percent, and the late bloom stage 24.32 percent. The total digestible nutrient contents in these three stages of maturity were 74.94, 68.86, and 65.44 percent, respectively. The artificially dried flat pea had digestible protein contents of 30.72, 27.09, and 20.12 percent, and total digestible nutrient contents of 73.47, 65.54, and 62.96 percent, respectively, at these three stages of maturity.

**Nutritive requirements of breeding ewes for maintenance, lactation, and growth,** C. L. SHREWSBURY, C. HARPER, and F. N. ANDREWS. (Ind. Expt. Sta.). (*Jour. Anim. Sci.*, 5 (1946), No. 1, pp. 47-54).—Two additional experiments (E. S. R.,

87, p. 556; 89, p. 719) showed the deficiencies of oat straw and the nutritive value of cereal grass fractions. Dehydrated ryegrass and oatgrass were found to have a high nutritive value with corn and silage for breeding ewes. First-cutting alfalfa hay was only slightly better than oat straw, but the second-cutting alfalfa hay approached the third cutting in nutritive value. The necessary supplementing factors for optimum performance of the breeding ewe were not present in the water-soluble fraction of ryegrass. The residue after water extraction retained the factors in concentration resembling the original cereal grass. Additions of protein (casein) and crystalline vitamins to the oat straw ration or a protein supplement of soybean meal and a poor quality alfalfa hay ration improved the ration but did not make it equal to rations containing dehydrated cereal grass. The study was conducted in 1942-43 with 12 lots of 15 2-year-old ewes and in 1943-44 with 5 lots of 10 3-year-old ewes and 4 lots of 15 4-year-old ewes each.

**The phosphorus requirement of ewes for pregnancy and lactation, W. M. BEESON, R. F. JOHNSON, D. W. BOLIN, and C. W. HICKMAN (*Idaho Sta. Bul.* 266 (1945), pp. 11).**—Continuing previous studies (E. S. R., 91, pp. 324, 452), it is shown that a level of 0.14 percent or less P in the ration of ewes is on the border line for adequately maintaining a normal P balance for pregnancy and is definitely inadequate for lactation. Rations containing 0.16 to 0.19 percent P were adequate for gestation. This allowed a daily intake per ewe of 3.21 to 3.26 gm. or 2.47 to 2.43 gm. per 100 lb. live weight. In practical terms, a ewe receiving 3.5 to 4 lb. of good quality alfalfa hay (0.19 to 0.22 percent P) daily would be amply supplied with P. The P requirement of a lactating ewe may be met by feeding rations containing 0.23 percent or more. Ewes should be wintered during gestation on range forage or roughage containing 0.16 percent or more P, and after lambing the addition of 1 lb. or more of grain to the alfalfa-salt ration will supply sufficient P. The study was conducted with 167 crossbred white-faced ewes. Blood P values were ascertained at frequent intervals.

**Wintering breeding ewes in Alaska, W. J. EBERT (*Alaska Sta. Cir.* 6 (1945), pp. 8, illus. 1).**—In 5 yr. Hampshire ewes were wintered successfully on seven different rations of locally grown roughages, mainly chopped tide-flat hay, chopped or unchopped oat-pea hay, or silage, or a combination of roughages. The ewes also produced a good fleece and a crop of healthy, vigorous lambs.

**Waxy corn versus non-waxy corn for growing fattening pigs fed in dry lot, L. E. HANSON. (Nebraska Expt. Sta.). (*Jour. Anim. Sci.*, 5 (1946), No. 1, pp. 36-41).**—Three trials were conducted for a comparison of nonwaxy and waxy corn for self-feeding of pigs with protein and mineral supplements, which showed practically equal results as far as gains and economy of feeding were concerned. In lots given a choice of both kinds of corn, about 2.6 times as much of the nonwaxy corn was consumed, but the over-all response of pigs fed only waxy corn was fully equal to that of the pigs fed nonwaxy corn. Chemical analyses showed the waxy corn to contain slightly more protein, fiber, ether extract, and ash, but less nitrogen-free extract.

**Cull peas as a protein supplement for fattening hogs on pasture, W. P. LEHRER, JR., W. M. BEESON, and A. WILSON (*Idaho Sta. Cir.* 108 (1946), pp. [4]).**—Three groups of 12 pigs each, averaging 58 lb. per head, were fed rolled wheat on pasture with protein supplements for 98 days. The protein of one group was made up of one-third ground peas and two-thirds meat meal. In the second group this consisted of 10 percent meat meal and 90 percent peas. The third protein supplement consisted of peas only. The average daily gains of the three groups were, respectively, 1.39, 1.47, and 1.55 lb. Favorable gains were thus made with cull peas alone. These are palatable and can be used to good advantage when the hogs are fattened on good pasture.

**Addition of synthetic nutrients to protein supplemental feeds in swine rations,** E. F. FERRIN. (Minn. Expt. Sta.). (*Jour. Anim. Sci.*, 5 (1946), No. 1, pp. 42-46).—The possibility of improving soybean meal protein by additions of choline and methionine was investigated with five lots of about nine 50-lb. pigs each fed for 103 days. All lots received 70 to 78 percent ground yellow corn, dried whey, and alfalfa meal. Individual lots received protein supplements of 14 percent tankage, 12.2 percent sardine meal, and the last three lots 19.6 percent soybean meal each, with two of these having added 0.1 percent choline chloride and *dl*-methionine, respectively. All lots received some riboflavin and niacin. The average daily gains per head with the protein supplements were tankage 1.38, sardine meal 1.60, soybean meal alone 1.41, soybean meal with choline 1.34, and soybean meal with *dl*-methionine 1.40 lb. The addition of choline to the soybean meal had a depressing effect on the feed consumption and rate of gain, whereas the addition of methionine to the soybean meal did not alter the daily gain or feed consumption in spite of severe scouring. The results of a reversal experiment indicated that the scouring may have been caused by a more active intestinal flora, because it was arrested by the oral administration of sulfathaladine.

**The relation of the amount of thiamine in the ration of the hog to the thiamine and riboflavin content of the tissue,** W. W. HEINEMANN, M. E. ENSMINGER, T. J. CUNHA, and E. C. McCULLOCH. (Wash. Expt. Sta.). (*Jour. Nutr.*, 31 (1946), No. 1, pp. 107-125, illus. 2).—Essentially noted (E. S. R., 94, p. 654).

**Single weight versus a three-day-average weight for swine,** H. W. BEAN. (Univ. Ill.). (*Jour. Anim. Sci.*, 5 (1946), No. 1, pp. 30-35, illus. 1).—Over a period of years, the deviations of the first-day and final weights from the 3-day averages of 3,323 pigs in self-feeding experiments were ascertained. The deviations between the first-day weight and the 3-day average increased as the size of the pig increased. Apparently the excitement created in handling the animals the first day had considerable influence on the second-day weight, and this condition is reflected in the 3-day average. There was usually less variation in the first-day weight than in the second or third or in the average. Thus errors are usually introduced in the 3-day average rather than making them smaller. Statistical analyses failed to show any advantage for using the 3-day average weight rather than a single weight at the beginning and again at the end of the feeding experiment. Careful weighing and reading scales on one day is therefore recommended.

**Successful broiler growing,** E. HOFFMANN and H. A. JOHNSON (*Mount Morris, Ill.: Watt Pub. Co., 1946, pp. 186, about 50 illus.*).—A popular presentation of broiler production, with emphasis on economic phases.

**Vegetable protein concentrates fed alone and in combination with soybean oil meal and fish meal as the chief supplementary protein in chick starting rations,** G. F. HEUSER, L. C. NORRIS, and J. MCGINNIS. (Cornell Univ.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 130-136, illus. 2).—Different proteins were compared as the single source of protein in 24 lots of 25 chicks each, with weights ascertained to 8 weeks of age. Soybean meal as the only source of protein in the starting ration produced heavier birds than peanut meal or wheat germ meal, but they in turn were better than cottonseed meal and corn gluten feed or linseed meal, which was definitely unsatisfactory. Replacing one-half of the protein of various vegetable protein concentrates with soybean meal protein improved the growth so that there was little difference between them, but linseed meal was still poor. The supplementary effect of soybean meal was greater for cottonseed meal and corn gluten feed than for peanut meal and wheat germ meal. In 11 of the lots 3 percent fish meal was included with the other sources of protein. The inclusion of the fish meal increased the response, which seemed to be additive rather than supplementary, indicating that it was not due chiefly to amino acids. Various combinations of fish meal, soybean

meal, peanut meal, wheat-germ meal, cottonseed meal, corn gluten feed, and linseed meal resulted in average weights classified as good, medium, and poor, the averages being 653, 508, and 324 gm., respectively. All rations classified as good included fish meal. Mortality was generally lowest in the lots showing most favorable growth. Livability seemed to be improved by fish meal, peanut meal, and wheat-germ meal. Gains were more economical on rations making good growth. Feed efficiency was increased by the inclusion of fish meal or soybean meal in the ration. The increase due to soybean meal was more marked when the rations included cottonseed meal or corn gluten feed than when they contained peanut meal or wheat-germ meal.

**Chick growth response resulting from methionine additions to various protein supplements with pea protein.** D. W. BOLIN, C. F. PETERSEN, C. E. LAMPMAN, and O. E. STAMBERG. (Idaho Expt. Sta.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 157-161).—Since Alaska pea meal was found to be deficient in methionine (E. S. R., 92, p. 102), the supplemental value of several proteins were investigated. There was a marked difference in the supplementary value of various feeds when fed with pea meal. Additional methionine was required in all rations to obtain maximum growth response, but there was a wide difference in various protein sources to supply methionine. Rendering plant meat meal produced average gains of only 54.9 gm., and packing plant meat meal produced gains of only 21.7 gm. However, with methionine the growth response was equal to that obtained by methionine-supplemented fish meal. Among the supplements tested, herring fish meal, casein, and dried milk were excellent supplements to the pea meal. The combination of pea meal and soybean meal used would not promote satisfactory growth even at the high levels in a chick starter mash because of a methionine deficiency. Groups of eight chicks each were provided with the supplementary rations for 2-week periods. All the supplements included tests with 0.25 percent methionine.

**Choline-like nutritional effect of dimethylaminoethanol.** T. H. JUKES and J. J. OLESON (*Jour. Biol. Chem.*, 157 (1945), No. 1, pp. 419-420).—Groups of 10 New Hampshire chicks were placed on rations which contained 18 percent casein and which were similar to those used in previous experiments.<sup>2</sup> When no supplements were added to this ration, 50 percent of the chicks developed perosis in 21 days and 60 percent in 28 days, whereas with supplements of 0.2 gm. of diethylaminoethanol or 0.1 gm. of choline chloride per 100 gm. of basal ration no perosis developed and gains in live weight in 28 days were 145 and 194 gm. as compared with 112 gm. in the group receiving no additional supplement. The structure of the molecule of diethylaminoethanol is considered as indicating a possible source of choline formation.

**An unexpected high requirement of chicks for pyridoxine.** H. L. LUCAS, G. F. HEUSER, and L. C. NORRIS. (Cornell Univ.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 137-142, illus. 2).—Symptoms of pyridoxine deficiency appeared in crossbred Rhode Island Red × Barred Plymouth Rock chicks, even though the rations were supplemented with pyridoxine in supposedly adequate amounts. Both purified and simplified rations were fed. The possibility was pointed out that the high requirement may have been due to genetic factors and also that the ration may have been contributing to this deficiency.

**Supplements for distillers' by-products in poultry breeding diets.** R. T. PARKHURST and J. W. KUZMESKI. (Mass. Expt. Sta.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 162-172, illus. 5).—"Milo-rye distillers' dried grains with solubles and distillers' dried solubles were used in complete all-mash diets. Riboflavin, pantothenic acid, choline, and biotin determinations of the diets were made, in addition to the usual chemical analyses. Excellent hatchability results were obtained with a diet

<sup>2</sup> *Jour. Biol. Chem.*, 146 (1942), No. 1, pp. 19-24.

containing 20 percent of dried distillers' grains with solubles and as little as 1.25 percent of Redfish meal as the only animal or marine protein supplement. Good results were obtained with 2.5 percent of meat scraps in the total ration. Two groups, one getting a diet containing 3 percent of liver meal as a supplement to 5 percent of distillers' dried solubles and the other a mixed protein diet, gave equally good hatchability. Very poor hatchability was obtained with all diets not containing some animal or marine protein concentrates. There was no indication that animal and marine protein concentrates were essential for egg production, egg size, palatability, feed efficiency, maintenance of body weight, or livability. Egg production, feed efficiency, and body weight maintenance seemed to be slightly better with diets containing distillers' dried solubles than with those containing the distillers' dried grains with solubles but were satisfactory with both products. The addition of choline chloride, synthetic riboflavin, and pantothenic acid to diets without animal proteins, and also to those containing meat scraps, did not improve their value for hatchability or egg production."

**The effect of feeding cow manure on egg production and hatchability,** D. WHITSON, H. W. TITUS, and H. R. BIRD. (U. S. D. A.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 143-147, illus. 1).—Contrary to the findings of Hammond (E. S. R., 88, p. 518), the inclusion of 8 percent of dried cow manure of high androgenic potency in a good practical all-mash ration significantly impaired egg production in a 48-week experiment. When the androgen potency of the cow manure was destroyed by drying at 80° C. for 24 hr., there was no effect on egg production. High hatchability was supported whether or not the ration was supplemented with cow manure. The inclusion of the dried cow manure in a ration high in soybean meal and containing no animal protein significantly improved hatchability, and largely eliminated the seasonal variation in hatchability which was characteristic of the basal ration used.

**The use of various vitamin supplements in rations for laying and breeding hens,** W. W. CRAVENS, J. G. HALPIN, and W. H. MCGIBBON. (Wis. Expt. Sta.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 99-104).—To ascertain if vitamin supplements other than riboflavin are essential in laying and breeding rations of practical feeding stuffs and to evaluate certain products for possible use in laying and breeding rations (E. S. R., 93, p. 612), fish solubles, ground fish viscera, and solubilized liver extract were tested. No significant differences in egg production were found between the basal ration and rations containing the various supplements. When alfalfa meal was fed at a level of 2 percent, 0.6 mg. of riboflavin was an effective supplement. When only riboflavin was added to rations containing no alfalfa meal, the hatchability of the eggs was unsatisfactory. Dried skim milk was also ineffective at levels of 2.5 percent. A significant increase in hatchability occurred when fish solubles and solubilized liver extract were fed in addition to riboflavin.

**Oyster shells, calcite grit, ground limestone, and granite grit in rations for hens,** G. F. HEUSER and L. C. NORRIS. (Cornell Univ.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 173-179, illus. 3).—The results of an experiment in which oyster shells, calcite grit, and ground limestone were compared as sources of calcium supplementary to that present in a representative commercial laying ration, the mash of which contained approximately 1 percent each of calcium and phosphorus fed as supplements to the laying ration with crushed oystershell and calcite grit gave better results as supplements to the laying ration than ground limestone, especially during the latter part of the year. There was no difference in egg production between hens getting crushed oystershell or calcite grit. Egg production was significantly lower on ground limestone than for the birds receiving crushed oystershell or calcite grit. Body weight was better maintained in hens receiving crushed oystershell than in those receiving calcite grit or ground limestone. The

birds receiving ground limestone showed higher mortality than the other groups. Eggshell strength rated in the order of oystershells, calcite grit, and ground limestone. Additional feeding of granite grit had a favorable effect on egg production and the pounds of feed required to produce a dozen eggs when fed with crushed oystershells or ground limestone. Calcite grit also had a favorable effect in this respect. Additional feeding of granite grit seemed to have no influence on body weight or mortality but a favorable influence on eggshell strength. Considering all factors studied, the best combination was the supplementation of the laying ration with crushed oystershells and granite grit. The studies were conducted over about 10 mo. with 6 lots of 60 Single-Comb White Leghorn pullets receiving oystershells, calcite grit, and 8 percent ground limestone added to each 100 lb. of mash, with and without granite grit. Data were recorded on the egg production, feed consumption, body weight, mortality, eggshell strength, and feed efficiency with the different grits.

**Energy and gaseous metabolism of the chicken from hatch to maturity as affected by temperature.** H. G. BAROTT and E. M. PRINGLE. (U. S. D. A.). (*Jour. Nutr.*, 31 (1946), No. 1, pp. 35-50, illus. 4).—More than 500 1-day experiments on the gaseous and energy metabolism of Rhode Island Red ♀ chicks of average ages of 4 days, 2, 5, 8, 12, 18, and 23 weeks, and 1 yr. were determined. The environmental temperatures ranged, at 5° intervals, from 20° to 103° F. Other conditions were relative humidity from 50 to 60 percent, oxygen content 21 percent, and CO<sub>2</sub> content less than 1 percent. Oxygen consumption was measured for each 2-hr. period, and the heat, water, and CO<sub>2</sub> elimination for each 4-hr. period. The results define the metabolic rate for each age of chicken studied, at each environmental temperature. A point of flexure occurred where metabolism was minimum, which was found at 95° for baby chicks and chicks 2 weeks of age. It became progressively lower with increasing age. The minimum occurred in 1-year-old hens at approximately 70°. The maximum occurred at the lowest temperature the chicken could survive, but the temperature was not determined for chickens older than 8 weeks. Each 24-hr. period showed a typical diurnal rhythm in the metabolism, with a maximum value at 8 a. m. and a minimum at 8 p. m. The amounts of the three feed constituents metabolized by the chick were protein 69 percent, fat 27 percent, and carbohydrate 4 percent. The observed respiratory quotient approximated 0.717 in all ages and at all temperatures. The observed oxygen thermal quotient was 3.11 and the observed CO<sub>2</sub> T.Q. 3.16. Water respiration below that where minimum metabolism occurred was fairly constant, but the large amount of water exhaled for cooling above this temperature made an enormous increase in water metabolism.

**Periodic increase in lighting versus continuous lighting for layers.** O. K. MOORE and N. R. MEHRHOF (*Florida Sta. Bul.* 420 (1946), pp. 12).—In 3 successive years, 2 lots of 50 Light Sussex pullets were exposed to different lighting conditions. In lot 1 in each of the 3 yr., the experimental periods were divided into 14-day intervals in which a changing schedule of artificial lighting was used. No artificial light was used in addition to daylight in the first interval in lot 1. In the second interval, the artificial light was provided from 5 a. m. to daylight and in the third interval from 3 a. m. until daylight, with a 2-hr. increase in succeeding intervals until the birds received continued lighting. The birds of lot 2 in each experiment were exposed to continuous lighting for the 24 hr.

The birds receiving the all-night lighting laid an average of 2.44 percent more eggs than those receiving the increased schedule of lighting. The gradual increase in length of day as administered in this experiment to birds in lot 1 produced a greater initial response in increased egg production, but later there was a greater refractoriness to light stimulation than occurred in all-night lighting. The birds receiving all-night lighting consumed 0.32 lb. less feed per dozen eggs than all

birds receiving the increased schedule of lighting. The time of laying was during the daylight hours and was unaffected by the changing schedule of lighting used in lot 1.

**The relationship of iris color to mortality and egg production in Single Comb White Leghorns.** R. F. BALL. ([N. Y.] Cornell Expt. Sta.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 105-114, illus. 4).—Data are presented on the relationship of iris color and irregularity of pupils to mortality and egg production in Single-Comb White Leghorns over a 3-year period. The findings involved the egg production of 4,662 pullets of the Cornell Resistant strain and 1,363 pullets of the Cornell Susceptible strain. At the time of housing, a large number of the pullets had depigmented irises, and at 500 days of age still more showed this condition. About 62 percent of the Resistant stock showed faded irises at 500 days, a condition which was believed to be related to the heavy egg production. Irregular pupils were frequently observed in ♀♀ of the Susceptible strain. The proportion of birds with faded irises and irregular pupils was increased in birds exposed to disease during the first 2 weeks of life. Susceptible pullets with depigmented irises had a greater rate of mortality from all causes than their sisters with normal iris color, although similar but insignificant losses from neoplasms were also seen in those with faded irises. In general, Resistant pullets with faded irises had but slightly greater mortality from all causes and from neoplasms than those classified as normal or reddish bay. There was no relation between the degree of iris depigmentation at housing time and the rate of mortality to 500 days of age. Pullets with irregular pupils experienced heavy losses in both Resistant and Susceptible strains. Low egg production was associated with iris depigmentation in Susceptible pullets, but not in those from Resistant stock. Neither the amount of depigmentation nor the disproportionate depigmentation of the left and right eye was related to egg production. Irregularity of pupils was indicative of a low rate of lay of both strains. Differences in mortality and egg production between ♀♀ with faded and normal irises were considerable in one strain (Susceptible) and only slight or nonexistent in the other strain (Resistant). The desirability of indiscriminately culling all ♀♀ with depigmented irises is questioned in view of these findings.

**Directory of U. S. Register of Merit sires and dams qualifying under the National Poultry Improvement Plan, 1943-1944** (*U. S. Dept. Agr., Misc. Pub. 587* (1945), pp. 62).—The usual list of birds qualifying for the Register of Merit by breeds in 1943-44 (*E. S. R.*, 93, p. 67).

## DAIRY FARMING—DAIRYING

[Investigations on dairy products and dairying by the Bureau of Dairy Industry] (*U. S. Dept. Agr., Bur. Dairy Indus. Rpt.*, 1945, pp. 2-7, 10-11, 12-15, 17; also in *U. S. Dept. Agr., Agr. Res. Admin. Rpt.*, 1945, pp. 100-105, 108-109, 110-113, 115).—Brief results are presented on the keeping quality of dried milk by double evacuation with inert gases, speeding up ripening of Cheddar cheese by raising the temperature and pasteurization, use of the phosphatase test to determine adequacy of pasteurization of milk for Cheddar cheese making, cheese whey may yield mold of the Roquefort-type cheese for use as a cheese spread, the physical condition of evaporated milk as related to spoilage, sugar may be more economically added to dried ice cream after drying than before, ice cream mixes need not be homogenized if homogenized cream is used, manufacture of a new type of canned milk with increased flavor, penicillin destroys bacteriological organisms which develop undesirable flavors, rate of grain feeding early in lactation for increasing milk yields, orchard grass and Ladino clover good pasture for dairy cattle, valuable fertilizing

material lost in dairy-barn drains, high vitamin A value of summer butter, high vitamin A value of winter milk with better hay-preserving methods, grain and corn silage produce milk without nutritional deficiencies, giving calves skim milk and grain at 5 to 12 days of age, and sanitary inspection of factories processing farm butter.

**Artificial insemination of dairy cattle**, H. A. HERMAN and A. C. RAGSDALE (*Missouri Sta. Bul* 494 (1946), pp. 32, illus. 26).—General directions are given for carrying out artificial insemination of the dairy herd. Advantages and disadvantages of artificial insemination are briefly reviewed. The various genital organs of the ♂ and ♀ reproductive tracts are briefly described.

**Simple vs. complex grain mixtures in dairy rations**.—I, **Winter feeding of milking cows**, C. F. MONROE and W. E. KRAUSS (*Ohio Sta. Bimo. Bul.* 238 (1946), pp. 19-24).—A simple mixture of 77.5 percent ground shelled corn, 20 percent soybean meal, and 2.5 percent minerals was compared with a complex mineral mixture for effects on milk and butterfat production and feed consumed. The 28 milk cows used in the study were fed for 40 days on each ration. The average daily milk production of each group for the 40 days was approximately 40 lb., and there was no significant difference in production of the 5 heaviest producers in each group.

**The thiamine, riboflavin, nicotinic acid, and pantothenic acid content of colostrum and milk of the cow and ewe**, P. B. PEARSON and A. L. DARNELL. (Tex. Expt. Sta.). (*Jour. Nutr.*, 31 (1946), No. 1, pp. 51-57).—The colostrum and milk of the ewe were much richer in thiamine, riboflavin, and nicotinic acid than the colostrum and milk of the cow. The colostrum of both the cow and the ewe was much higher in thiamine and riboflavin than the milk of these species. The colostrum of the cow contained an average of 0.62 µg. of thiamine and 6.10 µg. of riboflavin per cubic centimeter, while the corresponding values for milk were 0.38 and 1.77 µg. per cubic centimeter. Colostrum of the ewe contained 1.08 µg. of thiamine and 20.08 µg. of riboflavin per cubic centimeter, while the corresponding values for the milk of ewes were 0.60 and 4.36 µg. per cubic centimeter. There was no significant difference in the nicotinic acid content of cow's colostrum and milk, but ewe's milk contained almost twice as much as the colostrum. The milk of both species contained more pantothenic acid than was found in colostrum. Within less than a week after parturition, the riboflavin and pantothenic acid of the cow's milk attained the level for normal milk, but the high level for thiamine persisted beyond the tenth day.

**The relationship of sediment to the flavor of milk**, J. C. MARQUARDT (*Jour. Milk Technol.*, 9 (1946), No. 1, pp. 5-11).—The percentage of clean milk produced in three plants increased through a well-organized clean-up program. Dirty-flavored products resulted when a high percentage of dirt was found in the milk. Properly filtered milk will hold the score of 21.5 for 1 week in the average refrigerator, but milk with excess sediment cannot be processed into a fluid milk that will hold a satisfactory flavor for more than 2 or 3 days. Bad mastitis conditions and high counts frequently decrease as more attention is given to keeping the milk physically clean.

**Mastitis and the plate count of milk**.—VI, **The contribution of staphylococcal mastitis to the standard plate count of milk, and some cultural characteristics of the organisms isolated**, H. W. SEELEY, JR., E. O. ANDERSON, and W. N. PLASTRIDGE. ([Conn.] Storrs Expt. Sta.). (*Jour. Milk Technol.*, 8 (1945), No. 5, pp. 259-263).—In continuation of these studies (E. S. R., 93, p. 188), samples of milk from cows with chronic mastitis ranged from 200 to 42,000 staphylococcus colonies per cubic centimeter, with an arithmetic mean of 6,800. Of 289 isolations, 72 percent were coagulase-positive, 36 percent were hemolytic, and 44 percent produced some pigment. The plate count was not correlated with the leucocyte count,

Producers of low-count milk may have difficulties in meeting bacterial standards because of the presence of staphylococcal-infected animals in the herd.

**Sterilization of microorganisms, with special reference to new methods applicable to the dairy industry,** O. RAHN. (Cornell Univ.). (*Milk Plant Mo.*, 34 (1945), No. 12, pp. 24-26, 46, 52, illus. 2).—Present knowledge of physical methods of sterilization makes it improbable that they will play a major role in the dairy industry. Chemical sterilization looks most promising. More data on the use of weak acids and synthetic detergents seem needed.

**High-temperature short-time pasteurization,** compiled by G. M. TROUT and A. W. FARRALL (*Michigan Sta. Spec. Bul.* 335 (1946), pp. 95, illus. 20).—The following papers were presented before the Special High-Temperature, Short-Time Pasteurization Conference held at Michigan State College, May 22-23, 1945: Some Advantages and Disadvantages of High-Temperature Short-Time Pasteurization (pp. 5-9), and How Does the Quality of the Milk Supply Affect Its Pasteurizability by the Short-Time Method (pp. 10-13), both by L. H. Burgwald (Ohio State Univ.); Problems in the Operation of High-Temperature Short-Time Pasteurization—Cleaning, Sterilizing, Maintenance, and Timing of Operations, by W. W. Cavanaugh (pp. 14-19); Experience in Checking High-Temperature Short-Time Pasteurization to Meet the Public Health Requirements, by H. Cohen (pp. 20-27); Lessons to be Learned From the History of High-Temperature Short-Time Pasteurization (pp. 28-33), and The Effect of the Time and Temperature of Pasteurization Upon Some of the Properties and Constituents of Milk (pp. 34-40), both by A. C. Dahlberg (Cornell Univ.); Principles Involved in Various Types of High-Temperature Short-Time Pasteurization, by A. W. Farrall (pp. 41-54); Thermal Death Points of Various Microorganisms and Their Relation to Pasteurization Time, by W. L. Mallmann (pp. 55-62) (Mich. State Col.); Routine Maintenance of High-Temperature Short-Time Pasteurization Control Systems, by R. E. Olson (pp. 63-73); Highlights of Research on High-Temperature Short-Time Pasteurization, by G. M. Trout (pp. 74-82) (Mich. State Col.); Factors to Consider Before Adopting High-Temperature Short-Time Pasteurization, by C. F. Weinreich (pp. 83-91); and Michigan's New Short-Time Pasteurization Law, by F. M. Skiver (pp. 92-95).

**The control of slowness in making Cheddar cheese,** A. T. R. MATTICK, A. A. NICHOLS, and J. Z. WOLF (*Canad. Dairy and Ice Cream Jour.*, 24 (1945), No. 10, pp. 23-24, 50, 52).—Slowness in making cheese, usually due to the action of phages on specific organisms which are air-borne, may be best controlled in a simple isolated laboratory where starters are produced under regulated conditions.

**Sugar conservation practices,** W. J. CAULFIELD. (Iowa State Col.). (*Ice Cream Rev.*, 29 (1946), No. 7, pp. 42-43, 68-74, illus. 1).—The current sugar shortage in the ice cream industry may be met by reducing the gallonage of ices and sherbets, moderate reduction in the sugar content of the mix with an increase in the serum solids and stabilizer content of the mix, and replacement of sucrose with alternative sweetening agents.

## VETERINARY MEDICINE

[Research in animal diseases]. (Partly coop. Ga. Coastal Plain Expt. Sta. et al.). (*U. S. Dept. Agr., Bur. Anim. Indus. Rpt.*, 1945, pp. 2, 22-49; also in *U. S. Dept. Agr., Agr. Res. Admin. Rpt.*, 1945, pp. 50, 70-97).—Progress reports are made on disease-control measures to reduce livestock losses, studies of vesicular diseases, infectious equine encephalomyelitis, equine infectious anemia, hog cholera, bovine and swine brucellosis, hormones for treatment of sterility in cows, limitations of

penicillin for mastitis of cattle, control of fowl typhoid, persistence of anthrax organisms, swine erysipelas, infection in chickens and control by vaccination, serological diagnosis of dourine and glanders, tests for pullorum disease in turkeys, tuberculin and related allergens, John's disease in cattle, control of strongyles in horses and cattle parasites by phenothiazine, cattle-grub control, DDT for hog lice and sheep ticks, hexachlorethane-bentonite suspension for liver fluke in sheep, relation of diet to hookworms in lambs, antimony compounds for filariasis in sheep, phenothiazine for goat parasites, swine sarcocysts found to be fungi, control of swine parasites, sulfa drugs for cecal coccidiosis in poultry, eradicating scabies, dourine, ticks, tuberculosis, hog cholera, John's disease, and brucellosis, and virus-serum control.

[Miscellaneous papers] (*Cornell Vet.*, 35 (1945), No. 4, pp. 333-335, 365-373, 375-381, illus. 3).—These papers include A Simple Instrument for the Relief of Dystocia in the Bovine Due to Uterine Torsion, by A. R. Demott and S. J. Roberts (pp. 333-335) (Cornell Univ.); Ketonemia in Fetuses of a Heifer and a Ewe Affected With Severe Ketosis, by J. Sampson, C. C. Morrill, and J. O. Alberts (pp. 365-369) (Univ. Ill.); *Corynebacterium equi* Infection in a California Foal (pp. 370-373), and *Shigella equirulis* Infection in California (pp. 375-377), both by J. W. Britton (Univ. Calif.); and Treatment of Strangles in a Horse With Penicillin and Sulfamerazine, by S. J. Roberts (pp. 378-381) (Cornell Univ.).

Quantitative aspects of antigen-antibody reactions.—I, A theory and its corollaries. II, Some comparisons between the theory and the experimental results, T. TEORELL (*Jour. Hyg. [London]*, 44 (1946), No. 4, pp. 227-242, illus. 16).—In part 1 (pp. 227-236), a quantitative theory has been developed for the reactions between antigens and antibodies, applicable in particular to the precipitin reaction. The theory is equally applicable to unspecific precipitations, for instance the reaction between proteins and protein precipitating agents such as nucleic acids, etc.

In part 2 (pp. 237-242), the quantitative theory for the interaction between antigen and antibody presented in part 1 has been compared with some experimental precipitin reactions published in the literature. These reactions include Type VIII pneumococcus polysaccharide-homologous (horse) antibody, egg albumin-(rabbit) anti-egg albumin, and diphtheria toxin-(horse) antitoxin. The general course of the experimental precipitation curves (total amount of precipitate, amounts of precipitated antigen and antibody) corresponded well to the theoretical type curves. With regard to the location of the "equivalence zones," experiment and theory also showed a satisfactory agreement.

A hypothesis on the velocity of flocculation in the precipitin reaction is presented and compared with some recent results. The relation between the immunological concepts "equivalence (neutral) point," "optimum point," and "maximum precipitation point" is also discussed.

Blood groups and blood transfusion in veterinary practice, A. E. LAGER (*Middlesex Vet.*, 4 (1945), No. 3, pp. 103-108, 123).—A review of blood groups in cattle, sheep, swine, and dogs is briefly presented, and mention is made of their significance in blood transfusion therapy. Indications and contraindications for blood transfusion, as well as transfusion reactions, are discussed. The technic of cross-matching, collecting, and administering blood is outlined.

The nature and action of the antibiotics, E. H. FRIEDEN (*Tex. Rpts. Biol. and Med.*, 3 (1945), No. 4, pp. 569-646, illus. 2).—A comprehensive review, the term "antibiotic" being defined as "a chemical substance, produced by one or more living organisms, which possesses more or less selective antimicrobial properties at relatively low concentrations." There are over 200 literature citations.

Influence of pH and temperature on the survival of coliforms and enteric pathogens when exposed to chloramine, C. T. BUTTERFIELD and E. WATTIE (*Pub.*

*Health Rpts.* [U. S.], 61 (1946), No. 6, pp. 157-192, illus. 5).—Results from 193 series of experiments conducted at pH 6.5, 7.0, 7.8, 8.5, 9.5, and 10.5 and at two temperature ranges (2°-6° and 20°-25° C.), with species of *Escherichia*, *Aerobacter*, *Pseudomonas*, *Eberthella*, and *Shigella*, indicated that chloramines are much less efficient as bactericidal agents than free chlorine.

Studies in the dynamics of disinfection.—V, The temperature coefficient of the reaction between phenol and Bact[erium] coli, derived from data obtained by an improved technique. VI, Calculation of a new and constant temperature coefficient for the reaction between phenol and Bact. coli, R. C. JORDAN and S. E. JACOBS (*Jour. Hyg. [London]*, 44 (1946), No. 4, pp. 243-248, illus. 3; pp. 249-255, illus. 4).—The virtual sterilization time has been used as a measure of the rate of disinfection of *B. coli* cultures under carefully standardized conditions. The relationship of this time to temperature at each of five phenol concentrations has been reexamined. This relationship is such that a minimum or threshold temperature exists for each concentration.

Research on phenothiazine as an anthelmintic, P. D. HARWOOD (*Sci. Mo.*, 62 (1946), No. 1, pp. 32-42, illus. 5).—This popular account deals especially with the work of the U. S. Department of Agriculture in combating nodular-worm disease of sheep and other parasitic diseases of domestic animals.

The relationship of vitamin C to wound healing, C. L. DAVIDSON (*Vet. Med.*, 41 (1946), No. 4, pp. 140-141, illus. 1).—The importance of an adequate supply of vitamin C in wound healing is pointed out, and its administration to small animals following surgery is suggested under certain conditions.

Occurrence of *Brucella melitensis* in Iowa, C. F. JORDAN and I. H. BORTS (*Jour. Amer. Med. Assoc.*, 130 (1946), No. 2, pp. 72-75).—*B. melitensis* was isolated from the blood of 20 men, 10 of whom were farm residents and 10 packinghouse employees. The disease is now considered to be endemic in Iowa. It is thought that hogs were the probable and major source of infection.

Further isolation of St. Louis encephalitis virus; congenital transfer of virus in chicken mites (*Dermanyssus gallinae*), M. G. SMITH, R. J. BLATTNER, and F. M. HEYS (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 2, pp. 136-138, illus. 1).—Three further isolations from mites collected at the original site (E. S. R., 92, p. 420), and one isolation from each of two other chicken houses in St. Louis County, Mo., are reported.

Un piroplasma del tipo "Nuttallia equi," parasito de "Didelphis paraguayensis" en Colombia [A piroplasm of the *N. equi* type, a parasite of *D. paraguayensis* in Colombia], M. R. GARCIA (*Rev. Med. Vet. [Bogotá]*, 14 (1945), No. 89, pp. 70-79, illus. 5; *Eng. abs.*, p. 73).—This piroplasm was found in opossums and is thought to be the first record of a piroplasm from a marsupial host.

Warm-stage observations on the development of pseudo-mycelia in cultures of avian tubercle bacilli grown in dilute embryo extract, E. M. BRIEGER and H. B. FELL (*Jour. Hyg. [London]*, 44 (1946), No. 4, pp. 256-263, illus. 3).—"The results of this investigation shed light on the controversial question of whether the 'mycelial' form of the tubercle bacillus is a single individual formed by 'true' lateral budding or a composite structure produced by the terminal angular growth of coherent but independent bacilli. Our observations on the living organisms have shown that under appropriate experimental conditions both these forms may develop."

The toxicity of a spurge (*Phyllanthus abnormis*) for cattle, sheep, and goats, F. P. MATHEWS. (Tex. Expt. Sta. coop. U. S. D. A.). (*Cornell Vet.*, 35 (1945), No. 4, pp. 336-346, illus. 4).—Serious cattle losses in Culberson County, Tex., were found to be characterized by hepatic cirrhosis but not associated with the grazing

of Senecio. The presence of a toxic principle in another common plant, *P. abnormis*, was demonstrated by feeding it to 12 cattle, 5 goats, and 4 sheep. A destructive action on the liver and kidneys was noted, but the experimental feeding did not produce an extensive cirrhosis of the liver. A variation in toxicity in the plants from different areas was observed. Drying the plant appeared to have a destructive effect on the toxic principle. Goats and sheep appeared to be more resistant than cattle.

**Effect of infused penicillin in the bovine mammary gland**, F. J. WEIRETHER, D. E. JASPER, and W. E. PETERSEN. (Minn. Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 2, pp. 282-286, illus. 2).—This report deals primarily with studies on the rate of decline and irritating effects of infused penicillin immediately after milking. In the experiments where the cows were milked at regular intervals after infusions, no demonstrable decrease in the quantity of milk was observed. In cases where the intervals between milkings were lengthened, there were decreases in the amounts of milk that could be accounted for by the intraglandular pressure resulting from the delay in withdrawing the milk. In all cases, there were observed changes in the character of the milk which varied in general with the quantity of penicillin infused. A few small flakes, with increases in chloride, and leucocytes were noted, as well as a slightly yellow color. The milk returned to normal in 3 to 4 days.

The following conclusions were drawn: "Aqueous solutions of penicillin (sodium salt) containing 5,000 Oxford units per milliliter had slight irritating effects on the normal bovine mammary gland as measured by physical examination of the gland, body temperature, and changes in the character and quantity of milk. The largest dose infused was 40 ml. (200,000 O. U.). Increase in body temperature, tremors, and greater changes in the character of the milk were observed after penicillin was introduced in large volumes of water. Largest volume infused was 950 ml. (190,000 O. U.). These effects may have been due to the pyrogenic properties in the water used. In glands infused with small volumes of water containing 5,000 O. U. per milliliter, the rate of decline of penicillin per milliliter of milk is greatest during the first 10 hr., after which the decline is at a slower rate. The milk contained 0.5 or more units of penicillin per milliliter 24 hr. after the infusion of 30,000 or more units. The disappearance rate from pathologic glands was of the same order as for the normal gland except in coliform infections. When penicillin was introduced in large volumes of water the infused water was rapidly absorbed, leaving most of the penicillin in the gland."

**The opsonocytaphagic test in bovine brucellosis**, C. G. RICKARD. (Cornell Univ.). (*Cornell Vet.*, 35 (1945), No. 4, pp. 347-364, illus. 1).—In tests on cows of proved immune status, opsonocytaphagic activity did not appear to be a measure of immunity but rather to indicate the presence of antibody in any amount above a certain low level. Cows known to be immune showed wide variation in opsonocytaphagic activity, depending on the amount of circulating antibody present in their blood plasmas.

Tests on three vaccinated calves are also reported. In these, the rise in circulating antibody which occurs in calves after vaccination with the live Strain 19 vaccine was observed as simultaneous increases in opsonocytaphagic and agglutinative activities. "These observations favor the belief that opsonin and agglutinin in brucellosis are the same antibody, demonstrated in different ways. If this is true, there is little use for the opsonocytaphagic test, since the agglutination test is much simpler and easier to conduct."

**Contagious abortion vaccine prepared from strain 45(20): Field vaccination trials**, A. D. McEWEN (*Vet. Rec.*, 58 (1946), No. 6, pp. 57-64).—Field trials of the protection conferred against *Brucella abortus* infection by the inoculation of

heifers and cows of breeding age with a vaccine consisting of live culture of *B. abortus* strain 45(20) are described. Virgin heifers received two inoculations of vaccine and nonpregnant cows one inoculation of vaccine before service. As the vaccinated animals calved, those that were negative reactors to the agglutination test were revaccinated after every pregnancy. Vaccination of animals whose sera do not react positively to the agglutination test has been shown to confer protection against abortions caused by *B. abortus* infection. Moreover, vaccination which does not stimulate the production of serum agglutinins for *B. abortus* prevents all but a low percentage of animals exposed to infection from becoming positive reactors to the agglutination test for smooth strains of *B. abortus*.

The beneficial results derived from vaccination of nonreacting cattle in an infected environment were most clearly demonstrated in the second and later pregnancies following vaccination. Although the incidence of infection reaches its peak after the second pregnancy and a higher incidence of abortion occurs at the second pregnancy than at any other pregnancy, vaccination has been found to confer as satisfactory a protection against abortion and infection at this critical stage as at any other period. It is concluded that "vaccination, by limiting the spread of infection, should prove a valuable adjunct to a scheme for the eradication of contagious abortion when this is practicable, and . . . may be used to prepare the way for the introduction of a scheme of eradication."

**Vaccination against Johne's disease**, T. M. DOYLE (*Agriculture Jour. Min. Agr. [Gt. Brit.]*, 52 (1946), No. 10, pp. 442-444).—Tests on a small scale with cattle and goats are cited from which it is concluded that "in view of the now ascertained safety of the vaccine, an extensive trial in this country with heavily infected herds in which the usual measures of control have failed would seem to be justified. It is at present being used on a few selected herds, and the results to date are encouraging."

**Mastitis control**, E. F. WALLER. (Univ. Vt.). (*Vt. Dairy Plant Oper. and Milk Distrib., Ed. Conf.*, 24 (1945), pp. 9-12).—A practical discussion of the control of this disease, which is stated to be second in importance in Vermont only to brucellosis.

**A study of the diphtheroids found in infectious bovine pyelonephritis**, E. S. FEENSTRA, F. THORP, JR., and C. F. CLARK. (Mich. Expt. Sta.). (*Jour. Bact.*, 50 (1945), No. 5, pp. 497-504).—Some of the morphological, staining, cultural, biological, fermentative, and agglutinative properties of 19 diphtheroids from cases of pyelonephritis have been determined, and an attempt has been made to classify them, especially according to their relationship to *Corynebacterium renale*. From the data presented it is thought likely that there are two distinct species of corynebacteria involved as etiological agents, although heretofore only one has been described.

**Measures used in the control of an infectious type of calf scours**, G. H. WISE and R. W. COARSEY. (S. C. Expt. Sta.). (*Cornell Vet.*, 35 (1945), No. 4, pp. 320-328).—Supplementing a previous investigation (E. S. R., 92, p. 565), a survey was made of a diarrhea prevalent among calves in a large purebred dairy herd. Health records of 185 calves were obtained. The most characteristic symptoms of the disease was acute diarrhea, with pneumonia often either an accompaniment or a sequel. The highest incidence was during the second week following birth. Although the syndrome resembled "white scours" in many respects, the later age incidence and the prolonged course were the primary atypical characteristics that led to the conclusion that etiologically the maladies are different.

Meticulous sanitation and attempted isolation in the immediate herd environs were ineffective in reducing the incidence, but segregation of a small group of calves with nurse cows in a remote area lowered the occurrence significantly.

Prepartum immunization of the dam with autogenous bacterin and subsequent immunization of the new-born calf with antibacterial serum lowered the incidence

but not below the critical level. Symptomatic treatment of the diarrhetic calves by means of sulfaguanidine reduced the mortality rate to almost negligible losses.

**The administration of phenothiazine and hydrocarbons to sheep.** J. H. WHITLOCK. (Cornell Univ.). (*Cornell Vet.*, 35 (1945), No. 4, pp. 328-332, illus. 3).—In an effort to find effective equipment for the administration of drugs to sheep, 868 adult sheep and 506 lambs were treated with phenothiazine and 110 adult sheep and 42 lambs with a Monnig-Ortlepp (E. S. R., 84, p. 523) suspension of tetrachloroethylene, using a metal esophageal tube described by J. H. Whitlock<sup>4</sup> with various syringes and attachments. Some of the sheep given phenothiazine and all given tetrachloroethylene also received from 2.5 to 5 cc. of 10 percent copper sulfate to stimulate closing of the esophageal groove, and no sheep given tetrachloroethylene showed any signs of dizziness or coma.

The apparatus found most efficient consisted of a tightly covered 4-gal. cream can drained by a short piece of pipe. A length of heavy rubber tubing connects the can with a two-way T valve, which in turn is connected with a glass-barreled syringe and the metal esophageal tube. A Shikles valve may be substituted for the T valve in administering tetrachloroethylene, but was found to jam repeatedly with commercial suspensions of phenothiazine. A 40- or 60-cc. glass-barreled syringe was found superior to either a steel or leather plunger 2-oz. dose syringe. The method of administration is described and is said to make possible the handling of 200 sheep per hour.

**Enterotoxemias infecciosas de los ovinos juvenes en Colombia [Infectious enterotoxemias in lambs in Colombia]**, E. S. SCHULTZE F. and R. CAICEDO A. (*Rev. Med. Vet. [Bogotá]*, 14 (1945), No. 89, pp. 65-69).—*Clostridium septicum*, *C. perfringens* (probably *D. ovitoxicus*), *C. oedematiens*, and *C. gigas* are reported as having been encountered in Colombia for the first time as causative agents of anaerobic enterotoxemias in lambs. They resembled the enterotoxemias known in other countries as bradshot, braxy, and pulpy kidney.

**On the etiology of abscesses in goats.** H. J. STAFSETH, C. S. BRYAN, and L. NEU. (Mich. Expt. Sta.). (*North Amer. Vet.*, 27 (1946), No. 1, pp. 22-25).—An organism tentatively identified as *Corynebacterium ovis* is described as causing abscesses in goats, but with no indication of severe systemic reactions during their formation. Experimental infection of two cows with rather large doses produced abscesses of the same nature and a severe systemic reaction.

**A clinical and laboratory study of spontaneous listerellosis in a goat.** M. M. KAPLAN and A. E. LAGER (*Middlesex Vet.*, 5 (1945), No. 1, pp. 8-11, 35-36, illus. 2).—A case of spontaneous listerellosis in a goat is described as the first case of animal listerellosis from Massachusetts. The history, clinical observations and laboratory findings, post-mortem examination, histopathological examination, and bacteriological studies are presented and discussed. *Listerella monocytogenes* was isolated from the medulla when examined post mortem, but was not isolated from cerebrospinal fluid taken while the animal was alive.

**Virus encephalomyelitis in buffaloes.** T. S. SHENG (*Science*, 103 (1946), No. 2672, pp. 344, 346).—A disease among water buffaloes in Szechwan Province, China, locally known as "sze-giao-han" is described which is thought to be distinct from all other known forms of encephalomyelitis. It was found to be transmissible to goats, guinea pigs, and rabbits.

**A comparison of the effects of pyridoxine and pantothenic acid deficiencies on the nervous tissues of swine.** R. H. FOLLIS, JR., and M. M. WINTROBE. (U. S. D. A. et al.). (*Jour. Expt. Med.*, 81 (1945), No. 6, pp. 539-552, illus. 14).—When pigs were fed diets deficient in pyridoxine or pantothenic acid, ataxia developed and lesions were found in the sensory neuron. In pyridoxine deficiency, degeneration of

<sup>4</sup>Jen-Sal Jour., 25 (1942), No. 4, pp. 10-11, 30, illus. 2.

the peripheral process of the sensory neuron was the initial and most prominent feature, while chromatolysis was the first evidence of damage to the afferent neuron in pantothenic acid-deficient animals.

**A importância do lixo e resíduos alimentares na disseminação da peste suína em São Paulo** [The importance of street sweeping and garbage in the spread of swine plague in São Paulo], J. MOREIRA (*Biológico*, 11 (1945), No. 10, pp. 259-265, illus. 6).—Existing practices are described and improvements suggested for diminishing the danger of spreading infection through these materials.

**Xenodiagnóstico na habronemose dos equídeos: Estudo das larvas do helminto** [Xenodiagnosis of habronemosis in horses], J. F. DE SALES and J. JANSEN (*Mem. Inst. Oswaldo Cruz*, 42 (1945), No. 1, pp. 207-215, illus. 6; Eng. abs., p. 215).—In 87 horses examined from July to November 1944, xenodiagnosis for habronemosis was 96.6 percent positive. Measurements and drawings of the larvae are presented, but identification could not be made.

**Neoplastic lymphadenopathies in dogs**, E. BOND (*Middlesex Vet.*, 4 (1945), No. 3, pp. 91-94, illus. 7).—Leukemias and tumors of the lymphoid tissue as they occur in dogs have been differentiated by histologic studies and examinations of the peripheral blood. The tumors of the lymphoid tissue are classified into those resulting from leukemias and those resulting from neoplasia of the organs themselves.

**The relation of immunity in rabies to the antibody content of the serum**, F. B. SCHWEINBURG (*Middlesex Vet.*, 5 (1945), No. 1, pp. 3-5, 34-35).—It is concluded that the immunity resulting from antirabic treatment is not due to antibodies in the blood or tissues, but that substances responsible for the state of immunity are different from rabicidal antibodies.

**Deformity of the tongue associated with amino acid deficiencies in the chick**, C. R. GRAU, (Univ. Calif.). (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 2, pp. 177-178, illus. 1).—"A condition characterized by the folding-back of the tip of the tongue of chicks is described. A deficiency of isoleucine, leucine, or phenylalanine causes this syndrome, whereas deficiencies of protein or of several other amino acids have no effect. Gradual healing occurs about a week after chicks are placed on an adequate diet."

**Effect of excessive ingestion of sodium chloride on the chick, with particular reference to renal changes**, C. A. KRAKOWER and M. GOETTSCH (*Arch. Pathol.*, 40 (1945), No. 4, pp. 209-219, illus. 8).—Following reports of heavy losses of 10- to 20-day-old chicks, from many parts of Puerto Rico but all receiving a new lot of mixed feed of high salt content, experiments were undertaken to ascertain the effects on chicks of excessive salt intake. It is concluded that "the toxicity of sodium chloride for young chicks under the field and experimental conditions detailed here is to be ascribed to (1) the indiscriminate feeding habits of the fowl, (2) the morphologically different type of renal glomerulus in the fowl as compared with the mammal, which limits the effective area of filtration, and (3) the normally low total plasma proteins and the blood status represented in low hematocrit readings. The basis for the pathologic changes associated with the ingestion of excessive salt is the accompanying huge consumption of water. In view of the fact that birds are limited in their capacity to deal with these large quantities of water in part at least by the aforementioned factors, the early appearance, the persistence, and the progression of the edema are readily understandable. The earliest morphologic compensatory mechanism that is brought into play in order to aid in the elimination of the excess fluid is glomerular hypertrophy with associated new formation of loops and lobules. An extension of this process and cardiac hypertrophy are in the main the two anatomic factors concerned in determining the survival of the bird and its complete freedom from edema despite the increased consumption of water."

**An evaluation of the toxicity of certain sulfonamides for young chickens,** P. A. MATTIS, S. E. MCKINNEY, E. A. PATCH, and E. L. WILLIAMS (*Poultry Sci.*, 25 (1946), No. 1, pp. 59-64).—Data are presented from which it is concluded that "the administration, for therapeutic purposes, of sulfamerazine or SS2 in a dosage of 1 percent or less of the diet should not give rise to serious toxic manifestations in chickens."

**Chick rearing, V-VIII,** T. BARTON MANN (*Jour. Agr., Sci. [England]*, 35 (1945), No. 4, pp. 207-235, illus. 8).—These parts continue the series (E. S. R., 93, p. 773).

V. *The influence of diet on epidemic bacillary white diarrhoea (pullorum disease)* (pp. 207-213).—Control of bacillary white diarrhea could not be obtained by blood testing when foods of about 20 percent protein content were the sole diet of the chicks. The disease was found in brother chicks fed 20 percent of protein, but not in sister chicks fed crushed oats for the first 72 hr. and a diet of 14 percent protein intake thereafter. The disease also "not only did not occur in sister chicks in which *B[acillus] pullorum* had been demonstrated to be present in one of their number, but also epidemic bacillary white diarrhea failed to develop despite the lack of hygienic precautions when these chicks had been placed in an uncleaned brooder from which the survivors of a severe epidemic of this disease had just been removed, and when they were brooded adjacent to chicks which suffered severe mortality from the disease, thereby undergoing all the chances of infection by wide dissemination of *B. pullorum* within a small area."

VI. *The bacterial syndrome encountered in epidemic bacillary white diarrhoea of chicks (pullorum disease)* (pp. 214-224).—It is concluded that the bacterial syndrome encountered in epidemic bacillary white diarrhea of chicks is initially one of invasion by fecal type organisms, followed by invasion by anaerogenic *B. pullorum*.

"Evidence is presented to show that ostensibly pure cultures of anaerogenic *B. pullorum* consist of two organisms, a true aerogenic *B. pullorum* in symbiosis with an anaerobe, morphologically of the *welchii* type. Evidence is presented to show that variation in fermentation reactions of ostensibly pure cultures of anaerogenic *B. pullorum* depend upon the degree of symbiosis exerted between the anaerobe and the aerobe, and this degree of symbiosis is greatly affected by methods of cultivation on solid media. It is proposed that the ovarian blight peculiar to adult hens which are carriers of bacillary white diarrhea infection is caused by putrefaction of ovarian material in vivo by the activities of a morphologically *welchii* type organism. It is proposed that *B. pullorum* exists in one form only, namely, the aerogenic form, and that this organism is a potential pathogen only."

VII. *The control of epidemic bacillary white diarrhoea* (pp. 225-231).—A feeding test is reported which indicated that a diet conducive to intestinal putrefaction fed to chicks after 14 days from birth initiates an epidemic of bacillary white diarrhea. Measures for its control, which consist of the detection and removal of reacting hens from a flock by means of a diagnostic and sensitive antigen, are deemed ineffective unless accompanied by an alteration in nutrition for the purpose of reducing intestinal putrefaction. Experiments are cited to show that the agglutination test cannot differentiate between fowls which produce diseased chicks and fowls which produce chicks resistant to disease. Other experiments designed to show that the disease does not arise from infection from a contaminated brooder indicated that "*B. pullorum* as a potential pathogen does not remain viable to an extent that it is able to produce bacillary white diarrhea in chicks from an incubator or brooder which has held diseased hatchlings or broods, respectively."

VIII. *The preparation of a sensitive and diagnostic stained antigen for the rapid whole-blood test for bacillary white diarrhoea of chicks* (pp. 232-235).—A method is presented for the preparation of a sensitive and diagnostic stained antigen for the detection of fowls suspected of infection by the organisms found in epidemic bacillary

white diarrhea, together with evidence that an antigen prepared from organisms grown in a medium which provides for the peculiar growth requirements of the anaerobic organism associated with anaerogenic pullorum, is more sensitive than antigens prepared from organisms grown on media which lack these peculiar growth factors. A stained antigen has been prepared which is agglutinated by pullorum antisera in 15 sec. at 4° C. and in 6 sec. at 15°, and which is not agglutinated by normal sera in 5 min.

**Effect of streptomycin on avian malaria,** A. O. SEELER, C. MALANGA, and J. PIERSON (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 2, pp. 291-292).—Trophozoite-induced *Plasmodium gallinaceum* infections were established in 50-gm. Single-Comb White Leghorn chicks by an intravenous inoculum of 200,000,000 parasitized erythrocytes per kilogram. The tests for suppressive activity against both trophozoite-induced *P. cathemerium* and *P. lophurae* malaria were performed on 50-gm. Pekin ducklings inoculated intravenously with 500,000,000 parasitized erythrocytes per kilogram. The sporozoite-induced *P. gallinaceum* infections used for the prophylactic tests were established in 50-gm. Single-Comb White Leghorn chicks by the intravenous inoculation of 0.2 cc. per bird of a suspension of sporozoites prepared by grinding 100 infected mosquitoes in 20 cc. of chicken plasma. In all cases the streptomycin was administered as an aqueous solution intramuscularly every 3 hr.

"The effect of streptomycin therapy was judged by parasite counts made on the fifth day in the *P. cathemerium* experiment and on the eighth day *P. lophurae* experiment. Parasite counts on the trophozoite-induced *P. gallinaceum* infection were made on the fifth day, while the counts on the sporozoite-induced infection were made on the ninth day. The parasite counts were made by determining the number of parasitized erythrocytes among 10,000 erythrocytes on Giemsa stained thin blood smears. Streptomycin at a dose as high as 400,000 units per kilogram per day showed no suppressive activity against *P. cathemerium*, *P. gallinaceum*, or *P. lophurae* infections. The partially purified streptomycin used in these experiments did, however, have a slight effect on the sporozoite-induced *P. gallinaceum* infection. While the group of birds on each dose level was so small that the differences among the average parasite counts are not in themselves significant, the linear relationship between the dose of the drug and the parasite count is noteworthy."

**Poultry disease diagnosis chart, with suggestions for prevention and treatment,** S. ERIKSEN (*Poultry Tribune*, 51 (1945), No. 11, pp. 18-19).—This chart deals with the diagnosis in 49 cases, arranged by age groups.

## AGRICULTURAL ENGINEERING

**A new portable field water meter and new furrow water meter,** C. N. JOHNSTON. (Calif. Expt. Sta.). (*Agr. Engin.*, 27 (1946), No. 1, pp. 29-31, illus. 6).—An easily constructed, accurate instrument for practical and research application is described. Detailed sketches for construction and calibration procedures are given. A recorder unit or head with a case for a standard domestic water meter selling for about \$3.50 is the only item that need be purchased if a small amount of wood or sheet metal is on hand.

**A new priming valve for portable siphons,** C. N. JOHNSTON. (Calif. Expt. Sta.). (*Agr. Engin.*, 27 (1946), No. 1, pp. 31-32, illus. 1).—A useful easily constructed starting device for siphon sizes from 2 in. through 4 in. is described. A special adaptation of the valve, constructed of suitable size, could replace the multiple canvas sleeves now being used to seal larger diameter siphons. Stationary siphons having no water seal at the discharge end can also be started by preseating

the valve seat disk prior to priming operations. A detailed construction sketch with materials list is given.

**Operation efficiency and factors affecting operations at the Elizabeth Joint Meeting plant,** W. RUDOLFS and E. P. DECHER. (N. J. Expt. Stas.). (*Sewage Works Jour.*, 18 (1946), No. 1, pp. 66-81, illus. 2).—Studies made of the operation records for the past 7½ yr. maintained for the Joint Meeting trunk sewer and treatment plant serving 11 municipalities with an aggregate population of 360,000 show that though sewage flow and sludge production has increased about 30 percent, with an average volume around 37 million gal. per day, the percentage purification has remained fairly constant. There was no direct relation between total annual rainfall and sewage flow or purification. Sewage strength remained fairly constant, varying only during prolonged wet or dry periods. Amounts of pollutional matter increased with sewage flow producing greater volumes of settled sludge. Average annual degree of purification by settling varied from 65.8 to 69.7 percent removal of suspended solids and from 36.6 to 42.1 percent in bacteriological oxygen demand reduction. Sewage strength was stronger and degree of purification higher during the summer months, together with approximately one-third more sludge collected and stored as compared with the colder months. Concentration of stored sludge by decantation effected a decrease of over 36,000 tons of sludge barged during the past 3 yr. even though increased amounts of sludge were collected. Under present operation sewage flow can increase to 45 m.g.d. before revised procedures will be required. Total cost of operation and maintenance of trunk sewers and the treatment plant and of disposal of sludge varied from 37.2 to 40.1 ct. per capita during the past 4 yr., and sludge disposal cost varied from \$4.55 to \$4.73 per ton of dry solids barged.

**Design of sewers to facilitate flow,** T. R. CAMP (*Sewage Works Jour.*, 18 (1946), No. 1, pp. 3-16, illus. 7).—A brief review of some of the important considerations in the hydraulic design of sewers. Discussion is given of the functions of sanitary sewers, a determination of their size, self-cleansing velocities, sewer transitions, and sewer junctions.

**Installations for noting the water and thermal relationships in soils,** R. G. WHITE. (U. S. D. A.). (*Agr. Engin.*, 27 (1946), No. 1, pp. 21-25, 32, illus. 6).—The author gives a detailed description of the apparatus and the time synchronizing circuits which have been installed at the Michigan Hydrologic Research Project to study the effect of land use on the hydrology of farmland under varying types of snow cover and frozen soil. It is reported that with this installation it has been possible for one man with an average time requirement of 2 to 2½ hr. each day to collect data on the amounts of precipitation, water and erosion losses, soil moisture, air temperature and humidity, soil temperatures at predetermined levels, solar and sky radiation, and wind movement. This record does not, however, include time to clean or adjust equipment, clean silt boxes, or to process or analyze data.

**The home mechanic's handbook: An encyclopedia of tools, materials, methods, and directions** (New York: D. Van Nostrand Co., 1945, pp. 804+, illus. 790).—Information is assembled for a variety of practical work about the home and in the home workshop. Detailed operations for the following are given: Painting and decorating, by D. J. Di Bernardo (pp. 1-100); woodworking (pp. 101-251), and metal working (pp. 253-404), both sections by R. E. Haines, J. V. Adams, R. Van Tassel, and R. L. Thompson; plumbing, by J. G. Miller (pp. 405-509); masonry, by K. H. Bailey (pp. 511-648); and electricity, by J. F. Nowak (pp. 649-790).

**Utilization of nonpetroleum fuels in automotive engines,** J. T. DUCK and C. S. BRUCE (*Jour. Res. Natl. Bur. Standards [U. S.]*, 35 (1945), No. 6, pp. 439-465, illus. 20).—Substitute fuels and blends were tested to determine their relative efficiency in the operation of common types of engines. The fuels used were (1)

190-proof alcohol; (2) 200-proof alcohol; (3) acetone; (4) n-butanol (normal butyl alcohol); (5) Blend No. 1 (50 percent acetone and 50 percent butanol); (6) Blend No. 2 (67 percent butanol, 27 percent acetone, and 6 percent ethanol); (7) Blend No. 3 (71.5 percent butanol, 28.5 percent acetone); (8) Blend No. 4 (20 percent diethyl ether and 80 percent of 190-proof alcohol); (9) various low-proof alcohol blends varying from 70 to 180 percent; and (10) gasoline. The tests showed that the maximum power developed with alcohol and with some of the other fuels was slightly greater than with gasoline. The specific fuel consumption with the various fuels was approximately in inverse proportion to the heat of combustion of the fuel used. Analysis showed that the mixture distribution was less uniform with the substitute fuels than with gasoline. Tests made with low-proof alcohols showed that an engine can be operated on blends as low as 70 proof, but it is ordinarily impractical to use a blend much below 190 proof because of the excessive volume required.

**Digester gas for automobiles**, K. IMHOFF (*Sewage Works Jour.*, 18 (1946), No. 1, pp. 17-25, illus. 5).—Sanitary engineers have had broad experience in digesting and gasifying organic matter in municipal sewage treatment plants. In Germany, methane produced by such digestion has been proved to be a good substitute for gasoline as an automobile fuel. The gas is ordinarily carried in steel cylinders at 200 atmospheres pressure, but it may be stored in bags which are not under pressure.

The quantity of digester gas produced at municipal sewage treatment plants is small in comparison with the demand for gasoline, but can be increased enormously if solid organic wastes such as stable manure are digested. The quantity of gas available from the stable manure of one cow is more than 100 times the per capita gas production of typical municipal sewage treatment plants. The author illustrates the design of a rural gas works which is to operate on a farm having 50 cows, 10 calves, 8 horses, and 15 pigs. He estimates that the daily quantity of fresh wet stable manure, including straw, produced by these animals would be 2,500 kg. (650 kg. dry) and would give a daily gas production of 162 m.<sup>3</sup> (5,720 cu. ft.) of gas containing 60 percent methane, which is equivalent in heat value to 107 l. (28 gal.) of gasoline. The residues from the stable manure digestion may be used as fertilizer. There is no appreciable loss of fertilizer constituents over those associated with present methods of application of fresh fertilizer to land, as the methane is produced only from that part of the manure that would otherwise decompose in the manure pile or on the fields.

It is thought that rural digester gasworks may become important sources of automobile fuel for Germany and some other countries.

**Michigan State College reforestator**, T. D. STEVENS and L. E. BELL (*Michigan Sta. Quart. Bul.*, 28 (1945), No. 2, pp. 107-110, illus. 2).—A tree-planting machine which enables two men to field plant 10,000 trees in 8 hr. has been developed. The "Reforestator" is built on a standard farm implement uni-carrier, with power lifts and consists essentially of a rolling coultter, a right and left 12-in. moldboard plow, a specially designed easily demountable trencher, two packing wheels carrying an operator's seat, and two galvanized planting boxes each of a size which will hold 1,000 3-year-old coniferous transplants. The reforestator has been used successfully on a number of soil types, but is most effective on sands and loams, or any soil friable enough to flow around the tree roots. Adjustments in the elevations of the two rubber-tired wheels enable planting operations on the contour on slopes up to 30 percent. Rapid mobility is a feature in that it can be trailed behind a tractor or automobile. Power needed to operate is about equivalent to that required for a two bottom plow. Blueprint drawings are being made, to be available for a nominal fee.

**The mechanical features of farm dehydrators**, B. D. MOSES. (Calif. Expt. Sta.). (*Agr. Engin.*, 27 (1946), No. 1, pp. 14-16, 32, illus. 5).—A dehydrator is a mechanical device, and its limits follow definite mechanical laws which if correctly applied produce the proper results. There is a definite correlation between the fruit to be dried and the heat and air to dry it, also a correlation that controls hydrator design and its operation. The author discusses the fundamental laws of evaporation and the laws which hold for centrifugal and radial flow fans and blowers, presents heat and mass balance equations which have been developed, and reviews facts about dehydration which are of material assistance in the design of drying equipment.

**Modernizing a midwestern farmhouse**, C. H. VAN VLACK and R. SIMPSON (*Iowa Sta. Bul.* P78 (1946), pp. 577-596, illus. 18).—A typical example of modernizing, based on the three general points to be kept in mind in modernizing decision, (1) is the house worth modernizing, (2) will the remodeled house be satisfactory, and (3) what will be the cost.

## AGRICULTURAL ECONOMICS

[Investigations in agricultural economics at the Ohio Station] (*Ohio Sta. Bimo. Bul.* 238 (1946), pp. 24-27).—A second article (E. S. R., 93, p. 505) on Recent Trends in the Farm Real Estate Situation, by H. R. Moore (pp. 24-26), appraises "some recent tendencies which may determine whether or not land prices and debt structures will get dangerously out of line with the earning capacity of farm land in the post-World War II period." The table of index numbers of production, prices, and income by J. I. Falconer (p. 27) is brought down through November 1945.

**What peace can mean to American farmers: Agricultural policy**, H. R. TOLLEY ET AL. (*U. S. Dept. Agr., Misc. Pub.* 589 (1945), pp. 41+).—This fourth and last report of the series (E. S. R., 94, p. 386) "deals with problems and possible solutions in the field of agriculture itself." The principal specific objectives assumed to be essential to a farm program in line with national needs and wishes are: Adequate farm and forest production; parity of income for farmers; efficient production and distribution of farm products; parity of services and facilities for rural people; good tenure conditions, with special emphasis on the family farm; and productive farm, range, and forest land. Each of the objectives is discussed. The discussion of the leading problems is treated under the two major headings: If there is full employment, and if there is unemployment. Under a full-employment situation a farm program "will have to include measures for dealing with three types of major problems: (1) Problems of prices, production, and distribution; (2) conservation problems; and (3) problems relating to rural facilities and services. Such measures, moreover, will have different application to different types of farmers and to different regions." Different phases of these three problems are discussed in detail. Under the heading, if there is unemployment, the broadening of the farm program under full employment is discussed, in sections on maintenance of consumer demand, continuing the conversion program, other continuing programs, and supplementary measures.

**Nebraska looks ahead: Postwar agricultural problems and proposed programs**. (*Coop. U. S. D. A. et al.*). (*Nebraska Sta. Bul.* 380 (1945), pp. 115, illus. 14).—"This report on postwar agricultural conditions in Nebraska is the contribution of this State to a cooperative study initiated by a northern Great Plains agricultural committee which addressed itself during the war to the problems likely to arise in the Plains States in the postwar period and to feasible programs looking toward the solution or alleviation of such problems. Committees from the faculties of the Nebraska Agricultural Experiment Station, the Agricultural Extension Serv-

ice, and from the Conservation and Survey Division of the University of Nebraska, with assistance from other interested groups, participated in its preparation." The following committee reports are included: An Analysis and Synopsis of Postwar Agricultural Conditions in Nebraska, by W. W. Burr, F. Miller, and M. S. Peterson (pp. 8-16); Development and Conservation of Physical Resources, by E. H. Doll, F. Miller, J. Thorp, and M. L. Baker (pp. 17-29); Adjustments in Agricultural Production During Demobilization Period, by F. Miller, D. L. Gross, and J. Thorp (pp. 30-46); Marketing Problems in the Demobilization Period, by H. C. Filley, A. W. Epp, and F. J. Chase (pp. 47-52); Opportunities for Settlement on Land After the War Through Water Development, by G. E. Condra, E. C. Reed, H. Waite, and E. E. Brackett (pp. 53-58); Tenure Problems After the War, by W. H. Brokaw, F. D. Keim, H. C. Filley, and E. Frolik (pp. 59-66); Farm Credit in the Postwar Period, by A. W. Epp, H. C. Filley, W. H. Brokaw, F. D. Keim, and E. Frolik (pp. 67-70); Social Security, by H. C. Filley, A. W. Epp, and F. J. Chase (pp. 71-74); Rural Health Services and Facilities in Nebraska, by H. G. Gould, M. Fedde, R. Loper, and R. Gibbons (pp. 75-83); Postwar Housing and Equipment, by R. Loper, M. Fedde, M. Liston, T. A. Filipi, and F. Atwood (pp. 84-94); Postwar Needs in Nutrition, by M. Fedde, H. G. Gould, R. Gibbons, and R. Leverton (pp. 95-96); Industrial Development and Agricultural Relations, by J. F. Lawrence, H. G. Gould, E. C. Reed, and C. W. Smith (pp. 97-100); Rural Electrification in Nebraska, by E. E. Brackett, F. D. Yung, and L. Larsen (pp. 101-102); Rural Education, by H. E. Bradford and C. C. Minter (pp. 103-113); and Research, by E. H. Doll, F. Miller, and F. D. Keim (pp. 114-115).

**Arizona agriculture, 1946: Production, income, and costs,** G. W. BARR (*Arizona Sta. Bul.* 202 (1946), pp. 17+, illus. 6).—The production of and income in 1945 from truck crops; beef cattle, sheep, lambs, and wool; cotton; citrus fruits; dairying; alfalfa hay; seed crops; and feed grains and miscellaneous crops are discussed. Tables show for 1945, 1944, and average 1935-44, the cash income from different farm and ranch commodities, prices of different agricultural products in December, and the acreages of principal crops by counties. A brief description of the irrigation development in the State is included.

**The 1944 farm business report,** B. R. BOOKHOUT and A. H. HAIST (*Michigan Sta. Quart. Bul.*, 28 (1945), No. 2, pp. 131-144, illus. 2).—A financial summary of 1,031 Michigan farm records by type of farm areas (16) is included. Farm earnings in 1944, variations in individual farm incomes, farm investments, size of business, crops, livestock, farm expenses, State and area averages, and the changes on accounting farms, 1935-39 to 1944, are discussed briefly.

Labor incomes averaged \$2,406 in 1944 as compared with \$1,990 in 1943. Michigan prices of farm products declined about 1 percent during 1944. Gross income on the accounting farms increased 14 percent over 1943. Prices paid by Michigan farmers increased nearly 7 percent during 1944. Expenses on the accounting farms averaged 12 percent higher than in 1943. The cooperating farmers farmed 6 percent more land, handled 1 percent more livestock, and accomplished 6 percent more work in 1944 than in 1943. Labor efficiency has increased on these farms 26 percent during the war period.

**Some price factors affecting farm adjustment in cotton counties of Tennessee,** B. H. LUEBKE (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog.* 195 (1946), pp. 44+, illus. 28).—Since 1933, cotton acreage has been generally downward, but yield per acre has increased significantly partly in response to an improvement in prices. For the 63 yr. in which direct comparisons can be made, acreage moved in the same direction as prices of the preceding year 65.1 percent of the time. Inverse relationships between price and acreage occurred most frequently in the 1890's and the 1930's. During the price decline of the early thirties, farmers in-

creased acreage to maintain income; and during the ensuing recovery, yields were increased rather than acreage.

In a 33-yr. comparison of sweetpotato prices with acreage, the relation was positive 18 times. In a 2-yr. price lag comparison, a positive relationship occurred 19 times. Area planted to sweetpotatoes in this period changed an average of 74.2 acres for each 1 ct. change in price per bushel. Erratic acreage-price relationships occurred 4 yr. in a row, 1931-34, and also 1936. There appeared to be a tendency to overplant in all of these years except 1933. Annual fluctuations in acreage of sweetpotatoes are partly influenced by the price of cotton. Sweetpotato acreage moved inversely to that of annual average cotton prices of the preceding year in 15 out of 32 yr. The calculated regression curve shows that sweetpotato acreage decreased an average of 500 acres for each 1 ct. per pound advance in the price of cotton. Graphic multiple correlation analysis indicates that adjustment of sweetpotato acreage to price of sweetpotatoes is closer when the price of cotton is high. Overplanting is more pronounced when cotton is low than is underplanting when cotton is high.

**Cost of production and utilization of crested wheatgrass on eastern Oregon wheat farms.** H. L. THOMAS, G. W. KUHLMAN, and D. C. MUMFORD. (Coop. U. S. D. A.). (*Oregon Sta. Cir. 167 (1945)*, pp. 27, illus. 10).—"This study, started in 1943, included 16,752 acres of crested wheatgrass on 73 wheat farms in Jefferson, Wasco, Sherman, Morrow, and Umatilla Counties. Detailed records of the cost of establishing a stand of grass were completed on 55 farms, and detailed grazing records were completed on 99 fields aggregating 7,994 acres of grass." The area studied, present status of crested wheatgrass in the State, methods and cost of establishing a stand of the grass, and the uses made of it are discussed. The seasonal use of the grass for pasture, the carrying capacity of such pastures as compared with native pastures, and the place of crested wheatgrass on wheat farms are discussed more fully.

The total average cost per acre of establishing crested wheatgrass on summer fallow in 1943 was \$6.94. When planted in stubble without seedbed preparation, the cost per acre was \$3.30. The average rate of grazing for the years 1938, 1943, and 1944 was 0.92 animal unit months per acre. It is estimated that crested wheatgrass yields from two to four times as much grazing as native pasture.

**Costs, materials, and practices in growing Irish potatoes on Cumberland Plateau.** F. N. MASTERS and C. C. MANTLE (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog. 194 (1946)*, pp. 59+, illus. 39).—"The purpose of this study was: "To provide farmers, county agents, and other agencies with information concerning the requirements and cost of the various operations in production of Plateau Irish potatoes; also to acquaint those interested with the practices used in their production, harvesting, and storing." Most of the data were secured by the survey method. A total of 99 production records were taken on the Plateau portion of nine counties. "Information concerning size of farm, acres of potatoes, yield, and returns from potatoes was obtained for both 1943 and 1944 crop years. Detailed information regarding production practices was obtained for the 1944 crop year, including amounts of labor, seed, fertilizer, machinery, and equipment; power and workstock; and other requirements, such as methods of harvesting, storing, and selling potatoes." The physical features of the Cumberland Plateau are described. Analyses are made by items of land and material charges; machinery and equipment charges for seedbed preparation, planting, cultivating, spraying and dusting, harvesting, marketing and grading, and storing operation; and labor and power requirements for different cultural, harvesting, and marketing operations.

**Information basic to adjustments in rice production in Texas.** A. C. MAGEE and C. A. BONNEN (*Texas Sta. Bul. 676 (1945)*, pp. 46, illus. 5).—"This bulletin

"deals with production and production requirements, with the effect of changes in production practices, and in turn with the probable effect of these changes on earnings." Data for 1941 were obtained from 66 representative growers in three counties. "This survey included an inventory of the farm business, land use, crop and livestock organization, production and disposal, amounts and costs of hired labor, details concerning farm power, and input requirements for rice and beef cattle production." Data were obtained in 1943 from 44 rice growers relative to the use of combines. Data were also obtained from 15 operators of rice-drying plants. The area is described. Among the topics discussed are land tenure and lease arrangements; systems of farming associated with rice production; normal production and production requirements of rice, and labor and power requirements; production and production requirements of beef cattle on rice farms; cost of tractor work, power, and combining; overhead farm expense; etc. Analyses are made of the effects on earnings and income of size of farm, prices, type of lease, yields, systems of farming, tenure on rice-cattle farms, and method of harvesting.

The author directs attention to the following conclusions: "An annual rice crop of 400 acres is more profitable than either an average-sized crop of 282 acres or a small 180-acre crop. Larger earnings were obtained by tenant farmers under cash rent than under share-crop rent. A yield of about 10 bbl. per acre pays the expenses of making a rice crop but leaves the operator nothing for his labor and management. Yields must be kept above this level to insure profitable production. The 'rice-cattle' system of farming is more profitable than the 'rice' system but requires considerably more capital. Land values were high relative to cash rental rates, and it was more profitable to lease for cash than to own land used for rice and beef cattle production. Farm earnings are increased by combine harvesting and artificial drying as compared to the old method of binding and threshing. Combining reduces harvesting costs and results in less waste in harvesting."

**An economic study of the sweet potato enterprise in the north Louisiana upland cotton area in 1943, L. J. FENSKE and J. N. EFFERSON. (Coop. U. S. D. A.). (*Louisiana Sta. Bul.* 395 (1945), pp. 24, illus. 2).**—Detailed information on production practices, labor requirements, costs, and returns were obtained in the fall of 1943 from approximately 50 farmers in Bienville and Claiborne Parishes producing sweetpotatoes for the commercial markets. Yield and cost data were also secured for a number of years on sweetpotatoes and other important crops in the area—peanuts, cotton, and corn. The factors affecting sweetpotato yields, storage practices and costs, and marketing are discussed.

Sweetpotatoes produced with horsepower required 122 man and 62 horse hours per acre. With tractor and horsepower, 107 man hours, 25 horse hours, 7 tractor hours, and 5 truck hours were required. With tractor-drawn transplanting machines, 15 hr. of man labor were required per acre as compared with 25 hr. for hand-planting. In 1943, sweetpotatoes returned about 47 ct. per hour for man labor, and the net returns per acre and return for man labor were higher than those for cotton, peanuts, and corn. Under long-time average cost-price relationships, sweetpotatoes are in a strong competitive position compared with cotton, peanuts, and corn. Storage charges in 1942 averaged 8 ct. per crate in farm storage houses.

**Cost of producing apples and pears in the Hood River Valley, Oregon, G. W. KUHLMAN, J. H. BLOSSER, and D. C. MUMFORD (*Oregon Sta. Bul.* 429 (1945), pp. 22, illus. 1).**—This bulletin supplements Bulletin 420 (E. S. R., 92, p. 850), and reports the estimated costs with average yields (1940–42) and 1943 prices of materials and labor. In the present study data were collected for 33 of the orchards included in the previous study. The analyses made for the apple and pear orchards include land use, capital investment, cost of production by items, fixed and variable costs, and the major production operations.

With 1940-42 average yields and 1943 prices of materials and labor, the average cost of producing apples exclusive of packing-house costs was \$438.91 per acre, or \$1.55 per packed box. The cost for pears was \$363.37 per acre, or \$1.31 per box. Of the total cost for apples, labor constituted 61.6 percent, materials 10.3, general expenses 12.4, depreciation 4.0, and interest 11.7. For pears the respective percentages were 46.5, 16.0, 15.5, 5.5, and 16.5. The average labor requirement per acre was 404 hr. for apples and 252 hr. for pears.

**An economic study of peach production in Louisiana,** F. D. BARLOW, JR. (*Louisiana Sta. Bul. 398 (1945), pp. 32, illus. 8*).—The extent of the peach industry in Louisiana, the yields, production, prices, marketing practices, and the place of the enterprise in the farming systems of the State are discussed. Using data for 1944 for 31 farms on which peaches were grown commercially, analyses are made using 1944 and 1935-39 prices, of the labor and power requirements and cost of establishing a peach orchard, and for orchards in production and also of the returns from producing orchards.

The cost of developing an orchard at 1944 prices was \$102.39 per acre on farms using tractors, and \$87.93 on farms using mules as the principal source of power. With 1935-39 prices, the costs were \$75.68 and \$60.19, respectively. Approximately 90 hr. of man labor, 18.6 hr. of tractor work, and 23.8 hr. of mule work were required to develop an acre of peaches on tractor farms, and 104.6 hr. of man labor, 1.0 hr. tractor work, and 69.5 mule hours on farms on which mules were the chief source of power. On producing orchards about 115 hr. of man labor, 7.3 tractor hours, and 33.4 mule hours per acre are required on tractor farms, and about 106 man hours, 1.7 tractor hours, and 45 mule hours on mule-operated farms. Average net returns per acre in 1944 were \$196.56 on tractor farms and \$150.54 on mule-operated farms, or at 1935-39 prices and yields \$58.68 and \$44.08, respectively. The average yield per acre in 1944 was 106 bu. on tractor farms and 84 bu. on mule farms, and the average price per bushel was \$2.62. In 1935-39 the yields were 102 bu. on tractor and 80 bu. on mule farms, and the average price per bushel was \$1.09.

**Progress in development of a land and timber management program in northeastern Minnesota,** A. D. WILSON (*Minnesota Sta., 1944, pp. 46+, illus. 16*).—Part 1, Some History and Problems of Northeastern Minnesota, deals with the development of farming in the area, the discovery of iron ore, the development and decline of the timber industry, the tax situation, tax forfeiture and problems, tax-forfeited land, tax status of land, public indebtedness, problems of education and welfare, etc. The bringing together of facts through land use meetings is discussed. Part 2, Northeastern Minnesota People Study Future Possibilities of Their Land and Timber, shows "what local people think of the outlook and what they propose to do about it." It describes the legislation for land classification, zoning, land exchange, etc., and discusses the need for such laws and the progress being made under them. The further steps needed, how they may be obtained, etc., are also discussed. The timber resources, their future management, public revenue from timberland, sale of stumpage, and other problems are dealt with in a less extensive manner.

**Development of the dairy industry in Mississippi,** D. W. PARVIN (*Mississippi Sta. Bul. 422 (1945), pp. 52+, illus. 12*).—"This is the first of a series of studies designed to provide a general picture of dairying in Mississippi, to point out problems in milk production and processing, and to provide factual information that should aid in the solution of these problems." The chief sources of data for the present study were the annual reports of all dairy plants since 1929 and of manufacturing plants only, since 1919, filed with the Mississippi Department of Agriculture and Commerce. These were supplemented by the annual reports of the dairy specialists of the Mississippi Extension Service and information from the U. S. Census and

the U. S. Department of Agriculture. The data are tabulated by years (with discussions) to show the status of dairy farming in the State, the historical development of dairy manufacturing plants, butterfat purchased from producers, butterfat and solids-not-fat manufactured, volumes of different dairy products manufactured, fluid milk sales and ice cream produced, the relative importance of different products, etc. The development in different areas of the State, the seasonal variation in milk and butterfat purchases, the relation of seasonal production to plant capacity and efficiency of operation of plants and milk transportation, and the prices paid producers for milk and butterfat and the seasonal variation are also discussed. "No attempt was made to derive or work out possible solutions for problems confronting the dairy industry; however, data have been provided that should point the way to the solution of these problems by trained dairy production and marketing men."

**Prospective adjustments in the marketing of dairy products in Michigan,** C. M. HARDIN (*Michigan Sta. Quart. Bul.*, 28 (1945), No. 2, pp. 119-130, illus. 8).—Charts and maps are included and discussed showing the production and disposition of milk by farmers in the United States and Michigan, 1924-45; the increased sales of whole milk from Michigan farms by counties, 1939-44; the sales of whole milk and of farm-separated cream from Michigan farms by counties, 1944; comparison of prices, 1935-45, received by members of the Michigan Milk Producers Association in Zone 1 of the Detroit market and those paid by condenseries in the east North Central States; comparison of prices paid by condenseries and the average price paid to Michigan farmers for farm-separated cream, 1935-45; civilian consumption and military and lend-lease purchases of selected dairy products, United States, 1935-39 and 1942, 1943, and 1944; and the utilization of milk in production of selected dairy products in Michigan, 1935-39 and 1942, 1943, and 1944. The possible future demands for fluid milk, evaporated and condensed milk, new dairy products, powdered whole milk, nonfat dry milk solids, cheese, and butter are discussed.

**The economics of cotton gin operation,** D. G. MILEY and A. L. ROBERTS. (Coop. U. S. D. A.). (*Mississippi Sta. Bul.* 421 (1945), pp. 33+, illus. 2).—This bulletin supplements Bulletin 403 (E. S. R., 92, p. 425) by analyzing the data and presenting the findings for the second year (1944) of the study. The 1944 study included 50 gins in the central part of the State—the area studied in 1943—and 42 additional gins in four counties in northern Mississippi.

The average net profits on ginning operation were approximately \$1,227 for the modern gins, \$399 for average gins, and \$7 for substandard gins. Including the net income from cottonseed, bagging, and ties, the approximate total net profits were \$4,327, \$2,601, and \$1,497 for the respective groups of gins. The average profits per bale on ginning operation for the three groups of gins were 64 ct., 31, and 1 ct. Net income from cottonseed, bagging, and ties increased the total net profits per bale to \$2.25, \$1.99, and \$1.46 for the respective groups. An average of 2.9 hr. of man labor was required to gin a bale of cotton. Size of gin, volume ginned, and efficiency in use of labor, power, and capital were the major factors influencing ginning income.

**Marketing and manufacturing margins for tobacco,** L. D. HOWELL and W. P. YOUNG (*U. S. Dept. Agr., Tech. Bul.* 913 (1946), pp. 56+, illus. 3).—This report is similar to that previously noted on textiles (E. S. R., 94, p. 268), and deals with the break-down of farm-to-retail price spreads for tobacco and tobacco products into their component charges or costs, and with the possibilities of reducing them. Marketing channels and division of the consumer's dollar are discussed. The main sections deal with marketing margins for leaf tobacco, manufacturers' margins, and wholesalers' and retailers' margins, with subsections under each on the usual practices, charges or costs, items included in margins, means of reducing costs, and importance of reductions in costs. A bibliography is included.

"Estimates of the average distribution of the consumers' dollar for all tobacco products combined show that in 1939 about 11.6 percent went to growers for American tobacco, 3.6 percent for tobacco imported, 1.2 percent to wholesalers of leaf tobacco, 25.2 percent to manufacturers, 36 percent for Federal and State excise taxes, 4 percent to wholesalers of tobacco products, and 18.4 percent to retailers." On the basis of cost items, the average distribution was Federal and State excise taxes 36 percent, salaries and wages 17.8, advertising 4.2, operating profits for all agencies except farmers 10.3, and all other expenses of manufacturing and distributing about 16.5, imported tobacco 3.6, and farm production in the United States 11.6. "Data showing distribution of the consumer's dollar paid for tobacco products may serve as a basis for indicating the relative importance of bringing about increased efficiency and reductions in margins or costs for the various agencies and functions involved. According to these data, margins for marketing leaf tobacco in 1939 amounted to less than 1 percent of the consumer's dollar. Manufacturers' margins amounted to about one-fourth; Federal and State excise taxes, 36 percent; and wholesalers' and retailers' margins combined amounted to more than one-fifth of the retail value of the finished products. A reduction of 10 percent in Federal and State excise taxes, for example, would amount to more than one-fourth of the returns to growers for the American tobacco used. A similar reduction in margins for manufacturers, wholesalers, and retailers would amount to more than one-third of the returns to growers and to almost 5 percent of the costs of the finished products to consumers."

**Annual report on tobacco statistics, 1945** (*U. S. Dept. Agr., Prod. and Market Admin., 1945, CS-16, pp. 97+, illus. 1*).—The tenth report of the series (E. S. R., 93, p. 89).

**Tractors on upland farms in north Louisiana**, L. J. FENSKE and F. D. BARLOW, JR. (Coop. U. S. D. A.). (*Louisiana Sta. Bul. 399 (1945), pp. 30, illus. 1*).—Data on 1944 farming operations, with special emphasis on tractor costs and use, were obtained from 62 farmers who had one or more years' experience with tractors. In the analyses, several groupings were used—size of farm, type of equipment (mule or tractor), size of tractor, etc. The analyses cover machinery inventories; cost of operating mule and tractor equipment, combines, and stationary hay balers; cost of operating 1-plow and 2-plow tractors and keeping work stock; rates of performance of different operations on tractor and mule farms; labor and power requirements and production costs, man-labor hours per acre, returns to labor per hour, etc., for cotton, corn, peanuts, sweetpotatoes, watermelons, oats, soybeans, and lespedeza; and materials used in crop production.

The value of machinery inventories averaged \$2,365 per farm, of which 78 percent was in tractors and tractor equipment and 22 percent in mule-drawn equipment. Annual cost of operating tractor equipment averaged \$160 per farm as compared with \$128 for mule equipment. Tractor operating costs for all tractors averaged \$4.22 per 10-hr. day, ranging from \$3.88 for 1-plow tractors to \$4.87 for 2-plow tractors of 17 or more horsepower. Work-stock costs averaged \$161.12 per head in 1944, or 22 ct. per hour of field work. On an average, three mules were replaced by each tractor purchased. Savings in man labor through use of tractors varied from 25 to 60 percent, depending on the crop and extent of mechanization. Returns to labor for the crops studied were greatest when operations were highly mechanized as compared with mule production methods.

**Farm ownership in Louisiana financed under the Bankhead-Jones Farm Tenant Act**, W. M. ALEXANDER (*Louisiana Sta. Bul. 397 (1945), pp. 30, illus. 1*).—All the farmers in the five upland cotton parishes and two rice parishes who had Farm Security Administration land purchase loans and were operating their farms as owners were interviewed. Included were 27 white and 10 Negro farmers in the cotton area and 38 white and 2 Negro farmers in the rice area. Analyses are

made of size of farms purchased, prices paid and cost of improvements, relation of credit used to value of farms, total investment in real estate and operating capital, progress in paying for land, gain in net worth of farms, and characteristics of tenant purchase families.

The tenant purchase borrowers used borrowed funds to pay 98.1 percent of the total cost of the farms in the cotton area and 93.8 percent in the rice area. "When payments made from all sources of income are included, the 1943 operators in the cotton area had paid 168 percent of the amount due according to schedule to December 31, 1943, and in the rice area 152 percent. In the cotton area, 6 farmers were on schedule with their payments, 12 were ahead, and 19 were behind, while in the rice area 14 were on schedule, 22 were ahead, and only 4 were behind. With few exceptions, those who had not paid up to schedule had valid reasons, and were expected to become current within a reasonable period. The borrowers in the upland cotton area who had been operating their tenant purchase farms as owners for 5 yr. had made an average gain in net assets of \$379 per year, those operating for 4 yr. had made an average gain of \$438 per year, those operating for 3 yr., \$514, and those operating for 2 yr., \$733. The 5-yr. owners in the rice area had gained \$1,732 per year, the 4-yr. owners \$1,498, the 3-yr. owners \$2,093, and the 2-yr. owners \$1,781. . . . As a whole, the tenants purchasing farms by means of FSA loans prior to 1943 had progressed on the road to debt-free farm ownership, and most of them should be able to complete the payments on their farms in due time."

**Oklahoma farm real estate activity, 1941-1944, R. T. KLEMM and E. C. FORD.** (Coop. U. S. D. A.). (*Oklahoma Sta. Bul.* 291 (1946), pp. 36, illus. 3).—Data regarding farm real estate sales were gathered quarterly each year in eight sample counties representative of the major types of farming areas in the State, and are summarized and discussed for each of the sample counties and for the State as a whole. The discussion covers the price of farm land, volume sold, types of sellers and buyers, intent of buyers, and method of financing sales, including types of lenders, owner's equity and mortgage debt, and mortgage debt retirement.

**Capital needed to farm in the Midwest.** (Coop. 12 expt. stas., U. S. D. A., et al.). (*Minnesota Sta. Bul.* 389 (1946), pp. 34, illus. 2).—"The purpose of this report is to present information as to the capital needs of various types of farming in the Midwest, methods of using available capital most effectively, and the sources of capital to which farmers have access." It is prepared by a subcommittee of the North Central Regional Land Tenure Committee as North Central Regional Publication No. 5 (E. S. R., 93, p. 361). Tables based on data from records for 1937-40, inclusive, of farm management workers in 11 Midwestern States show by farm types and States the average investment and net cash income; number and size of farms, amount of livestock, and labor used; and the investment, adjusted to 1945 basis. The debt-paying ability of midwestern farmers, how to estimate capital needs and income for a farm, how the way the farm operator gets started in farming influences capital needs, and borrowing to obtain capital are discussed. Suggestions to prospective farmers are included.

**Report of the Manager of the Federal Crop Insurance Corporation, 1945, J. C. WRIGHT** (U. S. Dept. Agr., *Fed. Crop Ins. Corp. Rpt.*, 1945, pp. 25).—This is the report to the Secretary of Agriculture for the fiscal year ended June 30, 1945. "The corporation was in a liquidating status during approximately the first half of the fiscal year. An amendment to the Federal Crop Insurance Act, approved December 23, 1944, placed the corporation in active operation again. In 1945 the corporation insured spring-planted crops of wheat, flax, and cotton on a Nation-wide basis and corn and tobacco on a trial basis in a limited number of counties. This report deals primarily with the revived activities of the corporation rather than with the liquidating activities during the early part of the fiscal year. In

the report, emphasis has been placed on the changes that were made in the crop-insurance program, some as a result of the amendment to the legislation and some as a result of administrative action." Financial reports included consist of a comparative balance sheet and a comparative statement of administrative and operating expenses for the fiscal years ended June 30, 1944, and 1945, and a summary by years of the administrative and operating expenses since the organization of the corporation.

**Organizing a farmers' cooperative**, S. D. SANDERS (*U. S. Dept. Agr., Farm Credit Admin. Cir. C-108, rev. (1945), pp. 44+*, *illus. 1*).—This revision (E. S. R., 81, p. 725) discusses the items that should be considered in a survey to determine the conditions under which the association is to operate and some of the factors that should be reflected in the articles of incorporation and bylaws. Suggested organization forms—organization and marketing agreements, articles of incorporation, bylaws, minutes, revolving-fund certificate, etc.—and the Federal Capper-Volstead Act authorizing associations of producers of agricultural products are included.

**Farmer's stake in price control**, W. W. ARMENTROUT (*West Virginia Sta. Spec. Cir. 1 (1946), pp. 6*).—The author concludes: "During the next year or two the farmer stands to gain much more from price controls than he stands to lose. If price controls are generally removed at an early date, as many interested parties are urging, the farmer stands to lose much of his wartime savings by having to pay inflated prices for the things he will need to buy."

## RURAL SOCIOLOGY

**Farm Security Administration services** (*U. S. Dept. Agr., Sec. Agr. Rpt., 1945, pp. 107-113*).—"The Farm Security Administration's program of services to low-income farmers has operated in a depression period and in a period of high employment with heavy demand for farm products. . . . The FSA started as a subsistence program. Gradually it evolved during the prewar years into a plan for orderly rehabilitation of worthy but impoverished farm families with an ultimate goal of family-farm ownership. When the war suddenly expanded the farmer's markets and drained off much of the surplus manpower among low-income rural families, FSA's program of credit backed by practical on-the-farm planning and guidance provided a basis for increasing food production on the family-type farm. It enabled many small farmers to produce at nearer the full capacity of their available manpower and land resources. . . . Because of the rising real estate market, extreme care is taken in the tenant purchase program to avoid the dangers of inflationary land prices. Loans are made only to applicants who can find good land for sale at prices in line with earning-capacity values as computed on the basis of long-time average prices for farm products. Careful appraisals are emphasized more than ever before, to make sure that only sound buys are approved."

**Finnish farmers in Michigan**, J. F. THADEN (*Michigan Sta. Quart. Bul., 28 (1945), No. 2, pp. 90-96, illus. 1*).—At present, 63,671 of the 284,290 Finns and persons of Finnish parentage (one or both parents born in Finland) in the United States live in Michigan, 42,520 being native-born of foreign or mixed parentage. Four-fifths of them reside in Upper Michigan, where the topography, climate, and woodland are so similar to those of Finland that the transplanted Finn feels quite at home.

Where most of the Finnish farmers live, the major cash crop is generally potatoes. Hay is another important crop, and more than half of the farm is usually in tillable pasture. The major livestock enterprise is dairying, but one-half of the farmers have a small poultry flock.

Farms are small, averaging 78 acres in eight predominantly Finnish counties, or less than the State average of 96.2 acres. In general, the soils are of a relatively low or medium fertility and sandy. The growing season is short—90 to 130 days. Farms classed as "noncommercial" (those on which farm products used by the farm household are the major source of income) make up 53 percent as compared with the State average of 29. Low farm income compels many of the farmers to supplement their income from other sources, 49 percent working off their farms in 1939 as compared with 32 percent for the State.

Cooperative enterprises are important, with nearly half of the business of the supply co-ops made up of groceries and dry goods and the remainder of gasoline, oil, hardware, feed, and dairy products. Those at Pelkie and Hancock each have an annual business of approximately a quarter of a million dollars.

There are 108 Finnish churches in the State. At least six newspapers and church papers are published for those who read Finnish.

In the eight predominantly Finnish counties only 64 percent of the farms have automobiles, compared with 82 percent in the State as a whole; 48 percent have their homes lighted by electricity as compared with 71 percent for the State; and only 7 percent have telephones as compared with 28 percent for the State. In 1938, the Rural Electrification Administration brought light and electric power to 2,066 farm homes in the counties of Alger, Baraga, Houghton, and Ontonagon, and to Delta and Menominee farms.

Back of many a Finnish house is the Sauna or bathhouse where the bather gives himself a steam bath by throwing water on heated stones. One section of this bathhouse, in many instances, serves as a dressing room and on wash days as a laundry room.

The Finns as a group rate high in literacy, and school attendance on the part of farm children tends to be relatively high. Many county and township offices are held by Finns, but, in general, they are underrepresented in proportion to their number in the predominantly Finnish counties. Adaptations to their physical and changing occupational environments are being made gradually and successfully, and the contribution of Finns to the cultural heritage of rural Michigan is deemed considerable.

**Brazil: People and institutions**, T. L. SMITH (*Baton Rouge: La. State Univ. Press, 1946, pp. 843+*, about 100 illus.).—While spending a year attached to the American Embassy in Rio de Janeiro, the author traveled extensively over Brazil, observing life and the levels of human progress and gathering, organizing, and interpreting data on the demography and social institutions of the country. The book is divided into seven parts, including cultural diversity, the people, levels and standards of living, relations of the people to the land, and social institutions. Included also are a glossary, bibliography, and author and subject indexes.

**Population growth and the food demand** (*U. S. Dept. Agr., Sec. Agr. Rpt., 1945, pp. 105-107*).—"Basic in the food demand is the size of our population, which is still increasing rapidly. . . . With export demands unchanged and with per capita domestic consumption likewise static, this 8 percent increase in the population would have required an equal increase in food production. Actually, both exports and per capita consumption at home have increased. . . . In the immediate postwar years the birth rate may continue at the relatively high wartime level. One probable cause will be the return of men from the armed forces; another will be the high proportion in our population of women in the early child-bearing age."

**A study of the values of living and working in the rural environment.**—I, **The construction of rural living opinion scales.** II, **The opinions of young women university students**, W. A. ANDERSON (*[New York] Cornell Sta., Mimeog. Buls. 18 (1946), pp. 44+*; 19 (1946), pp. 23+).—"This is a study of the values of living

and working in the rural environment. It is presented in two parts. Part 1 is a description of the methods used in the construction of scales for measuring opinions toward 10 major aspects of living and working in the rural areas. The scales developed are included, together with instructions as to how they may be used. . . . Part 2 describes the opinions of 260 Cornell University students, chiefly young women, concerning living and working in the rural environment as measured by these scales." As a whole these opinions were slightly more favorable than unfavorable.

**Attitudes of rural people toward radio service: A Nation-wide survey of farm and small-town people** (*U. S. Dept. Agr., Bur. Agr. Econ., 1946, pp. 133+, illus. 11*).—This is the report of a survey undertaken at the request of the Federal Communications Commission, and is based on 4,293 interviews in 2,535 rural households between June 11 and July 28, 1945.

It was found that radio has become a highly valued aspect of everyday living in most rural homes which have radios; a highly desired one in most of those homes that do not. Those listeners, both men and women, who listen to their radios a good deal are more apt to value radio highly than are those who listen only a little. Radio is valued by rural listeners for the two great functions it serves—as a source of news and other information and as a source of entertainment and company. News programs are mentioned by an overwhelming majority of rural people who now have radios; much more often than any other type of program. Farm men and women again exceed rural nonfarm people somewhat in their emphasis on the importance of news programs. In general, farm people select the more "serious" programs. News and market reports, hymns and religious music, sermons and religious programs, and farm talks are given high preference by this group. Old-time music is preferred by approximately 50 percent of the men and women of the farm group. There is a strong tendency for those households which have had no radio for 5 yr. or more also to lack the other means of communication—telephones and daily newspapers.

**Rural health conditions** (*U. S. Dept. Agr., Sec. Agr. Rpt., 1945, pp. 85-87*).—According to this report, "alarming deficiencies in rural health resources are an increasing source of concern to all interested in rural welfare. The number of physicians available to serve the population on farms and in small towns has been steadily decreasing. There are too few dentists, nurses, druggists, health officers, sanitarians, laboratory technicians. Over 1,200 rural counties lack approved hospital facilities. These deficiencies reflect the low medical purchasing power that has existed in the past in rural areas. Associated with them, and with related economic factors, is a heavy burden of preventable illness, unnecessary disability, and premature death among under-served rural people. . . . State Farm Bureaus in some 20 States, mostly midwestern, have enrolled their members in either Blue Cross group hospitalization or hospital and surgical indemnity plans as a benefit of membership. The Grange has followed a similar course in some States. The Farmers Union is exploring prepayment plans for its members, and local units have set up and operate hospitals at Elk City, Okla., and Amherst, Tex."

## AGRICULTURAL AND HOME ECONOMICS EDUCATION

**Developing home economics leaders**, B. M. WATTS. (Wash. Expt. Sta.). (*Jour. Home Econ., 38 (1946), No. 2, pp. 65-68*).—The author divides home economics leaders into "fundamental experts," persons who have obtained doctorates in technical fields, and "rounded home economists," having a bachelor's degree in general home economics and a master's degree in education or home economics, and points out virtues and shortcomings in both groups. The need for the organization

of the resources of college home economics departments for adequate graduate training and possibilities for the unification of research and teaching are emphasized.

**Radio handbook for extension workers**, C. A. BOND and W. H. ZIFF (*U. S. Dept. Agr., Misc. Pub. 592* (1946), pp. 21+, illus. 24).—This handbook includes information, suggestions, etc., in preparing and broadcasting programs. It was prepared in cooperation with the Radio Committee of the American Association of Agricultural College Editors and the National Association of Radio Farm Directors, et al. The appendix, prepared by W. L. Kaddery and M. L. DuMars, includes a sample dialog and sample straight talk.

## FOODS—HUMAN NUTRITION

**Quality in meat and meat products**, O. G. HANKINS. (*U. S. D. A.*). (*Indus. and Engin. Chem.*, 37 (1945), No. 3, pp. 220–223, illus. 1).—The author notes some of the many factors which, taken together, determine the quality of meat, and further points out that the development of adequate methods for measuring characteristics of meat has been and, in certain respects, continues to be a difficult problem. Breeding, age, sex, feeding, rate of growth, and other animal production factors have important effects on quality. Examples, supplemented with a brief discussion of the significance of commercial meat grades, are presented. Of great influence on quality in meat are the following factors: Processing, preservation, and preparation which involve methods of chilling, ripening, curing, smoking, freezing, and freezer storage, dehydration, cooking, and other operations. Significant relations in this respect are discussed in some detail. Emphasis is placed on recent developments, particularly on those involved in the dehydration and freezing of meat.

[**Studies with meat and eggs**] (*U. S. Dept. Agr., Bur. Anim. Indus. Rpt.*, 1945, pp. 3–5, 18, 19; also in *U. S. Dept. Agr., Agr. Res. Admin. Rpt.*, 1945, pp. 51–53, 66, 67).—Progress notes are given on preservation of meat by freezing, storing cured lamb meat, nutritive value of pork protein (*E. S. R.*, 94, p. 686), value of corn, rye, and soybean flours as binders for meat loaf, addition of carbohydrates to improve dehydrated eggs, and retention of vitamins in dried eggs.

**Food quality and flavor** (*Indus. and Engin. Chem.*, 37 (1945), No. 3, pp. 208–223, illus. 9).—The following papers were presented in this symposium: Quality Control in the Dairy Industry, by E. C. Thompson (pp. 208–213); Volatility in Food Flavor, by E. C. Crocker (pp. 214–216); Flavors in Food Fats, by H. E. Robinson and H. C. Black (pp. 217–219); and Quality in Meat and Meat Products, by O. G. Hankins (pp. 220–223) (*U. S. D. A.*) noted above.

**Retaining nutritive value of fresh produce**, W. J. PETERSON. (*N. C. State Col.*). (*Ice and Refrig.*, 110 (1946), No. 1, pp. 33–34).—This gives a general discussion of original findings on the effect of icing on the retention of nutritive value in a number of fruits and vegetables held for a period of days after harvest. The results, favorable to the icing process, showed that the leafy type of vegetable such as kale, collards, and mustard greens lost ascorbic acid very quickly when not iced, and retained it remarkably well when iced. This was also true of lima beans. Some vegetables such as peppers, tomatoes, cabbage, and snap beans did not benefit from the icing from the standpoint of vitamin retention when compared with these vegetables un-iced, but did benefit from the standpoint of maintaining a fresh-looking marketable product. The blueberries and strawberries tested likewise did not lose ascorbic acid when stored without ice, but spoiled very quickly without it.

**The use of discriminant functions in comparing judges' scores concerning potatoes**, W. D. BATEN. (*Mich. Expt. Sta.*). (*Jour. Amer. Statist. Assoc.*, 40 (1945), No. 230, pp. 223–228; *abs. in Michigan Sta. Quart. Bul.*, 28 (1945), No. 2, p. 167).—Tests are described whereby by the use of discriminant functions made up

of scores on four characteristics (desirability of color, texture, flavor, and mealiness) it was found possible to test for significance between boiled potatoes from two States and also to ascertain the ranks of the importance of the characteristics.

**Sweet potato gels—something new**, G. L. BAKER and C. W. WOODMANSEE. (Del. Expt. Sta.). (*Food Indus.*, 18 (1946), No. 2, pp. 106-107, illus. 1).—Gels were made with the following ingredients: 1.67 parts Carrager (Irish moss extractive containing added potassium salt), 8.33 parts dextrose added to a mixture of 100 parts sweetpotato pulp (previously pressure sterilized and adjusted to 12 percent soluble solids), 16.67 parts corn sugar, 75 parts sucrose, and seasoning (as desired). The mixture, boiled to 65 percent soluble solids, made a gel stiff enough to be sliced. Powdered mixtures were made by combining 7.50 parts sweetpotato powder, 20.0 parts dextrose, 15.0 parts sucrose, 0.75 part Carrager, 0.15 part common salt, 0.10 part cinnamon, and 0.05 part nutmeg. These dry ingredients were mixed, 65 parts water were added, and 15 min. were allowed for soaking. After a slow boiling period of 5 min., the mixture was remade using 100 parts of water. Sweetpotato gels or dehydrated sweetpotato gelling mixtures are suggested as food products rich in vitamins A and C, and are adaptable for a byproduct industry.

**Pecans—their nutritive value**, M. C. SMITH, H. FARRANKOP, and H. WISEMAN (*Arizona Sta. Mimeog. Rpt.* 73 (1945), pp. 7).—Lots of 13 varieties of Arizona-grown pecans yielded an average 53 percent of edible meat; refuse (shells) ranged from 42 percent in the San Saba variety to 53 percent in the Success and Philomen varieties. Moisture, determined by drying at 128° C. for 20 min. in a forced-draft Brabender semi-automatic moisture determiner, varied little from lot to lot and averaged 2.0 percent. The protein content ( $N \times 6.25$ ) of the 13 varieties ranged from 9.2 to 13.4 gm./100 gm. of pecan meats, and averaged 10.9 gm. fat ranged from 62.3 percent in one lot of the Halberts to 76.2 percent in the San Saba pecans, averaging 71.5 percent for all the varieties analyzed. Carotene, determined by the method of Peterson (E. S. R., 87, p. 7), averaged 0.078 mg./100 gm. Thiamine and riboflavin, determined simultaneously, following in general the method of Conner and Straub (E. S. R., 87, p. 10) with final florescence measurement in a Pfaltz and Bauer Fluorophotometer, averaged, respectively, 0.889 mg. and 0.135 mg./100 gm. Significant differences were not noted for these vitamins in the varieties analyzed. The place of pecans in the human dietary is discussed. \*

**U. S. Army bread—its composition and vitamin retention** (*Baker's Digest*, 19 (1945), No. 6, pp. 22-23, 34, illus. 2).—Noted elsewhere (E. S. R., 94, p. 694).

**The forty-ninth report on food products and the thirty-seventh report on drug products, 1944**, E. M. BAILEY ET AL. (*Connecticut [New Haven] Sta. Bul.* 489 (1945), pp. 429-450).—This report summarizes examinations of foods and drugs submitted by the Dairy and Food Commissioner during 1944. Contaminated and decomposed foods, deceptive packaging, eggs, fats and oils, flavorings, meat products, milk, sprays, and miscellaneous drugs were among the products examined during the year.

**Varietal suitability in the dehydration of vegetables**, J. S. CALDWELL. (U. S. D. A.). (*Food Packer*, 26 (1945), Nos. 9, pp. 37-38, 54, illus. 2; 10, pp. 55-56, 58, illus. 1; 11, pp. 70-72).—This paper brings together information available on the comparative quality and suitability for dehydration of green or snap beans, lima beans, beets, cabbage, carrots, celery, peas, sweet corn, okra, kale, onions, pumpkin, winter squash, tomatoes, spinach, sweetpotatoes, and potatoes. Many of the studies reviewed were made by the author.

**New peroxidase test procedure for dehydrated potatoes to indicate adequacy of blanching**. (U. S. D. A.). (*Canner*, 100 (1945), No. 18, pp. 20, 22).—A new test adapted to determine the peroxidase activity in potatoes prepared in accordance with the lower blanching requirement is described here. Although the procedure was

developed to be used only on dehydrated potatoes, modification of the peroxidase test for undehydrated potatoes is also noted. It is based on the intensity of color developed in solution in a specified time by the enzymatic oxidation of guaiacol. The estimation is made by visual comparison of a solution with a set of standards containing  $K_2Cr_2O_7$  and  $Co(NO_3)_2 \cdot 6H_2O$  in the ratio of 1 to 65; the standard corresponding to the presently recommended tolerance contains 0.040 and 2.60 gm. of these reagents, respectively, per liter of solution.

**Dehydration of spinach: Variety as a factor in determining quality,** J. S. CALDWELL, B. D. EZELL, C. W. CULPEPPER, M. S. WILCOX, and M. C. HUTCHINS. [U. S. D. A.]. (*Canner*, 101 (1945), Nos. 9, pp. 12-14, 22; 10, pp. 22-24, 26, 32; 11, pp. 20, 22).—Twenty-five varieties of spinach were studied as to their suitability for dehydration. Following a blanching period of 2 to 3 min. at  $210^\circ$  to  $212^\circ$  F., the material was dried to a moisture content of 5 percent in a parallel-current dehydrator at a  $175^\circ$  beginning temperature, reduced to  $150^\circ$  to  $155^\circ$  for finishing. Each variety was then divided for storage in sealed containers containing carbon dioxide and in nonairtight tin cans; both were stored at  $32^\circ$  for an 8-mo. period.

Based on quality factors of the refreshed material, the varieties rated as best were: Harlem Market, Extra Large Leaved Savoy, Gould Round Thick Leaf Savoy, Virginia Savoy, Dreer Reselected Savoy, Long Standing Bloomsdale, Hollandia, Prickly Winter, Flanders Broad Leaf, and Old Dominion. These varieties were poor in quality: Princess Juliana, Improved Long Standing, King of Denmark, Viking, and Northland.

Fresh spinach averaged 6.37 mg. carotene per 100 gm. for 22 varieties; ascorbic acid content for all varieties averaged 82.3 mg./100 gm. The dehydrated materials stored in sealed containers with carbon dioxide showed a carotene content ranging from 1.74 to 4.30 mg./100 gm., while those stored in nonairtight containers contained 1.73 to 4.53 mg./100 gm. Ascorbic acid content of the series of samples stored in carbon dioxide was slightly greater than in the series stored in air, ranging from 0.0 to 18.76 and 0.0 to 12.85 in nonairtight containers. Results showed that blanching periods longer than 2 to 3 min. caused matting on trays, slow drying, and a dark-colored unattractive product; exposure to sulfur dioxide gas was not beneficial.

**Dehydration of Montmorency cherries,** D. C. ALDERMAN and B. NEWCOMBE (*Michigan Sta. Quart. Bul.*, 28 (1945), No. 2, pp. 97-106).—A series of experimental treatments were made on Montmorency cherries to ascertain the effect of enzyme inactivation prior to dehydration on the color retention and storage life of the dried product. Blanching of cherries in an open steam blancher resulted in color changes and a mushy texture. Hot water blanches of 3 and 4 minutes' duration ( $135^\circ$  F.) were the most satisfactory on color and texture retentions; but after a 6 months' storage period, these cherries turned brown. Supplementary treatments, including wetting agents, acids, salts, sugar, and liquid pectin, were used experimentally to determine their effect on the preservation of color. Dehydrated cherries from lots which showed favorable color retention before storage gave a poor dehydrated product after the 6 mo. of storage.

"It is apparent from the results obtained that further investigational work is necessary before dehydrated cherries will be able to compete economically with either canned or frozen cherries in the pie trade."

**Dehydration of small fruits,** E. M. LITWILLER. (Oreg. State Col.). (*Canner*, 100 (1945), No. 17, p. 23).—Essentially noted elsewhere (E. S. R., 94, p. 536).

**Freezing foods for the home,** D. E. BRADY, I. D. JONES, and M. L. McALLISTER (*N. C. Agr. Col. Ext. Cir.*, 280 (1945), pp. 23, illus. 15).—The recommendations given here for preparing and processing meats, fruits, and vegetables are based on 12 literature references.

**Preservation of orchard fruits by freezing**, J. G. WOODROOF. (Ga. Expt. Sta.). (*Va. Fruit*, 34 (1946), No. 1, pp. 105-112).—This is an address presented at the Virginia State Horticultural Society, December 5, 1945.

**Fruit varieties suitable for quick freezing**, J. H. CLARK. (N. J. Expt. Stas.). (*Food Packer*, 26 (1945), No. 10, pp. 66-67).—Tests were made on the freezing quality of varieties of yellow freestone peaches; white freestone peaches; strawberries; red, black, and purple raspberries; blackberries; dewberries; and blueberries. Tentative ratings of very good, good, medium, below medium, and poor were made for varieties of each of these fruits.

**Into the freezer instead of the oven**, G. SUNDERLIN. (Purdue Univ.). (*Quick Frozen Foods*, 7 (1945), No. 8, pp. 88-89, illus. 1).—Rolls, cookie, and biscuit doughs, pastry, pies, and cake batter frozen and held at 0° F. for varying lengths of time before baking compared more favorably with freshly mixed and baked products than those baked before freezing. Recipes and directions for freezing these products are given.

**Problems concerning frozen foods**, J. E. NICHOLAS and N. B. GUERRANT. (Pa. Expt. Sta.). (*Refrig. Engin.*, 50 (1945), No. 5, pp. 417-419, 466, 468).—This review of literature, relating to the stage of maturity, preparation prior to freezing, containers, rate of freezing, storage temperature, and preparation for the table summarizes the fundamental practices of successful food freezing and suggests goals for evaluation of technics in future research efforts.

**Vegetables as a source of spoilage bacteria in home canning**, C. DUBORD and W. B. ESSELEN, JR. (Mass. Expt. Sta.). (*Jour. Home Econ.*, 37 (1945), No. 4, pp. 221-224).—A study was made of the spore-forming anaerobes and thermophiles present on fresh vegetables, and the effects of washing, washing and blanching, blanching, or holding on the initial number of organisms present. Most of the vegetables studied were picked from local gardens or grown in the region. The bacterial counts varied widely—ranging from 10 to 30,000,000 anaerobes per gram of green beans (10 samples) and from 1 to 1,584,000 thermophiles per gram of sweet corn (8 samples). No positive correlation between bacterial findings and weather could be established. Putrefactive anaerobes, a frequent cause of home-canning spoilage, were only found twice (out of 91 vegetable samples tested). Both washing and blanching reduced the bacterial count of the vegetables—with blanching alone more effective than washing alone. Washing followed by blanching proved most effective. Results of holding or storing the vegetables for a few hours or overnight were variable and inconclusive.

**d-Isoascorbic acid as an antioxidant**, W. B. ESSELEN, JR., J. J. POWERS, and R. WOODWARD. (Mass. Expt. Sta.). (*Indus. and Engin. Chem.*, 37 (1945), No. 3, pp. 295-299, illus. 3).—"Under the experimental conditions 20 mg. of d-isoascorbic acid per 100 cc. in grape juice fortified with 50 mg. of l-ascorbic acid per 100 cc. was sufficient to protect the l-ascorbic acid during processing and storage. In the case of the tomato juice 6 mg. of d-isoascorbic acid per 100 cc. was almost adequate to protect the natural l-ascorbic acid in the juice during storage, even under adverse conditions." The ascorbic acid additions to the tomato juice were also effective in preventing changes in color and flavor which occurred during a 5-mo. storage period at 49° C. It appeared to have little effect on the flavor of the grape juice and produced some color change not noticeable to the eye. The addition of 95 mg. of d-isoascorbic acid to a pint of tomato juice resulted in a flavor more characteristic of uncooked tomato juice than of the processed product.

**Preventing surface darkening in certain home-canned foods**, J. J. POWERS and C. R. FELLERS. (Mass. Expt. Sta.). (*Jour. Home Econ.*, 37 (1945), No. 5, pp. 294-296).—Surface darkening antioxidants, l-ascorbic acid, d-isoascorbic acid, and d-

gluco ascorbic acid were used experimentally to ascertain the minimum amount which would remove all oxygen from trial packs of peaches and pears. The packs of the first series showed that 135 mg. of any one of the ascorbic acids was sufficient to prevent surface darkenings for a 2-yr. storage period. Tablets (containing 64.8 mg. of ascorbic acid) were added to packs of pears, apple sauce, plums, peas, raspberries, beets, and snap beans. At the rate of 129 mg. per pint jar, they were found to eliminate oxidative off-flavors.

**Why canned citrus juices deteriorate in storage**, D. W. RIESTER, O. G. BRAUN, and W. E. PEARCE (*Food Indus.*, 17 (1945), No. 7, pp. 76-78, 184-192, illus. 6).—Research on canned orange and grapefruit juices was directed toward studying the effects of storage temperatures upon the retention of flavor, color, and ascorbic acid. At a sustained temperature in excess of 70° F., deterioration in these factors was rapid; at 40° storage, the retention increased. In determining quantities of peel oil affecting the quality of canned orange juice, the results of periodic examinations during a storage period of 13 mo. at room temperature indicated the optimum content to be between 0.030 and 0.040 percent. Juice which contained more than 0.050 percent peel oil developed an objectionable terpene flavor within 1 mo. after canning. Dextrose, sucrose, and levulose in ratios of equivalent sweetnesses were added to canned orange juice to determine the effect of the added sugar upon flavor during storage. The sweetened juices appeared to maintain a more desirable flavor after extended storage than did the unsweetened. In studying the effect of deaeration on the flavor of grapefruit juice, it was found that after 14 mo. of storage that there was appreciably little difference between the deaerated and the control samples; however, physical advantages gained in the production, such as increased pasteurizer efficiency and reduced foaming in the filler bowl, appeared practical for commercial use. Evidence indicated that the gradual development of off-flavors over an extended storage period was due to some extent to free oxygen enclosed in the can. Anti-oxidants (tyrosine, butyl ester of tyrosine, du Pont's L-11-A, *p*-methylanilphenol sulfate, and *l*-ascorbic acid) were added to canned orange juice to ascertain these oxidative changes. In concentrations as low as 500 p. p. m., the butyl ester of tyrosine caused a pronounced off-flavor after 26 days' storage. Flavor changes in juice packed in enameled-lined cans v. plain tins were also considered.

**The home pickling of olives**, W. V. CRUESS and R. H. VAUGHN (*California Sta.*, 1945, pp. 7).—Working directions are given for processing ripe olives by: (1) Pickling by a one-lye process which will produce olives yellow or brown in color; (2) pickling by a three-lye process which will produce olives brown or black in color; (3) home canning with and without acid; (4) drying; (5) freezing; and (6) salt-curing Greek style. Directions are also given for preparing Spanish-style and Sicilian-style green olives. Precautions to prevent botulism after home canning are listed.

**Pressure cooker gauges and food spoilage**, E. J. THIESSEN. (Wyo. Expt. Sta.). (*Jour. Home Econ.*, 38 (1946), No. 2, pp. 85-87).—Data obtained from homemakers' records showed that 17 percent of 718 gages were between 0.5 and 1 lb. in error; 24 percent between 1 and 2 lb. More than 35 percent of the cookers tested inadequate pressure and equal percentages reported canned food spoilage of low acid vegetables and fruits. Findings of the survey indicated that gages should be checked once a year—preferably before the canning season starts.

**The electronic blanching of vegetables**, J. C. MOYER and E. STOTZ. (N. Y. State Expt. Sta.). (*Science*, 102 (1945), No. 2638, pp. 68-69).—Essentially noted elsewhere (E. S. R., 94, p. 533).

**The application of electronics to blanching**, J. C. MOYER and E. STOTZ. (N. Y. State Expt. Sta.). (*Canner*, 102 (1946), No. 5, pp. 63, 148, illus. 2).—This is a report on the study noted above.

**Electronic mold destruction** (*Baker's Digest*, 19 (1945), No. 6, p. 35, illus. 1).—The process described here involves the use of an electronic oven which sends a high frequency current of 5-sec. duration through a loaf of wrapped bread. After 3 weeks of ordinary kitchen storage, mold did not appear on the bread so treated.

**Sulphur vs steam blanching of fruits**, L. A. HOHL. (Univ. Calif.). (*Quick Frozen Foods*, 7 (1945), No. 6, pp. 38-39, illus. 1).—The author describes two treatments, pointing out their respective advantages and disadvantages, and submits a review of methods of prevention of oxidative changes during processing, freezing, storage, and thawing of fruits.

**Sulphur dioxide solution: Preservation for fruits and vegetables**, J. G. WOODROOF and S. R. CECIL. (Ga. Expt. Sta. et al.). (*Food Packer*, 26 (1945), No. 10, pp. 48-54, illus. 4).—Essentially noted elsewhere (E. S. R., 93, p. 681).

**Control of microbiological food spoilage by fumigation with epoxides**, R. WHELTON, H. J. PHAFF, E. M. MRAK, and C. D. FISHER. (Univ. Calif. et al.). (*Food Indus.*, 18 (1946), Nos. 1, pp. 91-93, illus. 2; 2, pp. 84-86, 228, 230, illus. 3).—Experiments were made on the germicidal effects of ethylene oxide, propylene oxide, isopropyl formate, ethyl formate, and "Oxyfume" (20 percent ethylene oxide in ethylene dichloride) on yeasts, molds, and bacteria that attack unsulphured fruits with high moisture contents. It was found that the ethylene oxide-ethylene dichloride mixture at a concentration of 1 cc. per liter completely killed all organisms tested after a 3-hr. exposure at 86° F. Experiments made in large scale runs in commercial plants showed that a mixture of isopropyl formate-ethylene oxide prevented molding and fermentation of figs with a 30 percent moisture for an indefinite time. The nature of the residues left by such fumigants and their possible toxicities is discussed. Possible applications of the fumigation technic as a method of food preservation are evident.

**Postwar packages and containers for marketing foods**, D. R. FRENCH (*U. S. Dept. Agr., Bur. Agr. Econ.*, 1945, pp. 64+).—New types of containers and packages and materials for their construction as affected by the war and postwar uses are discussed here. It is pointed out that although some standardization has been accomplished by State and Federal laws, wartime conservation regulations brought further temporary standardization which, from the standpoint of economy in marketing, it may be desirable to continue and enlarge.

**Apparatus for measuring rate of gas penetration through food-packaging materials**, F. R. SMITH and M. KLEIBER. (Univ. Calif.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 9, pp. 586-587, illus. 1).—"An apparatus is described for measuring the rate of gas penetration through flexible materials. The apparatus is particularly suitable for determining the rate of oxygen penetration into pouches used for food packaging. The absolute accuracy of the measurements is determined mainly by the accuracy of gas analysis."

**Sanitization of institution equipment**, W. L. MALLMANN. (Mich. State Col.). (*Jour. Amer. Dietet. Assoc.*, 21 (1945), No. 3, pp. 142-144).—In this address it is pointed out that even if disease-producing organisms were absent, sanitation would still be necessary to reduce contamination hazards in the preparation and serving of food. "Heat is by far the best means of sanitation from the standpoint of convenience, economy, and efficiency. Heat, unlike chemical sanitation, has the property of penetration." Previously unpublished data here presented show that vegetative bacteria are easily destroyed by hot water, and that exposures of 15 to 60 sec. at 150° F. destroy any disease-producing organisms present. The principal compounds for chemical food sanitation are sodium and calcium hypochlorites (chlorinated lime, HTH, Perchloron, B-K powder, and Diversol). Chloramine compounds, more stable than the hypochlorites, may be used in hot water rinses. Principles observed in the application of chemical sterilizers are that (1) 30 sec. be allowed to effect the kill,

(2) a dose of 100 to 200 p. p. m. available chlorine be applied, (3) the warmer the solution, the more rapid the action. Testing cooking utensils for bacteria indicates whether proper results have been obtained.

**Sanitation in frozen food locker plants, W. L. MALLMANN.** (Mich. State Col.). (*Quick Frozen Foods*, 7 (1945), No. 6, pp. 80-81, 88, illus. 1).—Although sanitation is a necessary part of any food processing plant, it becomes more necessary in frozen food locker plants because fresh food holds microbe populations intact. Food poisoning and spoilage bacteria should be eliminated during the handling subsequent to processing. Plant cleanliness, using heat and the proper cleaning agent, is discussed from the standpoint of methods noted above.

**Symposium on nutrition surveys (Fed. Proc. [Fed. Amer. Soc. Expt. Biol.], 4 (1945), No. 3, pp. 252-281, illus. 14).**—The papers presented in this symposium deal with technics and findings that characterize outstanding recent nutrition surveys in the United States, and include the following: Introduction, by C. G. King (p. 252); Techniques of Finding Out What People Eat, by H. K. Stiebeling (pp. 253-258) (U. S. D. A.); Developments in Public Health Nutrition Appraisal, by W. Wilkins and W. H. Sebrell (pp. 258-263); Nutrition Studies in the New Orleans Area, by G. A. Goldsmith (pp. 263-268); Microchemical Methods for Nutritional Studies, by O. H. Lowry and O. A. Bessey (pp. 268-271); and Findings on Examinations of Newborn Infants and Infants During the Neo-Natal Period Which Appear to Have a Relationship to the Diets of Their Mothers During Pregnancy, by H. C. Stuart (pp. 271-281).

**New developments in nutrition, J. O. HOLMES.** (Mass. State Col.). (*Vt. Dairy Plant Oper. and Milk Distrib., Ed. Conf.*, 24 (1945), pp. 99-105).—An address.

**Composition of typical Mexican foods, R. CRAVIOTO B., E. E. LOCKHART, R. K. ANDERSON, F. DE P. MIRANDA, and R. S. HARRIS** (*Jour. Nutr.*, 29 (1945), No. 5, pp. 317-329).—Assays for carotene, thiamine, riboflavin, niacin, ascorbic acid, calcium, phosphorus, iron, nitrogen, ash, and total solids were made on 112 samples of food from Mexico. The samples, bought in public markets, were packed in wax cartons, shipped frozen in dry ice, and held thus until analyzed. The foods are listed under their Spanish and botanical names, with English names included when known. Data are presented in terms of the food as received or "wet basis." Many of the foods are little known or have not been previously assayed.

Several of these foods, commonly eaten in Mexico, have been found to be exceptionally good sources of minerals and vitamins. Malva, an uncultivated plant tasting like spinach, is rich in calcium, iron, carotene, and ascorbic acid. Charal, an air-dried fresh water fish usually eaten whole, is high in protein and calcium. Quesa de tuna, a cheese-like preparation from the fruit of the prickly pear cactus, is rich in iron and ascorbic acid. Pulque, a fermented drink prepared from maguey cactus juice, provides significant quantities of minerals and vitamins, especially ascorbic acid, when consumed in amounts of 1 pt. or more. Dried chili or chili seeds are rich sources of ascorbic acid. Extensive use of beans as well as sesame seed, guaje seed, peanuts, and piñón nuts can furnish liberal amounts of iron, calcium, protein, and niacin.

The authors emphasize the fact that Mexican food patterns differ widely from those in the United States, and that an adequate diet may be possible without much use of dairy or meat products.

**Effect of the war on food habits in Hawaii, K. B. GRUELLE.** (Univ. Hawaii). (*Jour. Home Econ.*, 38 (1946), No. 2, pp. 91-94).—Prior to 1941, Hawaii depended upon imports for 70 percent of her food supply. Adult education classes were taught through the work of the territorial nutrition committee, and residents were urged to produce and can more fruits and vegetables, experiment with substitutes, and choose food wisely. Tastes have become more cosmopolitan as a result of the war.

**The amino acid composition of proteins,** H. B. VICKERY and H. T. CLARKE (Conn. [New Haven] Expt. Sta. et al.). (*Science*, 102 (1945), No. 2653, pp. 454-456).—This discussion presents the plea that data on the amino acid content of proteins be calculated upon the basis of the actual nitrogen content of the protein rather than upon the basis of a hypothetical nitrogen content of 16 percent, as has been the practice of Block and Bolling (E. S. R., 92, p. 753).

**The utilization of d-amino acids by man.—II, Cystine,** A. A. ALBANESE (*Jour. Biol. Chem.*, 158 (1945), No. 1, pp. 101-105, illus. 1).—This second study of the series, carried on with the assistance of V. Irby, D. L. Wagner, and J. E. Frankston, follows the pattern outlined previously (E. S. R., 92, p. 738).

Urinary output of total N, total S, inorganic S, cystine, methionine, and indican was measured over a 6- to 8-hr. period following ingestion of 2.4 gm. of *l*(—)-cystine or *dl*-cystine. When *l*(—)-cystine was fed, no apparent increase over normal fasting values was observed. The feeding of racemic cystine markedly increased the cystine output (196.8 mg. v. 41.8 mg. over a 6-hr. period). An increase in total S also occurred, but the chemical identity of the substance responsible for this increase was not established. From these results, the authors conclude that from 15 to 25 percent of the *dl*-cystine fed is not utilized by man. The availability of the *d*-amino acids is considered to be a function of two competing processes, "(1) the rate at which the organism can convert the unnatural into the natural variety and (2) the speed with which the respective *d*-amino acids are excreted by the kidney."

**Relative effects of casein and tryptophane on the health and xanthurenic acid excretion of pyridoxine-deficient mice,** E. C. MILLER and C. A. BAUMANN. (Wis. Expt. Sta.). (*Jour. Biol. Chem.*, 157 (1945), No. 2, pp. 551-562).—A procedure is outlined for the quantitative determination of xanthurenic acid in urine. It involves acidification to pH 2.5, followed by extraction of the chromogen-producing substance in ether-alcohol.

Mice were fed diets containing variable amounts of casein and pyridoxine with or without added tryptophan. The experiments showed that "pyridoxine-deficient mice fed diets containing 60 percent of casein lived only one-third as long as those fed 10 percent of casein. Although pyridoxine restored growth and minimized the excretion of chromogen on both diets, about 3 times as much pyridoxine was required on 60 percent of casein as when 20 percent was fed. Increases in the excretion of chromogen were quantitatively similar whether *l*-tryptophan was fed as the amino acid or as a component of casein. . . . *l*-Tryptophan decreased the survival time of mice deficient in pyridoxine, but not so much as casein of equivalent tryptophan content. . . . Tyrosine or histidine did not affect either the health or the chromogen excretion of deficient mice."

Administration of phenylalanine apparently had no effect on the growth or survival time of the deficient mice but gave rise to a different chromogen, considered to be probably *p*-hydroxyphenylpyruvic or phenylpyruvic acid. Rats fed a series of pyridoxine-deficient diets containing 60 and 20 percent casein exhibited reactions similar to, but less pronounced than, those observed in the mice.

**Effect of the ingestion of excessive quantities of choline on the amount in tissues and urine,** R. W. LUECKE and P. B. PEARSON. (Tex. Expt. Sta.). (*Jour. Biol. Chem.*, 158 (1945), No. 3, pp. 561-566).—Sheep and dogs were used in these experiments as large amounts of blood were needed for the determination of free choline. Both total and free choline in plasma, liver, kidney as well as choline in urine were determined by the method previously outlined (E. S. R., 93, pp. 249, 531).

In preliminary experiments, sheep fed 10 and 20 gm. of choline chloride excreted about 1 percent of the amount ingested during the following 48 hr. No effect on the free or total choline values in the tissues could be found. Larger doses (40 gm.) fed daily for 6 days produced similar results, with approximately 2.5 percent of the amount ingested being excreted in any 24-hr. period. Similar experiments on dogs

in which 5 gm. of choline were fed daily for a 5-day period gave comparable results, only 0.5 percent of the amount fed being recovered in the urine and no change in tissue values. Urinary nitrogen increased during choline supplementation—the increment being virtually equivalent to the choline ingested.

Betaine hydrochloride given per os was not excreted in urine as choline or betaine.

**The effect of chain length of the dietary fatty acid upon the fatty liver of choline deficiency.** D. STETTEN, JR. and J. SALCEDO, JR. (*Jour. Nutr.*, 29 (1945), No. 3, pp. 167-170).—Young male rats, on a choline-free diet, were fed each member of the homologous series of even-numbered fatty acids, from butyric to stearic. The fatty acids, in the form of ethyl ester, were fed at a 35 percent level for a 14-day period.

The results obtained indicated that the degree of fatty liver produced increased markedly as the chain length of the dietary fatty acid decreased from 18- to 16- to 14-carbon atoms. Severe fatty livers were not found when the esters of fatty acids of less than 12-carbon atoms were fed.

A fatal myocarditis occurred when ethyl laurate was used, while renal hemorrhage and necrosis was observed in several of the animals fed ethyl caprylate.

**Studies on the comparative nutritive value of fats.—VI, Growth and reproduction over ten generations on Sherman diet B where butterfat was replaced by a margarine fat.** H. J. DEUEL, JR., L. F. HALLMAN, and E. MOVITT (*Jour. Nutr.*, 29 (1945), No. 5, pp. 309-316, illus. 2).—Previous studies of Deuel et al. (*E. S. R.*, 92, p. 857; 94, p. 686) on the influence of fat on growth and lactation in the rat have been continued. A modified Sherman B diet composed of skimmed milk powder, ground whole wheat, NaCl, and margarine fat in place of butterfat was used. Supplements of lean meat and lettuce were given weekly. The margarine provided adequate quantities of vitamins D and E as well as 12,000 to 15,000 International Units of vitamin A per pound.

The effect of this modified diet upon the reproduction and growth rate in rats is presented. Ten generations in which the lineage was through the first litter and eight generations in which the lineage was through the second litter were studied. The growth rate of the margarine-fed rats exceeded that obtained with animals fed a stock diet. Improvement in growth rate increased with later generations. The authors conclude that "a vegetable fat such as that contained in a margarine can serve adequately in place of butterfat for growth and reproduction on a diet otherwise nutritionally satisfactory."

**Citrate metabolism of preschool children.** E. R. METCALF and M. L. HATHAWAY. (Cornell Univ.). (*Jour. Nutr.*, 29 (1945), No. 3, pp. 211-218).—Four of the preschool children participating in the ascorbic acid metabolism studies of Meyer and Hathaway (*E. S. R.*, 85, p. 861; 93, p. 231) served concurrently as subjects for citric acid metabolism experiments. Over a 16-week period, the children were fed a controlled diet or the same diet supplemented with either 100 mg. of ascorbic acid, 3.38 gm. potassium citrate, or equivalent amounts of orange juice.

The results showed that on the basal diet, urinary citric acid excretion ranged from 55 to 247 mg. daily or 3 to 13 mg./kg. of body weight. No consistent change in citric acid excretion occurred on the addition of 100 mg. of ascorbic acid daily. Addition of potassium citrate, with or without added ascorbic acid, caused a pronounced increase in citrate excretion (153 to 167 mg. or 7.1 to 8.1 of the added citrate intake). Addition of orange juice corresponding to approximate equal amounts of the potassium citrate supplement produced similar results averaging somewhat lower (63 to 126 mg. excreted or 2.8 to 7.0 percent of the added citrate intake).

The authors conclude that "the increase in citrate excretion on the addition of potassium citrate or orange juice to the diet appears to be related to the rise in alkalinity of the urine rather than to the citrate content of the diet."

**The relative absorption and utilization of ferrous and ferric iron in anemia as determined with the radioactive isotope.** P. F. HAHN, E. JONES, R. C. LOWE, G. R. MENEELY, and W. PEACOCK (*Amer. Jour. Physiol.*, 143 (1945), No. 2, pp. 191-197, illus. 2).—Employing the experimental technics previously outlined by Hahn et al. (*E. S. R.*, 82, p. 703; 91, p. 363), the authors have studied the relative uptake of iron by the use of radioactive isotopes. Results showed that in nine human subjects with various clinical symptoms, the ferrous iron salt (ferrous sulfate or ferrous chloride) was much more readily absorbed and utilized than the corresponding ferric salt or ferric ammonium citrate fed under the same conditions. In experiments on 11 dogs, exhibiting an iron deficiency anemia of long duration produced by bleeding, the uptake of ferrous iron was two to three times that of ferric iron. The authors note that individual responses to a given dose of tagged iron are so variable that it is advisable to study the relative utilization of different iron preparations in the same individual to eliminate this source of error.

**Dental caries in the cotton rat.—II, Production and description of the carious lesions.** J. H. SHAW, B. S. SCHWEIGERT, C. A. ELVEHJEM, and P. H. PHILLIPS. (Wis. Expt. Sta.). (*Jour. Dent. Res.*, 23 (1944), No. 6, pp. 417-425, illus. 9).—The methods of production, determination, and description of the carious lesions in cotton rats are reported in detail. The rats were fed the diets previously described (*E. S. R.*, 94, p. 130).

The authors again note that the optimum time for observation occurs after 14 weeks on the experimental diet. Although the number of lesions apparent on the sucrose diet averages from 4 to 10 times as many as found on a stock or dextrin diet, the extent of each carious lesion is approximately the same on either diet.

**The Atwater system of calculating the caloric value of diets.** L. A. MAYNARD. (Cornell Univ.). (*Jour. Nutr.*, 28 (1944), No. 6, pp. 443-452).—In this editorial review, the author has emphasized the reasons why the factors 4-9-4 used by Atwater in his calculations of the caloric value of protein, fat, and carbohydrate are still valid for present day use in this country. The British system of expressing carbohydrate as "available carbohydrate" in terms of their starch equivalent before multiplying by the factor four is discussed and criticized. One of Atwater's original tables is presented showing the percentage of protein, fat, and carbohydrate provided by each food group, the calories calculated by combustion experiments, and the percentage actually available obtained by digestibility experiments. The overall fuel value of 4 for protein was based upon an approximately 60:40 distribution of animal protein averaging 4.25 calories per gram and of vegetable protein averaging 3.55 calories/gm. Where this distribution has been radically changed, due to wartime or other conditions, corrections should be applied. A table is presented showing the factors to be used for certain general food groups. The factor for fat is 9.00 for animal products or animal and vegetable fats, 8.35 for all other groups, which include cereals, pulses and nuts, vegetables (including potatoes), and fruits. The factors for total carbohydrates are 4.1 for 70 percent extraction cereals; 4.0 for vegetables, pulses, and nuts; 3.85 for sugar (sucrose); 3.8 for animal products and 85 percent extraction cereals; and 3.6 for fruits. Protein figures are more variable, being 4.25 for animal products, 3.70 for 70 percent and 3.60 for 85 percent extraction cereal, 3.20 for pulses and nuts, 3.15 for fruits, and 2.90 for vegetables including potatoes.

The author concludes that for international comparisons in which wide differences may exist in the character of the food supply, some modifications from the use of a single set of overall factors are essential. A common or comparable basis for computing caloric supplies is considered necessary—the use of the above figures is considered a possible solution.

The refinement of metabolic calculations for nutritional purposes and the problem of "availability", A. KEYS (*Jour. Nutr.*, 29 (1945), No. 1, pp. 81-84).—In this editorial review, the author emphasizes the discrepancies which may occur in the concept of availability of carbohydrate or other nutrients. Stress is placed upon more detailed research, especially on quantitative studies in man, before accurate conclusion can be drawn.

The preventive and therapeutic use of vitamins, N. JOLLIFFE (*Jour. Amer. Med. Assoc.*, 129 (1945), No. 9, pp. 613-617).—This is an authoritative discussion of the use and abuse of vitamins.

The ascorbic acid and carotene content of three varieties of sweet potatoes grown in Arizona and their losses during storage, M. C. SMITH, H. WISEMAN, E. CALDWELL, and H. FARRANKOP (*Arizona Sta. Mimeog. Rpt.* 71 (1945), pp. 9).—Three varieties, Nancy Hall, Porto Rico, and Red Velvet, were planted in April and harvested in November. The potatoes were then stored in pits, in a potato house, or allowed to remain in the ground until ready for market. The total ascorbic acid content per freshly harvested potato averaged 46, 39, and 34 mg., respectively, for the Nancy Hall, Porto Rico, and Red Velvet varieties. From 5 to 7 mg. of the total ascorbic acid was in the dehydro form. Pit storage caused progressive loss of ascorbic acid. At the end of the 4 months' period, reduced ascorbic acid values for all three varieties ranged between 15 to 25 mg./100 gm. Total ascorbic acid values ranged from 24 to 28 mg./100 gm. Laboratory storage for 16 days caused proportionately greater losses in relation to the length of storage period, averaging 22 to 30 percent loss on a dry weight basis.

Carotene values were unaffected by storage, but differed widely with the variety of sweetpotato. Carotene values in milligrams per 100 gm. averaged 1.31 to 2.62 in the Nancy Hall variety; 4.97 to 5.79 in the Porto Rico variety; and 3.76 to 5.28 in the Red Velvet variety. Wide ranges in values within a single variety were attributed to size of potato, difficulties in sampling, and possible irregular distribution of the carotenoid pigments.

The use of sweetpotatoes as a fairly stable source of ascorbic acid and carotene is recommended. Tabulated data are presented showing the relative value of sweetpotatoes as a source of ascorbic acid and carotene in relation to other common fruits and vegetables.

Cooking losses of ascorbic acid and carotene in large scale cooking (*Alabama Sta. Bien. Rpt.* 1943-44, pp. 18-19).—"In large scale cooking practice, losses of ascorbic acid for different vegetables averaged as follows (in percent): Lima beans 81.0; string beans 74.5; cabbage 76.0; carrots 46.0; cauliflower 44.5; boiled potatoes 50.8; mashed potatoes 47.3; oven-browned potatoes 80.0; spinach 95.8; baked sweetpotatoes 11.0; turnip greens 58.8; and turnip roots 55.6. The use of large quantities of cooking water, which was discarded, and excessive cooking time appeared to be the factors responsible for the high losses.

"Carotene losses were less serious than the ascorbic acid losses."

Ice cream as a source of riboflavin, carotene and ascorbic acid, A. D. HOLMES, J. W. KUZMESKI, C. P. JONES, and F. T. CANAVAN. (Mass. Expt. Sta.). (*New England Jour. Med.*, 234 (1946), No. 2, pp. 47-49).—"The coffee, maple, and vanilla ice cream contained 0.09 mg., 0.12 mg., and 0.09 mg. of carotene and 0.27 mg., 0.26 mg., and 0.26 mg. of riboflavin per 100 gm., respectively. No ascorbic acid was found, probably because of the large amount of air incorporated in commercial ice cream to increase its bulk.

"Comparison of these ice creams with numerous widely used foods shows them to be excellent sources of carotene and riboflavin for the human dietary. The nutritive value of ice cream, however, varies with the nature and amount of the ingredients used and the process of manufacture."

**Effects of home freezing and cooking on snap beans:** Thiamin, riboflavin, ascorbic acid, M. G. PHILLIPS and F. FENTON. (Cornell Univ.). (*Jour. Home Econ.*, 37 (1945), No. 3, pp. 164-170).—Freshly harvested Tendergreen snap beans were found to average (per 100 gm. fresh weight) 22.6 mg. ascorbic acid, 0.071 mg. thiamine, and 0.140 mg. riboflavin. As the maturity of the beans increased, the ascorbic acid values fell, but the thiamine values rose. In the overmature beans, the seeds contained only half as much ascorbic acid and riboflavin as the pods, but nearly three times as much thiamine (0.991 mg. v. 0.366 mg./100 gm. dry weight).

Blanching in boiling water, preparatory to freezing, caused vitamin losses ranging from 10 to 15 percent. Subsequent chilling losses equaled approximately 5 percent, while no apparent additional loss was sustained on freezing.

After cooking, fresh beans retained roughly 75 percent of the original amount of the three vitamins, while about 20 percent of each vitamin could be found in the cooking water. Both frozen beans and partially defrosted beans (held 1 to 3 hr. at room temperature) showed somewhat greater vitamin losses than the fresh beans, when cooked in comparable amounts of water (ratio of beans to water approximately 1:1). Cooking the frozen products in just enough water to prevent burning (ratio 6:1) produced a more flavorful product with greater vitamin retention. "Keeping the cooked frozen beans warm in a double boiler for 1 hr. over a low flame resulted in a loss of most of the ascorbic acid but no appreciable loss of thiamine or riboflavin."

**The mode of occurrence of carotene and vitamin A in human blood plasma,** L. M. DZIALOSZYNSKI, E. M. MYSTKOWSKI, and C. P. STEWART (*Biochem. Jour.*, 39 (1945), No. 1, pp. 63-69).—The extraction of carotene and vitamin A from citrated human plasma has been studied in relation to various physical and chemical conditions.

The results show that only small amounts of carotene and vitamin A are extracted by shaking with ether. Over a pH range of 3 to 12, maximum extraction and protein precipitation occur between pH 4-5. The addition of an equal volume of ethanol to the plasma increases the subsequent carotene extraction by ether. The amounts of carotene and vitamin A extracted by ether are reduced in the presence of bile salts. Half saturation of plasma with ammonium sulfate inhibits the precipitation of the vitamins, while three-fourths or full saturation precipitates them with the albumin fraction. Freezing of an ether-plasma mixture at  $-25^{\circ}$  C. increases the amount of carotene and vitamin A extracted by the ether. Aqueous colloidal solutions of carotene react qualitatively like plasma when treated as described above; but important quantitative differences exist. Carotene in aqueous colloidal solution added to normal plasma cannot be extracted by ether. This effect does not occur when denatured plasma is used.

The authors conclude from these experiments that "the evidence is held to indicate the existence of compounds of carotene and vitamin A with protein, the protein concerned being probably, but not certainly, albumin. Denaturation and precipitation of the protein appears to weaken or disrupt the compounds."

**The relationship between the weight of young vitamin A-deficient rats and the increase in weight after  $\beta$ -carotene administration,** M. C. A. CROSS (*Biochem. Jour.*, 39 (1945), No. 1, pp. 113-115, illus. 2).—No correlation was found between the initial body weight of rats on a vitamin A-deficient diet and the increase in weight resulting from feeding  $\beta$ -carotene.

**The nutritive value of the fatty acids of butter including their effect on the utilization of carotene,** E. F. BROWN and W. R. BLOOR (*Jour. Nutr.*, 29 (1945), No. 5, pp. 349-360, illus. 2).—Rats were fed a modified Sherman B diet in which the fat component was butter or one of five fatty acid fractions—volatile, low liquid, high liquid, low solid, or high solid fraction. Weekly supplements of vitamin A in

the form of 3 gm. of raw carrot and 1 drop of a vitamin D concentrate were added. Rats fed butter received considerably more vitamin A than the other groups.

Tabulations are made of the relative growth rates, the amounts of vitamin A stored in the livers, the lipide content of the livers, and the lipide content of the feces.

Results showed that poorest growth occurred when the volatile acids were fed. Both liquid acid diets proved equal or superior to the butter diet. The liquid acids were well absorbed, while absorption of the low solid acids was 71.3 percent and of the high solid acids only 42.2 percent. No significant differences could be observed in the lipide content of the livers studied.

"The nature of the fat being absorbed seemed to be of importance in the utilization of carotene from carrot by the rat. The amount of storage of vitamin A in the livers of the rats fed the liquid acid diets was greater than that in the livers of the rats fed the solid acid diets. In the six liquid groups the average amounts of vitamin A stored varied from 125.5 to 152.7 International Units. Corresponding values for the six solid groups ranged from 66.0 to 88.0 I. U."

**The effect of the level of protein in the diet on the utilization of vitamin A.** M. DYE, I. BATEMAN, and T. PORTER. (Mich. Expt. Sta.). (*Jour. Nutr.*, 29 (1945), No. 5, pp. 341-347).—This report extends the studies of Muelder and Kelly (E. S. R., 88, p. 553) on the effects of dietary factors upon the utilization of vitamin A. Rats were fed a diet of vitamin A-extracted casein, irradiated cornstarch, cottonseed oil, salt mixture, cystine, and baker's yeast. During the depletion period, which averaged 6.3 weeks, an 18 percent casein level was fed. During the experimental period, triads from groups of 24 rats were fed an equicaloric diet containing, respectively, 9, 18, and 36 percent casein, and 0, 1, 3, or 6 International Units of vitamin A per day.

Results showed that "the level of protein had little effect upon the utilization of vitamin A as judged by weight gains, length of the rat, and incidence of foci of keratinized epithelium. The level of vitamin A intake was directly related to rate of gain up to the level of 3 International Units per day regardless of the level of protein in the diet. There were slightly greater gains in weight on the 18 percent level of protein regardless of the level of vitamin A than on other quantities of protein."

Variation in protein intake produced no noticeable effect on the leucocyte count. However, when low vitamin A levels were fed, the total leucocyte count nearly doubled, and the percentage of polymorphonuclear cells increased as the vitamin A intake decreased.

"The teeth did not show a normal midlingual to midlabial dentin ratio until 6 International Units of vitamin A were present in the diet."

**The vitamin A potency of creamery butter produced in Minnesota.** R. JENNESS and L. S. PALMER. (Minn. Expt. Sta.). (*Jour. Dairy Sci.*, 28 (1945), No. 6, pp. 473-494, illus. 4).—This is a detailed report of a study conducted as part of a national cooperative project on the vitamin A potency of butter and summarized elsewhere (E. S. R., 92, p. 865).

**The investigation of human requirements for vitamins of the B complex.** A. KEYS (*Jour. Amer. Dietet. Assoc.*, 21 (1945), No. 4, pp. 211-213).—In this report, emphasis is placed upon the inadequacies in our present knowledge of the vitamin requirements of man. The author stresses the fact that most of the evidence used is based upon calculations from animal experimentation, inferences from clinical observations, arguments based on urinary excretions, and population mortality and morbidity records.

Based upon published and unpublished data from the author's laboratory, a tentative list of minimal requirements is presented. Experiments indicate that if previous dietary habits have been adequate, one may eliminate riboflavin or niacin

from the diet for as long as 30 days without producing any functional impairment. The critical intake of thiamine for this period or longer approximates 0.5 to 0.7 mg. per day. The minimal daily requirements, calculated with only a small margin of safety, are tabulated in terms of 3,000 and 4,500 calorie intakes: Thiamine, 0.8 and 1.0 mg.; riboflavin, 1.0 and 1.2 mg.; and niacin, 8 (?) and 10 (?). The author believes that "practical requirements should be defined in terms of time duration, and practical recommendations should be adjusted to the facts of seasonal dietary alterations."

**The biological activity of biotin and related compounds,** G. A. EMERSON (*Jour. Biol. Chem.*, 157 (1945), No. 1, pp. 127-130, illus. 1).—"Synthetic and natural biotin had identical activity when assayed curatively with rats maintained on an egg white-containing ration. *dl*-Biotin was one-half as active as biotin. *l*-Biotin was inactive when fed at  $7\frac{1}{2}$  times the level of biotin. *dl*-Allobiotin was without effect when fed at a tenfold increase in intake over biotin. Diaminocarboxylic acid (corresponding to biotin), *dl*-diamino acid, *dl*-allodiamino acid, and *dl*-epiallodiamino acid were inactive at levels 100 to 250 times that of biotin."

**Studies on the activity of synthetic biotin, its enantiomorph, and related racemic forms for the chick,** W. H. OTT (*Jour. Biol. Chem.*, 157 (1945), No. 1, pp. 131-133).—"In chicks fed a purified diet containing 15 percent dried raw egg white, synthetic biotin was as effective as natural biotin in promoting growth and preventing dermatitis. Both *l*-biotin and *dl*-allobiotin were without activity when fed in amounts ranging from four to nine times as much as the active compounds."

**Biological activity of synthetic d,l-desthiobiotin,** S. H. RUBIN, L. DREKTER, and E. H. MOYER (*Soc. Expt. Biol. and Med. Proc.*, 58 (1945), No. 4, pp. 352-356, illus. 4).—"Results of microbiological assays showed that *dl*-desthiobiotin was 50 percent as active as *d*-biotin for *Saccharomyces cerevisiae*, and approximately one-half as effective as *d*-desthiobiotin in inhibiting fermentation by *Lactobacillus casei*. Biological assays on rats fed dried egg white or succinylsulfathiazole indicated that the activity of *dl*-desthiobiotin was very slight, being only 0.1 to 0.01 percent that of biotin."

**The existence of a microbiologically inactive "folic acid"-like material possessing vitamin activity in the rat,** L. D. WRIGHT, H. R. SKEGGS, A. D. WELCH, K. L. SPRAGUE, and P. A. MATTIS (*Jour. Nutr.*, 29 (1945), No. 5, pp. 289-298, illus. 1).—"Rats were fed a purified casein diet, or a milk powder diet, to which succinylsulfathiazole (SST) was added in varying amounts—0, 1, 2, 5, 10, or 20 percent. These diets had a very low folic acid (FA) content when assayed by the usual microbiological tests. On the casein diet, addition of 2 percent SST was sufficient to produce symptoms of FA deficiency in the rats. The folic acid content in the liver of the deficient rats averaged less than 0.5  $\mu\text{g./gm.}$  of fresh liver. Other deficiency symptoms noted were growth failure, low total leucocyte count, low percentage of granulocytes, and reduced fecal elimination of FA. On the milk powder diet, a concentration of 10 or 20 percent SST was necessary to produce these same deficiency symptoms, while the rats showed normal growth when 1, 2, or 5 percent SST was fed."

Samples of powdered milk were then digested with highly purified enzyme preparations obtained from rat liver, according to the technic of Mims et al. (E. S. R., 93, p. 675). After this treatment, significantly higher values were found for FA in powdered milk—0.48-0.60  $\mu\text{g./gm.}$  v. 0.016-0.021  $\mu\text{g./gm.}$  observed previously.

The authors conclude "that the 'potential FA' of milk, unavailable as such to micro-organisms, is utilizable by the rat. The existence of such potential FA offers an explanation for the apparent discrepancy between the FA content of milk powder found microbiologically and that indicated by the results of growth experiments in rats."

**The importance of "folic acid" in rations low in nicotinic acid,** W. A. KREHL and C. A. ELVEHJEM. (Wis. Expt. Sta.). (*Jour. Biol. Chem.*, 158 (1945), No. 1, pp. 173-179, illus. 1).—Weanling mongrel puppies 6 to 8 weeks old were used for this study. A purified basal ration was fed, supplemented with halibut liver oil, riboflavin, pyridoxine hydrochloride, calcium pantothenate, and choline chloride. One group of dogs received additional supplements of folic acid concentrate (B<sub>12</sub> or norit eluate factor). On these diets, marked nicotinic acid deficiency occurred as characterized by: "(1) Drastic loss in weight, (2) anorexia, (3) inflammation of the gums with palatine redness, and (4) bloody diarrhea."

After these symptoms appeared, a 25 mg. dose of nicotinic acid was given by mouth and the growth response noted. Results showed that when folic acid was fed, the nicotinic acid deficiency appeared somewhat sooner, but the response to the 25 mg. dose of nicotinic acid was much greater, the severity of the mouth lesions was lessened, and the dogs could be used repeatedly for the tests. When folic acid was lacking in the diet, the response to nicotinic acid was poor, blacktongue was more severe, a watery eye condition with considerable exudate frequently appeared, and death occurred despite nicotinic acid treatment.

The appearance of the deficiency symptoms as affected by folic acid administration, possible synthesis of folic acid by intestinal bacteria, and relative age of the animals when tested is discussed.

**Effect of corn grits on nicotinic acid requirements of the dog,** W. A. KREHL, L. J. TEPLY, and C. A. ELVEHJEM. (Wis. Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc.*, 58 (1945), No. 4, pp. 334-337, illus. 1).—Dogs maintained on a synthetic ration low in nicotinic acid and having had one or more attacks of blacktongue were used. They were given 5 mg. of nicotinic acid one week before the experiment began. Five different diets were fed to a small number of dogs: Group 1 (4 dogs) received 60 percent corn grits in place of the sucrose in the diet, and enough nicotinic acid was added to equal a level of 2.0 mg. percent; group 2, (3 dogs) same as group 1 with the nicotinic acid level at 5.0 mg. percent; group 3, (2 dogs) on mineralized whole milk containing approximately 0.7 mg. percent nicotinic acid; group 4, (2 dogs) same as group 1 with nicotinic acid level at 1.0 mg. percent; and group 5, (1 dog) 36 percent enriched corn grits containing 1.6 mg. percent nicotinic acid for the entire ration.

Results showed that groups 2 and 5 made comparable weight gains, the two dogs in group 4 died before the end of the test, and the best growth occurred in group 3.

The authors conclude that on a diet high in corn, a nicotinic acid level of 5.0 mg. percent in the corn grits is necessary to produce good growth in dogs. Comparable or better growth is obtained at one-third this level with whole milk or synthetic rations.

**Corn as an etiological factor in the production of a nicotinic acid deficiency in the rat,** W. A. KREHL, L. J. TEPLY, and C. A. ELVEHJEM. (Wis. Expt. Sta.). (*Science*, 101 (1945), No. 2620, p. 283).—Rats were fed a synthetic ration essentially free of nicotinic acid but adequate in the other known vitamins (with the exception of folic acid and *p*-aminobenzoic acid). On this ration, a weight gain of 30 gm. in 4 weeks was observed. Replacement of 40 percent of the entire ration by yellow corn, white corn, or corn grits produced marked growth inhibition with only 13 gm. gain in 4 weeks. Addition of 0.5 to 1.0 mg. of nicotinic acid per 100 gm. of the corn-supplemented ration completely counteracted the growth-depressing action of corn. Addition of folic acid instead of nicotinic acid did not neutralize the depressant effect of the corn. When glucose replaced sucrose in the synthetic ration or when the casein level was increased from 15 to 20 percent, the growth depressing effect of corn was lessened.

Unenriched corn grits containing 0.7 to 1.0 mg. percent nicotinic acid showed a greater inhibitory effect on growth than corn meal containing 2 mg. percent nicotinic acid.

**Production of nicotinic acid deficiency with 3-acetylpyridine, the ketone analogue of nicotinic acid,** D. W. WOOLLEY (*Jour. Biol. Chem.*, 157 (1945), No. 2, pp. 455-459).—"Typical signs of nicotinic acid deficiency as seen in susceptible species were caused by 3-acetylpyridine when 2 or more milligrams per day were fed to mice. This species was not susceptible to nicotinic acid deficiency produced by the usual dietary means. The signs of the disease were prevented by sufficient amounts of nicotinic acid or of nicotinamide in the ration. 3-Acetylpyridine was regarded as the structural analogue of nicotinic acid in which the—COOH group of vitamin had been exchanged for—COCH<sub>3</sub>. In contrast to the results with animals, 3-acetylpyridine was relatively ineffective for the inhibition of growth of microbial species, and in those instances in which inhibition of growth was produced it was not reversed specifically by nicotinic acid. This ineffectiveness against bacteria was not due to the ability of these organisms to inactivate the compound."

**A study of nicotinic acid restriction in man,** A. P. BRIGGS, S. A. SINGAL, and V. P. SYDENSTRICKER (*Jour. Nutr.*, 29 (1945), No. 5, pp. 331-339, illus. 1).—Two subjects, both previously treated for pellagra, were fed a restricted diet low in trigonelline and containing only about 3 mg. nicotinic acid per day. This diet, which contained 50 gm. of hominy but no corn, was eaten for 9 weeks by one subject and 42 weeks by the other. Minimal lesions considered characteristic of nicotinic acid deficiency were apparent at the start, but no significant changes appeared during the course of the experiment. The nicotinic acid excretion of both subjects remained essentially the same at the end of the study as at the beginning. Trigonelline excretion decreased rapidly for about 3 weeks and then stayed at a low level comparable to the nicotinic output for the remainder of the restricted diet period. The fluorescent substance F<sub>2</sub> could not be detected throughout the experiment. Results of niacin tolerance tests were interpreted to indicate a mild state of deficiency. The authors suggest that under their experimental conditions, either because little corn was fed or intestinal biosynthesis of nicotinic acid occurred, the 3 mg. of nicotinic acid supplied daily provided an intake somewhat near the minimal niacin requirement of man.

**A comparison of the nutritive value of dextrose and sucrose and of the effects produced on their utilization by thiamine hydrochloride,** C. P. RICHTER and K. K. RICE (*Amer. Jour. Physiol.*, 143 (1945), No. 3, pp. 336-343, illus. 3).—Two-month old rats were fed a diet in which sucrose or dextrose provided the sole source of nourishment. Average survival times were 37 days in both cases. Addition of thiamine hydrochloride (0.02 percent solution) increased the survival times to 56 and 74 days, respectively. The rats on the sucrose diet developed vitamin A deficiency sooner than rats on the dextrose diet. After elimination of vitamin A deficiency, no appreciable differences in growth rates, activity, or survival time were apparent in the two groups of rats.

**Vitamin-C content of potatoes, I, II,** L. H. LAMPITT, L. C. BAKER, and T. L. PARKINSON (*Jour. Soc. Chem. Indus., Trans. and Commun.*, 64 (1945), No. 1, pp. 18-22, illus. 2; pp. 22-26, illus. 2).

**I. Distribution in the potato plant.**—Investigations were carried out on several varieties of potatoes, and assays were made on the various parts of the potato plant (flower, leafy parts, stems and stalks, roots, stolons, and tubers) as well as the potato itself (peel, inside, and sprouts). Old and new potatoes were studied directly after harvesting and after various periods of storage in the dark, daylight, and ultra-violet light at 3°, 20°, and 31° C.

No significant difference was observed in the vitamin-C content of the peel and tissue unless the condition of storage induced sprouting, in which case the concen-

tration of vitamin C in the sprouts and surrounding eyes was greater than in the remainder of the tissues.

Results also showed that mincing of the raw potato tissue produced a rapid loss of ascorbic acid (approximately 60 percent in less than 20 min.). "The highest concentration of vitamin-C was found in the leaves, which, together with the new tubers, contributed the bulk of the vitamin C present in the plant. The concentration of vitamin C in the new tubers showed a tendency to increase with time of growth and to reach a maximum shortly before the normal harvesting time."

II. *The effect of variety, soil, and storage.*—"A survey of the vitamin-C content of potatoes sold to the public over a period August, 1943, to the following July was made by drawing samples at monthly intervals of five varieties grown commercially from four districts in England and Scotland, the initial samples during harvesting and later samples from clamps. The average concentration of vitamin C in the raw potatoes declined steadily from 0.3 mg./gm. at the end of August to 0.08 mg./gm. at the end of January and thereafter remained steady at about that level. The only significant varietal difference found was that, during the period of steady decline in vitamin-C concentration, the results for King Edward potatoes were consistently slightly higher than those for the other varieties studied. No significant difference in vitamin-C concentration was found between potatoes of two varieties grown on two different but well-defined types of soil, e.g., black land and silt-land."

The retention of vitamin-C during the "cold-process" preservation of black-currants, S. G. KENDRICK and A. W. E. DOWNER (*Jour. Soc. Chem. Indus., Trans. and Commun.*, 64 (1945), No. 5, pp. 145-147, illus. 1).—Attempts were made to preserve black currants by adding to the fresh fruit varying proportions of bisulfite solution containing from 2,200 to 3,150 p. p. m. of  $\text{SO}_2$ . Bottles and Kilner jars were used for small-batch experiments and 40-gal. casks containing 3 cwt. of black currants and 10 gal. of preservative were used for the large-scale tests.

The mean ascorbic acid content of 27 samples of fresh black currants was 195 mg./100 gm. Results of the preserving tests showed that during a storage period lasting over 300 days, ascorbic acid losses were less than 10 percent in the large-scale preparations. Losses ranged from 20 to 30 percent in the small-scale tests. A proportion of preservative solution of at least 23 percent with an  $\text{SO}_2$  content of 700 p. p. m. or higher was needed to prevent fermentation and spoilage during storage.

The authors indicate that the ascorbic acid losses incurred by this method of preservation approximate those found in normally stored black currant sirup.

**Tangerines—their ascorbic acid content and factors affecting it**, M. C. SMITH, E. CALDWELL, and H. WISEMAN (*Arizona Sta. Mimeog. Rpt. 72* (1945), pp. 7+).—Dancy and Algerian varieties of tangerine were simultaneously assayed for vitamin A values (E. S. R., 94, p. 274) and ascorbic acid; results from over 400 assays for the latter are here reported. The effects of variety, position on the tree, seasonal changes, and rootstock on the ascorbic acid content of tangerine segments have been tabulated. In the Dancy variety, the ascorbic acid content ranged from 16 to 65 mg. (average 34 mg.) per 100 gm. edible portion; in the Algerian variety, the range was from 32 to 91 mg. (average 54 mg.) per 100 gm.

As was previously found for oranges (E. S. R., 92, p. 868), highest ascorbic acid values for tangerines were noted consistently in the fruit picked from the south or west sides of a tree. Fruit from the center, north, or east part of the tree had about 25 percent less ascorbic acid. Fruit left on the trees 2 to 4 mo. after reaching maturity showed a slight fall in ascorbic acid content—more noticeable in the Algerian than in the Dancy variety. The influence of rootstock on the ascorbic acid of tangerines of the same variety was noted. Algerian tangerines grown on rough lemon rootstock contained less ascorbic acid than similar fruit grown side by side on sour orange rootstock.

**Flavor and ascorbic acid retention in fresh Florida citrus juices**, E. L. MOORE, C. D. ATKINS, E. WIEDERHOLD, and L. G. MACDOWELL. (U. S. D. A. et al.). (*Jour. Home Econ.*, 37 (1945), No. 5, pp. 290-293).—Hand-reamed and machine-reamed orange and grapefruit juices, stored covered and uncovered at room temperature for 3 days, retained 97 percent of their original ascorbic acid content. Covered juices, held in cold room storage, showed a better retention of flavor than did the juices stored uncovered at cold room or room temperatures. Ascorbic acid retention was not appreciably influenced by either method of extraction. The results of the determinations made indicated that the length of time fruit juices may be allowed to stand before use in the home is limited by loss of palatability and the beginning of fermentation, not by ascorbic acid losses.

**The nature of some new dietary factors required by guinea pigs**, D. W. WOOLLEY and H. SPRINCE (*Jour. Biol. Chem.*, 157 (1945), No. 2, pp. 447-453).—The studies of Woolley (E. S. R., 88, p. 705) and Woolley and Sprince (E. S. R., 93, p. 659) have been elaborated in an effort to identify further the three new growth factors required by guinea pigs. The procedures described by Woolley were employed in a series of experiments in which the following results were noted:

"The dietary essential GFP-2, previously demonstrated to be required by guinea pigs, was replaceable by a mixture of cellulose and casein or cellulose, arginine, cystine, and glycine. The optimal amount of casein for growth of guinea pigs fed a highly purified ration was found to be 30 percent of the diet. The dietary essential GPF-1 was identified with folic acid, and the behavior of guinea pigs on a folic acid-deficient ration was described. A highly purified diet for the assay of the unidentified nutritional essential GPF-3 was developed. Some improvement in survival time of GPF-3-deficient animals was observed when biotin and *p*-aminobenzoic acid were fed. It was shown that GPF-3 was not precipitated by lead acetate, was not readily adsorbed by norit, and that while it was insoluble in alcohol it was soluble in alcohol and HCl. It resembled streptogenin, an unidentified growth factor required by certain bacteria."

## TEXTILES AND CLOTHING

**Flow characteristics of dispersions of cotton and regenerated cellulose rayon fabrics in cuprammonium: Their significance in fluidity calculations**, W. C. JELINEK. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 3, pp. 172-178, illus. 8).—Flow-pressure and fluidity-velocity gradient graphs were used to determine the flow properties of cuprammonium dispersions of cellulose fabrics and to evaluate the method of calculating the fluidity values. The limits of application of the kinetic energy and velocity gradient adjustments were determined for cellulose-cuprammonium dispersions under experimental conditions very similar to those recommended by the American Society for Testing Materials. The viscometer and buret consistometer were compared in the fluidity technic.

**Fading of colored textiles**, A. H. TAYLOR (*Illum. Engin. Soc. Trans.*, 41 (1946), No. 1, pp. 35-38).—Extensive studies over a period of years on the fading of colored textiles, exposed to natural daylight and to various artificial light sources, were concerned primarily with the determination of the relative exposures (footcandle-hours) to produce equal fading of representative textiles. As a result of the extensive tests, the following conclusions are considered as representative for the average of all specimens tested: (1) The fading of a colored textile is approximately proportional to the exposure in footcandle-hours for a particular light source; (2) atmospheric humidity has little influence on the rate of fading; (3) the rate of fading is about the same for exposures at 85° and 120° F., but is appreciably increased by raising the temperature to 150°; and (4) fading produced by natural daylight is caused chiefly by energy of wave lengths shorter than approximately 46,000. Exposures of 108 colored textiles to natural daylight (combined sunlight

and skylight), tungsten-filament lamps, and fluorescent daylight lamps gave the following average relative exposures in footcandle-hours to produce equal fading: Sunlight and skylight 1.00, tungsten-filament light 1.81, and fluorescent daylight 1.68. Exposures of a few colored textiles to a germicidal lamp, radiating most of its energy at  $\lambda 2,537$ , caused a much faster rate of fading than comparable exposure to fluorescent daylight lamps. These results, it is pointed out, emphasize the need for care in the installation of germicidal lamps where fading of textiles or other objects may be undesirable. They also indicate the possibility that the lamps might be used for accelerated tests of light fastness.

**How to tailor a woman's suit**, M. SMITH (*U. S. Dept. Agr., Misc. Pub. 591 (1946)*, pp. 24, illus. 65).—Simplified tailoring technics (pressing, fitting, cutting, interfacings, undercollar, etc.) are presented with directions accompanying illustrations.

## HOME MANAGEMENT AND EQUIPMENT

**Farm incomes and living costs for certain Kansas families**, M. A. GUNSELMAN (*Kansas Sta. Bul. 327 (1945)*, pp. 35, illus. 7).—This study of Kansas farm family income and expenditure is based on data taken from the farm and home account books kept by 346 farm families during 1934-40. These families were classified into groups according to family type—type 1 including those families consisting of husband and wife only; type 2, husband and wife and 1 or 2 children less than 16 yr. of age; type 3, husband and wife and 1 child 16 yr. of age or older with or without up to 3 other children; type 4, husband and wife, at least 1 child who was less than 16 yr. of age, and 2 to 5 other children regardless of age; and type 5, 5 to 14 members, consisting of husband and wife and 3 or more other adults, or a husband and wife and 5 or more other persons regardless of age.

The farms operated by these families varied in size from 94 to 8,012 acres—the average size being 464 acres, with 57 percent of the land under cultivation. Nearly 60 percent of the families owned all or a part of the land operated.

Net farm incomes varied from \$958 in 1938 to \$2,057 in 1935 during the 7-yr. period. Six percent of the annual records showed a loss, and 22 percent showed incomes above \$2,500. In most of the years, type 5 had the largest net farm incomes, and type 1 averaged the lowest with the exception of 1935, although the author believes that there was no consistent relationship between the size of the family and the size of the net farm income.

Analysis of the annual records revealed definite similarities in the patterns of spending for the groups studied, although the total value of the items used in family living varied with the size and the composition of the family. Families in type 1 averaged an expenditure of \$992 annually for all consumption items, whereas the average expenditure for families in type 5 was \$1,696; families in type 3 spent \$78 more on consumption items than the average family in type 5; the money value of food, household operation, and medical care for families in type 4 was more than for the same groups on items for families in type 3. The average value of living (including gifts, small savings, and life insurance payments) was \$1,426 for the 7-yr. period.

**Pressure cooker gauge testers**, A. BARAGAR and M. E. RUNNALLS (*Nebr. Agr. Col. Ext. [Pub.] CC-88 (1945)*, pp. 4, illus. 7).—Materials for constructing and directions for assembling and using the pump- and tank-type gage testers are given. Both types use air pressure and are modifications of other testers which have been used by county extension agents. In analyzing the data obtained on 710 gages, it was found that 42 percent had an error greater than 1 lb. per square inch, and 20 percent had an error greater than 20 lb. This latter error may be a contributing factor to food spoilage. The testers described here check the gage while it is still fastened to the lid—this is advantageous from the standpoint of the time required to test the gage.

**Jar rings for use in home canning:** Their testing and a proposed specification, R. H. TAYLOR, H. G. WHEELER, and F. BENEDICT (*U. S. Dept. Com., Bur. Standards Misc. Pub. 181 (1945), pp. 18, illus. 4*).—"Canning tests were made on 20 rings from each of 50 different samples. The rings were analyzed for rubber content, and measurements were made of their tensile strength, ultimate elongation, stress at 100-percent elongation, swelling on processing, indentation by a ring simulating a jar cap, and hardness. The canning failures in tests by the pressure-cooker method bore no relation to rubber content or tensile properties of the rings but were related to swelling, indentation, and hardness, and to the change of these properties with processing. The relation was not exact, because some failures probably resulted from excessive variations in jars and tops. Apparatus was developed for accurately measuring profiles of sealing surfaces. The results of the investigation are expressed in terms of a proposed specification for jar rings."

**Composition of some trade name solvents used for cleaning and degreasing, and for thinning paints,** A. D. BRANDT, W. J. MCCONNELL, and R. H. FLINN (*Pub. Health Rpts. [U. S.], 61 (1946), No. 5, pp. 132-143*).—The information here presented was obtained in the course of an investigation of acute cases of systemic poisoning among war plant workers using industrial solvents. The solvents, listed by their trade names and including a number of dry-cleaning solvents, are described as to their composition in terms of aromatics; halogenated hydrocarbons; alcohols, esters, ethers, and ketones; paraffins and naphthenes; and other components. The boiling range (degree C.) and the supplier or manufacturer are also listed.

## REPORTS AND PROCEEDINGS

**Report of the Secretary of Agriculture, 1945,** C. P. ANDERSON (*U. S. Dept. Agr., Sec. Agr. Rpt., 1945, pp. 167+*).—This report covers the activities of the Department of Agriculture and of the Food and Agriculture Organization of the United Nations (pp. 15-19). Findings of the State experiment stations are also included (pp. 119-124).

Among the subjects discussed and not noted elsewhere in this issue are food as a weapon of war, the farm reconversion problem, strength of agriculture's production forces, food throughout the world, agriculture's need of world trade, the year's production, cotton and farm economy, what's ahead for wheat, feed-grains problem, dairying, meat animals and meats, fruits and vegetables, fats and oils, poultry and egg products, sugar, the changing wool situation, tobacco, farm income in 1945, the price supports in 1945, agriculture's balance sheet, credit requirements for reconversion years, the rise in farm-land values, farm efficiency and farm opportunity, farm labor, machinery on farms, increasing use of fertilizer, the housing of farm people, distribution problems, our national nutrition, farmer discussion of world-peace organization, surplus-property activities, lag in market facilities, agricultural cooperatives, water policy and agriculture, soil conservation service, improvement of western grazing lands, crop insurance, extension programs, entomology during the war years, research in dairy problems and livestock production, forests and the war, electrification on the family-sized farm, progress with crop plants, and chemistry and crop utilization.

**Report of the Administrator of Agricultural Research, 1945,** P. V. CARDON (*U. S. Dept. Agr., Agr. Res. Admin. Rpt., 1945, pp. 238+*).—This report includes a discussion of the future of agricultural research, needs in animal research, better feeding of farm animals, expanding uses of farm products, goals in human nutrition, and using results of research. Appended are reports, also issued as separates and noted elsewhere in this issue, of the Bureaus of Agricultural and Industrial Chemistry (pp. 9-47); Animal Industry (pp. 49-98); Dairy Industry (pp. 99-115); Entomology and Plant Quarantine (pp. 117-177); Human Nutrition and Home Economics (pp.

179-190); and Plant Industry, Soils, and Agricultural Engineering (pp. 191-228); and the Office of Experiment Stations (pp. 229-238).

**Report of the Chief of the Bureau of Agricultural and Industrial Chemistry, Agricultural Research Administration, 1945, O. E. MAY** (*U. S. Dept. Agr., Bur. Agr. and Indus. Chem. Rpt., 1945, pp. 39; also in U. S. Dept. Agr., Agr. Res. Admin. Rpt., 1945, pp. 9-47*).—The following, among other accomplishments, are reported upon by the Bureau and the U. S. D. A. Regional Research Laboratories: Research to maintain cotton production by development of better tire cords, chemical treatments for cotton fabrics, and utilization of cottonseed and peanut oils; simplified pricing of peanuts; sweetpotato utilization; leaf meals for poultry; riboflavin production from yeast; allyl starch for protein coatings; starch in sponge form; enzyme research to alleviate shortage of malt; fermentable sugars from crop wastes and fiberboard from crop residues; soybean and linseed oils; soybean meal for plywood adhesives; use of itaconic acid for making plastics; vulcanizing recipes for acrylic "rubbers"; casein fractionation and use in bristles; fibers from feathers; increased penicillin yields; tomatin, lysozyme, citrinin, subtilin, tyrothrycin, and gramicidin as antibiotics; commercial extraction of rutin; gluten sulfate manufacture; allergens of eggs and castor-beans; improvement of egg powders, dehydrated vegetables, frozen fruits, canned citrus juices, and production of pectin and apple-flavoring constituents; recovery of citrus byproduct wastes and sugar cane products; reduction of sugar losses in beets in storage by whitewashing; naval stores studies; treatment of leather for mold resistance; production of improved tallow emulsifiers and oleic acid; new nicotine compounds as fungicides; and tests of canaigre, scrub oak bark, and sumac as sources of tanning extracts.

**Report of the Chief of the Bureau of Animal Industry, Agricultural Research Administration, 1945, A. W. MILLER** (*U. S. Dept. Agr., Bur. Anim. Indus. Rpt., 1945, pp. 50; also in U. S. Dept. Agr., Agr. Res. Admin. Rpt., 1945, pp. 49-98*).—The research reported is for the most part noted elsewhere in this issue.

**Report of the Chief of the Bureau of Dairy Industry, Agricultural Research Administration, 1945, O. E. REED** (*U. S. Dept. Agr., Bur. Dairy Indus. Rpt., 1945, pp. 17; also in U. S. Dept. Agr., Agr. Res. Admin. Rpt., 1945, pp. 99-115*).—The research reported is for the most part abstracted elsewhere in this issue.

**Report of the Chief of the Bureau of Entomology and Plant Quarantine, Agricultural Research Administration, 1945, P. N. ANNAND** (*U. S. Dept. Agr., Bur. Ent. and Plant Quar. Rpt., 1945, pp. 62; also in U. S. Dept. Agr., Agr. Res. Admin. Rpt., 1945, pp. 117-177*).—This report notes the progress of research on insect-control devices and methods, tests of DDT, rotenone and other materials, baits and barriers, fumigants, a cotton-mopping mixture, termite and decay preventives, biological control with various parasites, disease-vector studies, development of insect-resistant plants, bee culture and diseases, insect pest surveys, including insects infesting cereal and forage crops, forest and shade trees, and cotton, and of screwworm, control of the Japanese beetle, gypsy and brown-tail moths, sweetpotato weevil, pink bollworm, grasshoppers, mormon crickets, chinch bugs, armyworms and cutworms, white-fringed beetle, pear psylla, Hall scale, mole crickets, dog flies, phony peach and peach mosaic, and Dutch elm disease, barberry eradication, and quarantines against pink bollworm and other pests.

**Report of the Chief of the Bureau of Human Nutrition and Home Economics, Agricultural Research Administration, 1945, H. K. STIEBELING** (*U. S. Dept. Agr., Bur. Human Nutr. and Home Econ. Rpt., 1945, pp. 12; also in U. S. Dept. Agr., Agr. Res. Admin. Rpt., 1945, pp. 179-190*).—This administrative report includes data on adjustments of rural families to economic change; income, food consumption, and dietary adequacy; nutritive value of civilian food supply; family food plans; research on nutritive value of foods, especially wheat germ; vitamin A and

carotene; dried eggs for the postwar market; home food preservation; equipment for home freezing; textiles and clothing in wartime; serviceability studies on household fabrics; cotton fabric utilization; making household cotton mildew-resistant; and standards for clothing construction and sizing.

**Report of the Chief of the Bureau of Plant Industry, Soils, and Agricultural Engineering, Agricultural Research Administration, 1945, R. M. SALTER** (*U. S. Dept. Agr., Bur. Plant Indus., Soils, and Agr. Engin. Rpt., 1945, pp. 38; also in U. S. Dept. Agr., Agr. Res. Admin. Rpt., 1945, pp. 191-228*).—This report summarizes progress results of research in uses of 2,4-D; development of improved corn, wheat, oats, barley, and sorghum; bindweed control by sheep; cotton improvement, fiber measurement, and verticillium resistance; culture of castorbeans and hops; dry-land management and use of shelter belts; design of a grain bin and studies of storage problems; drying peanut vines and hay; corn borer control; improved crimson clovers, vetches, and lespedeza; reduction of sweetclover seed production by clipping; losses by soybean diseases; range and pasture studies; hybrid pearl millet seed; irrigation of Kentucky bluegrass-clover sod; forest pathology, including studies of little leaf disease of pine, control of mold on wood containers, *Fomes annosus* on western pine, and *Fusarium* canker on southern pines; fruit and vegetable crops, including new peach varieties, new sprays for preharvest fruit drop, control of cranberry fruit rots with Fermate, culture of potatoes, pecans, and peanuts, nitrogen fertilizers for tung trees, aerosol technic for colchicine, new strains of lettuce, cantaloups, onions, tomatoes, and potatoes, sulfur dusting for bean rust, control of virus diseases of Easter lilies, use of sterile mica in place of soil for seedlings, and regulation of temperature in tomato shipments; irrigation agriculture, including phosphorus content of irrigated soils, boron concentration in well waters, and green manures in rotations; nematology, including studies of the potato rot nematode and longevity of a nematode in rye; rubber investigations, including studies of guayule, *Hevea*, and *Cryptostegia* spp.; use of nitrogen for corn in North Carolina; soil depletion in North Dakota; sugar plants, including weed control in cane fields and breeding sugar-sorghums and disease-resistant sugar beets; and tobacco, including culture, weed control in plant beds, breeding for wildfire resistance, and dust treatments for blue mold.

**Report of the Chief of the Office of Experiment Stations, Agricultural Research Administration, 1945, J. T. JARDINE** (*U. S. Dept. Agr., Off. Expt. Stas. Rpt., 1945, pp. 10; also in U. S. Dept. Agr., Agr. Res. Admin. Rpt., 1945, pp. 229-238*).—An administrative report for the fiscal year ended June 30, 1945, including brief notes on the progress of research at the Puerto Rico Experiment Station.

**Experiment Station progress in insect and plant disease control, 1945, F. ANDRE, H. P. BARSS, and F. V. RAND** (*U. S. Dept. Agr., Off. Expt. Stas., 1946, OES-R1, pp. 32+*).—This is a reprint from the report noted above of the sections on control of insects and plant diseases.

**Report on the agricultural experiment stations, 1945, J. T. JARDINE ET AL.** (*U. S. Dept. Agr., Off. Expt. Stas., Rpt. Agr. Expt. Stas., 1945, pp. 172+*).—This report consists mainly of a review of progress in agricultural, nutrition, and rural-life research during the fiscal year ended June 30, 1945. The major headings are: Highlights of the Year in Station Research; Increasing Soil Productivity; Producing Field-Grown Food and Feed Crops; Forage, Pasture, and Range; Fruit Production; Vegetable Production; Special Crops; Control of Insects; Plant Disease Control; Weed Control; Better Feeding Practices for Livestock; Increasing Productivity of Livestock; Maintaining Health of Farm Animals; Maintaining Quality of Animal Products; Food and Nutrition Investigations; Economic and Social Adjustments; and Statistics.

Appended statistics show that the total income of the stations for 1945 was \$28,082,086, an increase as compared with 1944 of \$1,139,424, derived entirely from non-Federal sources. Included were Federal-grant funds which totaled \$7,001,208 and non-Federal funds of \$21,080,879, or \$1 of Federal funds to \$3.01 from other sources.

The total number of research workers in 1945 is shown as 4,370, including 2,163 full-time staff members and 2,207 who divided time between research and teaching or extension work. As compared with 1944, there was a decrease of 63 full-time and 92 part-time research workers.

The publications of the stations in 1945 included 722 bulletins, circulars, and reports, 1,741 articles in scientific journals, and 457 miscellaneous publications. In 1944, the comparable figures were 933, 1,753, and 560.

[**Fifty-fourth and Fifty-fifth Annual Reports of the Alabama Station, 1943-44**], M. J. FUNCHESS ET AL. (*Alabama Sta. Bien. Rpt. 1943-44*, p. 39).—In addition to a project reported on page 131, notes are given of progress in agricultural economics, including tenant-purchase farms and 1944 losses in peanut harvesting; agricultural engineering, including the dynamics of soil erosion and its control, equipment for dehydration of sweetpotatoes and kudzu, distribution of ammonium hydroxide, sweetpotato production, and grain sorghum cultural tests; agronomy and soils, including the use of nitrogen for peanuts and green-manure oats, lime for peanuts and Caley peas, boron for alfalfa and legume seed production and susceptibility of winter legumes to borax injury, fertilizers for alfalfa, need for magnesium and sulfur, pasture improvement, and cotton breeding; animal husbandry, including grazing kudzu with cattle and hogs, green feed for laying hens, farm poultry management, effect of cottonseed, swine breeding, vitamin A and carotene content of milk and butter, relation of B vitamins, fats, and amino acids to growth of rats, and lathyrism in relation to the use of Caley peas for livestock; cause and control of concealed damage to peanuts; horticulture and forestry, including yields of slash and loblolly pines, growth of wood in young stands and influence of pruning, returns from slash pine in short rotations, response of hybrid sweet corn to intensive methods, cultural and fertilizer studies with sweetpotatoes, nitrogen requirements of sweetpotatoes and sweet corn, sweetpotato flour and its uses, and use of kudzu for terraces and hay; and zoology-entomology, including boll weevil control, fumigation of plants and potting soil with methyl bromide, production of camellia cuttings and fertilizers for camellias, control of the velvetbean caterpillar on soybeans and peanuts and of weevils in stored corn with DDT, management of farm fishponds, and preservation of quick-frozen fish.

**Food and Agriculture Organization of the United Nations: Report of the first session of the conference held at the city of Quebec, Canada, October 16 to November 1, 1945** (*Washington, D. C.: Food and Agr. Organ. of the United Nations, 1946*, pp. 89+).—This contains the reports of Commission A (Policy and Program) and Commission B (Organization and Administration), with supplementary data relating to resolutions and recommendations, the budget, rules of procedure, financial regulations, and the constitution.

## MISCELLANEOUS

**Rocks and rivers**, E. W. SHULER (*Lancaster, Pa.: Jaques Cuttall Press, 1945*, pp. 300+, illus. 105).—In this volume, an "effort is made to include the fundamental philosophies of geology but to save them from the maze of technical terms, which, however important to the geologist, are soon forgotten by those who do not follow this profession." Among the 16 chapters are those on soils and on the economic landscape, i. e., mineral resources.

## NOTES

---

**Kansas College and Station.**—The recent death is noted of Dr. Thomas P. Haslam, assistant professor and assistant in veterinary medicine from 1909 to 1917. He was a graduate of the college in 1908 and received his D. V. M. degree in 1914, as well as an M. S. degree from the University of Kansas and an M. D. from the University of Nebraska. While on the station staff he developed the immunization agent known as blackleg aggressin. At the time of his death he was a practicing physician in Council Grove, Kans.

The resignations are noted of Elmer H. Smith, extension assistant professor in agricultural engineering, Walter M. Carleton, instructor in agricultural engineering, S. W. Decker, associate professor of horticulture, and Charles J. Birkeland, research assistant in horticulture. J. C. Hide, associate professor of agronomy, Glen H. Beck, assistant professor of dairy husbandry, and Wilfred H. Pine and C. P. Wilson, assistant professors of agricultural economics, have returned from military service. New appointments include Richard C. Eaton, research assistant in poultry husbandry, T. J. Claydon, associate professor in dairy husbandry, Ray M. Hoss, assistant professor of agricultural economics, and Harold B. Harper, professor of agronomy.

**Minnesota Station.**—Dr. Harold Macy, dairy bacteriologist, has been appointed associate director.

**New York State Station.**—Fred C. Stewart, associated with the botanical work of the station from 1894 until his retirement in 1936, died April 24 in his seventy-ninth year. A native of New York State, he received his B. S. and M. S. degrees from the Iowa College and had studied at Harvard and Cornell Universities and the University of Munich. His service included three years as mycologist at the newly established Long Island substation and the organization and administration of the department of botany and its later successor, the division of plant pathology. A recent tribute from the station notes that he was "the author of more than 200 scientific articles and bulletins and of numerous popular articles. He was also much in demand as a speaker at farmer gatherings. He did pioneer work on potato diseases, particularly virus diseases, and the control measures he developed are still standard practice to a large degree. He also made many contributions in the field of mycology, with special reference to the classification of the wild mushrooms of the Adirondacks."

Walter O. Gloyer, assistant professor of plant pathology, retired June 1 after 34 years' service.

**Ontario Agricultural College.**—The death in his eighty-first year is noted on February 4 of Henry H. Dean, head of the dairy department from 1891 until his retirement in 1932. A native of Ontario and a graduate from the college in its first class in 1890, he served for a few months at the New York State Station. Following his return to Ontario, he rendered a notable pioneer service in developing the educational and experimental work of the department. In 1893 he established the annual dairy short course, and a few years later the "dairy option" for long-course students desiring to specialize in dairying. Among other writings, he was the author of *Canadian Dairying*, a textbook first published in 1903 and still in use in revised edition.

No. 2

## RECENT WORK IN AGRICULTURAL SCIENCE<sup>1</sup>

### AGRICULTURAL AND BIOLOGICAL CHEMISTRY

**Base exchange of crystalline silicates**, S. B. HENDRICKS. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 7, pp. 625-630, illus. 8).—The author presents certain concepts which he holds to be "fundamental for an understanding of base exchange by silicates." Necessary conditions for cation exchange in zeolite structures are the presence of negative portions in the lattice frameworks and of multiconnected channels large enough for ionic migration. The ways in which negative portions of lattices arise in zeolites and clay minerals are discussed in detail. Termination of an ionic lattice at a surface often involves incomplete balancing of charge with a corresponding requirement for presence of external ions. Base exchange capacity of kaolin minerals is due to this factor.

**Properties of granular and monocrystalline ammonium nitrate**, W. H. ROSS, J. Y. YEE, and S. B. HENDRICKS. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 11, pp. 1079-1083, illus. 6).—The authors point out that although such properties of the salt as its hygroscopicity, melting point, solubility, and absolute density are inherent and independent of the manufacturing process, certain properties including moisture holding capacity, caking tendency, crushing strength, and apparent density vary with the size, shape, and porosity of its particles, which vary with the process used in its preparation. This paper presents experimental data on the relation of porosity, size, and shape of ammonium nitrate to its behavior in storage and its drillability in the field. The results show that ammonium nitrate in the form of porous granules of uniform size and shape flows more freely, exhibits less tendency to cake, and has a greater capacity to hold moisture before becoming undrillable than other types of the material which are less porous and more irregular in particle size and shape.

**Formic acid content of milk heated to high temperatures as determined by the distillation procedure**, I. A. GOULD and R. S. FRANTZ. (Mich. Expt. Sta.). (*Jour. Dairy Sci.*, 29 (1946), No. 1, pp. 27-31).—Formic acid determinations were made by the distillation method on milk to which known quantities of formic acid were added and on milk which had been heated for 1- and 2-hr. periods at 116° C.

From 60 to 71 percent of the added formic acid was recovered by the method used, the average recovery being 66.5 percent. Milk heated for 1 hr. averaged 9.9 mg. of

<sup>1</sup> The publications abstracted in these columns are seldom available for distribution by the Office of Experiment Stations. In general, application should be made to the Office of Information of the U. S. Department of Agriculture, Washington 25, D. C., for publications of the Department; to the directors of the State agricultural experiment stations, as listed on page 3 of the cover of this issue, for publications of the several experiment stations; and to publishers of books and journals for material issued by them. Microfilms and photostatic copies, the latter legible without magnifying equipment, may be purchased from the Library, U. S. Department of Agriculture, Washington 25, D. C. Rates and other details will be supplied by the Library on request.

formic acid per 100 cc. of milk when the retention correction was used. This represented approximately 49 percent of the total titrable acidity increase. In contrast, milk heated for 2 hr. contained a corrected average of 21.8 mg. formic acid per 100 cc. of milk or a concentration equivalent to approximately 57 percent of the total titrable acidity increase.

**Preparation of methyl lactate: Continuous alcoholysis of lactic acid polymers,** E. M. FILACHIONE, J. H. LENGEL, and C. H. FISHER. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 4, pp. 388-390).—The authors note that although the esterification of lactic acid with methanol is troublesome, it is important because methyl lactate can be converted readily into higher lactic esters by alcoholysis or into methyl acrylate by pyrolysis of its acetyl derivative. The present paper describes the preparation (both batch and continuous) of methyl lactate by alcoholysis of lactic acid polymers, a method that for the most part avoids the difficulties encountered when water is present.

**Methyl acrylate by pyrolysis of methyl acetoxypionate: Effect of pressures of 1 to 67 atmospheres,** W. P. RATCHFORD and C. H. FISHER. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 4, pp. 382-387, illus. 5).—Methyl acrylate was made by pyrolyzing the acetyl derivative of methyl lactate in stainless steel equipment at various temperatures and pressures between 500° and 625° C. and 1 to 67 atmospheres. Moderate pressures had little effect, but lower yields of methyl acrylate were obtained at the higher pressures, primarily because of the formation of the dimer and higher polymers of methyl acrylate. Other byproducts were formaldehyde, acetaldehyde, methyl acetate, carbonaceous material, oxides of carbon, and gaseous hydrocarbons. High yields of methyl acrylate and acetic acid were obtained below 565° under approximately atmospheric pressure. The decomposition of the ester appeared to be a reaction of the first order. Specific velocity constant (sec.<sup>-1</sup>) is illustrated by the equation:

$$K_1 = 7.8 \times 10^9 \times e^{\frac{-38,200}{RT}}$$

**Emulsion polymerization of acrylic esters,** W. C. MAST, L. T. SMITH, and C. H. FISHER. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 4, pp. 365-369, illus. 4).—Effects of various agents on the emulsion polymerization of acrylic esters are described, and directions are given for preparing several types of resin emulsions. The emulsifying agents specified are, for the most part, commercial proprietary preparations. For the conversion of the monomeric esters into polymers or copolymers of relatively high molecular weight, a specified commercial emulsifier with ammonium persulfate as polymerization catalyst served satisfactorily. The resulting emulsion was only moderately stable and could be coagulated readily by the addition of aqueous solutions of sodium chloride, acetic acid, or mixtures of the two. Another proprietary emulsifier and hydrogen peroxide also could be used conveniently to produce emulsions of only moderate stability. Emulsions remarkably stable to electrolytes (but not to mechanical agitation or solvents such as acetone and ethanol) could be made with still another commercial preparation. Two of these emulsifiers used together in various proportions produced emulsions of almost any desired degree of stability toward electrolytes. Stable emulsions for brushing and spraying were made with various combinations of agents, of which one was composed of an emulsifier, ammonium alginate, ammonium hydroxide, and ammonium persulfate. The viscosity of acrylic resin emulsions could be controlled over a wide range by using various quantities of ammonium alginate, modified casein, and a proprietary emulsifier. Films obtained from these emulsions adhered well to smooth surfaces.

**Preparation and reclamation of copper—chromium oxide catalyst,** R. E. DUNBAR and M. R. ARNOLD. (N. Dak. Agr. Col.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 7, p. 441).—Carborundum aggregates, Celite pellets, and

granular Celite were tested as supporting materials for copper-chromium oxide catalyst, and this combination was found satisfactory for dehydrogenation of alcohols. The usual acetic acid leaching and washing of the catalyst could be omitted if adequate heat treatment at 150° C. was substituted. Copper-chromium oxide catalyst which had become sluggish in its action through prolonged use could be reactivated or reclaimed by heating to expel absorbed organic material and reoxidize the reduced metals. Acetic acid leaching and washing then provided a catalyst as active as the original for the dehydrogenation of alcohols.

**Solvent extraction of cottonseed and peanut oils:** Boiling point, vapor pressure, composition relations for miscellas of oils in hexane, E. F. POLLARD, H. L. E. VIX, and E. A. GASTROCK. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 10, pp. 1022-1026, *illus.* 6).—The boiling points and densities of mixtures of cottonseed and peanut oils with commercial hexane are reported. They were useful in the design of vacuum evaporators and strippers and for control operations involving temperature, time of heating, and concentration of oil-solvent mixtures of various compositions, to prevent or minimize fixation of objectionable coloring matter or other deteriorative heat effects. Boiling point data are determined at various concentrations of crude cottonseed oil and crude peanut oil, over a range of pressures from 160 to 760 mm. absolute in commercial hexane. The reported data are considered likely to be of value in the further development of the technology of the solvent extraction of vegetable oils. Observations of the effect of agitation in establishing equilibrium conditions of the oil-solvent mixtures were made. The Raoult law and the Dühring rule could not be applied for predicting data of the necessary accuracy within the critical operating region.

**Viscosities and densities of solvent-vegetable oil mixtures**, F. C. MAGNE and E. L. SKAU. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 11, pp. 1097-1101, *illus.* 6).—A pycnometer and a viscometer suitable for use with volatile mixtures and for low-temperature determinations are described. Density and viscosity measurements were made from incipient crystallization to a temperature near the boiling point of the solvent for the complete binary systems cottonseed oil-commercial hexane, cottonseed oil-acetone, cottonseed oil-2-butanone, peanut oil-commercial hexane, and soybean oil-commercial hexane. From these data it was possible to construct for any of these systems the density-composition and viscosity-composition curves for temperature as well as the density-temperature and viscosity-temperature curves for any composition. The various systems are compared and their idealities discussed. The density-composition curves for the binary systems of commercial hexane with the three oils practically coincided. The viscosity-composition curves for these systems almost coincided up to about 60 percent by weight of oil and then diverged to the values for 100 percent oil. The same was true of the binary systems of cottonseed oil with the three solvents, except that the curves started to converge again at about 90 percent to meet at the 100 percent oil value. The applicability of these data to other random samples of these vegetable oils is discussed.

**The action of copper and antioxidants in linoleic acid autoxidation**, F. G. SMITH and E. SROTZ (*New York State Sta. Tech. Bul.* 276 (1946), pp. 30, *illus.* 13).—The effects of copper (significant acceleration by concentrations as low as 0.005 p. p. m., maximal acceleration by about 5 p. p. m.), a typical heavy metal catalyst, and several types of antioxidants on linoleic acid autoxidation were studied by measuring the rate of oxygen uptake of aqueous suspensions in Warburg apparatus.

Added copper increased the maximum rate, approximately in proportion to the logarithm of concentration. This catalyst also shortened the induction period and at any stage of reaction immediately caused rates paralleling copper controls. This evidence, together with the results of the contaminating copper in the controls,

pointed to the copper content as the controlling factor in autoxidation rate under these experimental conditions.

The effect of three copper-complex-forming compounds, sodium diethyl-dithiocarbamate, 8-hydroxyquinoline, and cyanide, was investigated both with and without added copper and by addition at various stages of the reaction. The degree of inhibition effected by each of these compounds depended on the concentration of copper and the time of addition.

The inhibitive action of hydroquinone, a typical oxidizable antioxidant, and its corresponding quinone varied less with copper concentration and showed other evidences of difference in mechanism of action from the copper inhibitors. Comparison of the stability of 8-hydroxyquinoline and sodium 2,6-dichlorobenzeneoneindophenol during linoleic acid autoxidation provided further evidence of difference in action of copper inhibitors and oxidizable antioxidants, suggesting that the distinction may be of general importance in the investigation of fat preservation.

Peroxidase was found to accelerate and catalase to inhibit linoleic acid autoxidation.

**Alkaloid distribution in the bark of some Peruvian cinchonas**, W. H. HODGE (U. S. Dept. Agr., Forest Serv., *Caribbean Forester*, 7 (1946), No. 1, pp. 79-92; *Span. trans.*, pp. 86-91; *Fr. abs.*, pp. 91-92).—The analyses of selected bark samples of wild cinchona trees growing in Peru indicated that the alkaloid content varies appreciably in ascending from the base of a tree towards the top. In some types of cinchonas alkaloids were higher in quantity at the base of the trunk than in the upper parts of the tree, but in still other types of cinchonas the reverse condition existed with alkaloids lower in quantity at the base of the trunk than in the upper parts of the tree. Samples of wild trees taken for purposes of estimating commercial yields must include therefore bark from these two parts of the tree. A relationship also appeared to exist between the quantity of alkaloids present in a tree and the girth (or age) of the tree. Alkaloids either increased or decreased in quantity with increase in girth of the tree, and this increase or decrease depended upon the alkaloid and upon the type of cinchonal involved.

On the basis of the physiological evidence obtained, there appeared to be some question as to the correctness of the present taxonomic classification with the genus. This evidence is held to suggest that the bark collector's type *morada* is incorrectly included in the species *Cinchona pubescens*.

**A product of oxidative metabolism of pyridoxine, 2-methyl-3-hydroxy-4-carboxy-5-hydroxy-methylpyridine (4-pyridoxic acid).**—I, Isolation from urine, structure, and synthesis, J. W. HUFF and W. A. PERLZWEIG (*Jour. Biol. Chem.*, 155 (1944), No. 1, pp. 345-355, illus. 3).—Detailed experiments are presented on the isolation, identification, and synthesis of the metabolite of pyridoxine, previously reported (E. S. R., 93, p. 370). The name 4-pyridoxic acid has been given to the fluorescent compound which appears in urine after the ingestion of pyridoxine. Based upon characteristic fluorescent curves of this metabolite and its lactone, a method was developed for the quantitative determination of either compound. The application of the method to the direct estimation of the lactone in urine is presented.

**Production of tyrothricin in cultures of *Bacillus brevis***, J. C. LEWIS, K. P. DIMICK, and I. C. FEUSTEL. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 10, pp. 996-1004, illus. 8).—Yields of tyrothricin better than 2 gm. per liter of medium were obtained through the growth of *B. brevis* (B. G.) in shallow layers of medium. Maximum yields were found after 10 or 16 days of incubation at about 35° C. with the medium disposed in 11-mm. layers. Complex sources of nitrogen, including acid hydrolyzate of casein, corn-steep liquor, tryptic digest of soybean meal, and press juice concentrates from waste asparagus butts, proved most suitable; relatively simple substances, such as glutamic acid, asparagine, or

ammonium sulfate plus citric or malic acid, proved moderately effective in the presence of 0.2 percent of a specified proprietary bacterial nutrient. About 3 to 5 percent of a fermentable carbon compound, such as glucose, mannitol, or glycerol, was necessary for best yields. Fructose, sucrose, lactose, and maltose proved much less effective. Requirements for calcium, magnesium, and manganese were demonstrated. Unlike the other nitrogen sources mentioned, properly processed asparagus concentrates yielded nutritionally complete media without addition of sugar or inorganic elements.

**A centrifuge tube agitator**, R. F. REITEMEIER. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 4, p. 267, illus. 2).—The essential component of this device is the actuating mechanism of a manual valve grinder of a specified commercial make. The gears in the body of this tool are so designed that when the crank is turned in one direction the chuck moves  $\frac{2}{3}$  revolution clockwise, then 1 revolution counterclockwise, and repeats this movement. Thus the motion of a centrifuge tube that rotates with the chuck somewhat resembles that of a tube rotated between the palms of the hands. When the crank is turned rapidly, the tube is agitated sufficiently to provide rapid mixing of the contents. A plastic holder for the centrifuge tube is described and is shown in a cross-section drawing. The agitator, arranged for motor operation and combined with a microburette titration assembly, is shown in a reproduction of a photograph. Constructional detail is given and dimensions fully specified.

**An extractor for use with reduced pressure**, W. F. BARTHEL. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 1, pp. 53-54, illus. 1).—Among the modifications described and figured are a glass extraction thimble with overflow tube, designed to keep the material being extracted covered continuously with fresh solvent, a long finger condenser with provision against vibration of its inner tube, and a side tube attached to the boiling flask to permit adding solvent and introducing a capillary leakage tube to induce smooth boiling. The finger condenser was substituted for the spiral or Allihn condensers of apparatus of the Soxhlet type because condensers of either of the last-named forms flooded when used under reduced pressure. The modified apparatus could be used at atmospheric as well as at reduced pressures.

**Apparatus for measuring rate of gas penetration through food-packaging materials**, F. R. SMITH and M. KLEIBER. (Univ. Calif.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 9, pp. 586-587, illus. 1).—The authors describe an apparatus for measuring the rate of gas penetration through flexible materials. The apparatus was particularly suitable for determining the rate of oxygen penetration into pouches used for food packaging. The absolute accuracy of the measurements was determined mainly by the accuracy of gas analysis. The relative accuracy can be changed by varying the time of penetration and thus the difference between start and end concentration of oxygen in the gas inside the pouch.

**Alternating current-operated thermionic titrimeter with adjustable range and sensitivity**, E. M. BURAS, JR., and J. D. REID. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 2, pp. 120-125, illus. 4).—A stable, alternating current-operated, continuous reading, inexpensive vacuum tube voltmeter is described, the instrument having been designed to be simple in construction and operating. Its use as a titrimeter, a pH meter, and a direct current voltmeter is detailed. In the last-named application it served as a continuous reading potentiometer. It had a range of approximately 10 v. and a sensitivity of  $\pm 0.0001$  v. A calibration switch provided standard reference points for pH measurements. Independence of range and sensitivity controls made it versatile in electrochemical measurements with all the usual electrode systems, including the glass electrode.

**Weighing funnels**, M. S. SCHECHTER and H. L. HALLER. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 2, p. 133, illus. 1).—One of

these funnels has a body similar to that of a thistle tube, its stem being bent to form two return bends, the open end of the resulting S terminating a little below the level of the first turn. This funnel was suspended from the balance-pan hook by a fine wire at an angle such that a small liquid sample could be placed in the body of the funnel for weighing. By turning the funnel into a vertical position with the end of the stem hanging into the neck of the reaction flask, the sample could be washed into the flask, the solvent added from a washbottle siphoning intermittently in a manner which facilitated the transfer of samples of solids from the funnel into the flask.

The second funnel is of a pear shape, with a wide opening at its larger end, one side flattened to permit placing the funnel on the balance pan, and a short stem at the narrower end of the pear.

**Mineral contamination resulting from grinding plant samples**, S. L. HOOD, R. Q. PARKS, and C. HURWITZ. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 3, pp. 202-205, illus. 2).—Various grinding methods were compared to determine the number of elements added during grinding and their relative seriousness as contaminants in preparation of plant samples. This paper reports the effects of type of method, type of plant material, duration of grinding, and size of plant sample upon contamination.

**Color of aqueous potassium dichromate solutions**, R. E. KITSON and M. G. MELLON. (Purdue Univ.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 1, pp. 42-44, illus. 3).—A spectrophotometric study of the color of aqueous potassium dichromate solutions included the effect of pH and of the concentration of acid, base, and dichromate. All these variables had an effect on the color of the solutions. Any recommendations of potassium dichromate solutions as permanent colorimetric standards should specify the exact nature of the solution.

**Determination of water in dry food materials: Application of the Fischer volumetric method**, C. M. JOHNSON. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 5, pp. 312-316, illus. 2).—With the Fischer volumetric method it was possible to determine the moisture content of starches, sugars, pectin, and spray-dried egg powder fairly rapidly and to get results that agreed with those obtained by the standard vacuum-oven technic. The apparent moisture contents of a number of dehydrated vegetables and fruit powders when determined by electrometric titration were generally slightly higher than those obtained by the vacuum-oven method.

In uncolored solutions, the end point of the Fischer titration could be detected fairly accurately by observing the appearance of the brown color of free iodine. In solutions containing colored substances or considerable quantities of spent reagent, the end point became exceedingly difficult to see, however. One of the most important adaptations of the Fischer method discussed in this paper consisted in the development of an electrometric detection of the end point. Interferences are discussed and are shown to be unlikely to introduce significant errors into the results of determinations of the moisture contents of foodstuffs.

**Determination of moisture in naval stores products by the Karl Fischer method**, V. E. GROTLISCH and H. N. BURSTEIN. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 6, pp. 382-383).—Although the moisture content in pine oils has been determined in a method of the Bidwell and Sterling type (E. S. R., 53, p. 805) with toluene as the solvent, the normal percentage of moisture in turpentine and other terpene solvents is too low to be determined in this way. The inapplicability of cloud-point moisture determinations is also shown. Separate Fischer titration procedures adapted for pine oils and for the terpene solvents, respectively, are detailed.

**Microdetermination of nitrates by the Devarda method**, R. KIESELBACH (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 12, pp. 764-766, illus. 1).—It is shown that microquantities (0.05 milliequivalent) of nitrates can be determined with a precision and accuracy of 99.8 percent by reduction with Devarda's alloy, the ammonia liberated being absorbed in boric acid and titrated with 0.01 N hydrochloric acid to bromocresol green-methyl red end point. It is stated that by following the procedure given, a single determination could easily be made in 20 min. Nitrites and ammonia interfered, but interference of ammonia could be easily overcome. Special apparatus described was convenient, but not essential.

**Catalytic activity of selenates in the Kjeldahl method for determination of nitrogen**, R. S. DALRYMPLE and G. B. KING. (Wash. State Col.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 6, pp. 403-404, illus. 1).—For a sample of pea meal, chosen as very difficult to decompose completely, digestion with metallic selenium as the catalyst required 6 hr. The use of copper selenate cut the digestion time to 2.5 hr., calcium selenate to 3 hr., and cadmium selenate to 3.5 hr. The nitrogen content determined by the Official (Kjeldahl-Gunning-Arnold) method was somewhat less than the maximum found when selenium or the selenates were used as the oxidation catalysts, but this method gave good agreement with the selenate methods in the analysis of some other samples. The nitrogen content determined with the aid of the selenates rose to a maximum and then fell off after more prolonged digestion, and so, because the optimum time of digestion would have determined for each type of protein sample and somewhat exactly adhered to, the authors do not consider the use of selenates to be practicable.

**Factors affecting determination of potash in fertilizers**, H. L. MITCHELL and O. W. FORD. (Ind. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 2, pp. 115-116).—It was found that the presence of phosphates led to appreciably low results in the determination of potash by the official Lindo-Gladding method. Somewhat higher potash values were obtained when the phosphate was removed by precipitating with magnesium chloride. When freshly prepared sodium hydroxide solutions were used, the potassium chloroplatinate was contaminated with little or no water-insoluble residue. However, upon standing for some time, sufficient sodium silicate was produced by action of the alkali on the glass container to cause the formation of considerable residue.

**Photometric determination of phosphorus in limestone**, J. A. BRABSON, J. H. KARCHMER, and M. S. KATZ (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 9, pp. 553-554, illus. 1).—The authors describe a photometric method for the determination of phosphorus in limestone when present in amounts ranging from 0.002 to 0.4 percent  $P_2O_5$ . The sample is ignited to destroy organic matter, which is removed by dehydration with perchloric acid, and phosphorus is determined in the filtrate by the phosphovanadomolybdate method. When applied to National Bureau of Standards samples of argillaceous limestone 1 and 1-a, containing 0.18 and 0.14 percent  $P_2O_5$ , respectively, results within 0.01 percent of the Bureau of Standards values were found. The effect of interfering elements and the use of a filter photometer are discussed.

**Determination of cobalt in biological materials with nitrosocresol**, G. H. ELLIS and J. F. THOMPSON. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 4, pp. 254-257, illus. 1).—A quantitative colorimetric procedure for the determination of from 0.02 to 25  $\mu$  of cobalt in plant or animal tissues is described. The method depends on the formation of the colored complex of cobalt with o-nitrosocresol, which is extracted from the aqueous phase by ligroin and measured in a photoelectric colorimeter fitted with absorption cells 10 cm. in depth, requiring a volume of 1.8 cc.

It was found that in most plant and animal tissues the cobalt concentrations are so small in proportion to those of iron that the use of a citrate buffer was not sufficient to prevent iron interference in the cobalt determination. The iron could, however, be separated completely from the cobalt by extraction with suitable solutions either of dithizone or of sodium diethyldithiocarbamate, the first-named of these reagents being the more generally applicable. The compound referred to as nitrosocresol or as *o*-nitrosocresol was 3-hydroxy-4-nitrosotoluene, and was prepared as a solution of its copper salt by treating a solution of *m*-cresol and cupric chloride with hydroxylamine and adding 30 percent hydrogen peroxide. In a refrigerator, this stock solution was stable for months. For the cobalt determination, a solution of the less stable sodium salt of the nitroso compound was prepared from the stock copper-salt solution.

**Ashing procedures for the determination of copper in plant material**, L. F. BAILEY and J. S. MCHARGUE. (Ky. Expt. Sta.). (*Plant Physiol.*, 20 (1945), No. 1, pp. 79-85).—Porcelain and silica dishes used for ashing tomato and alfalfa plant materials altered the copper content of these materials. Platinum crucibles interfered in the determination of copper with sodium diethyldithiocarbamate. Wet ashing appeared to be much more reliable when copper was to be determined. Results from three wet ashing procedures were in good agreement.

**Colorimetric determination of iron with disodium-1,2-dihydroxybenzene-3,5-disulfonate**, J. H. YOE and A. L. JONES (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 2, pp. 111-115, illus. 3).—The catechol derivative named was found to constitute a sensitive, stable, and widely applicable reagent for the colorimetric determination of ferric iron. The nature of the reaction and chemical behavior of the ferric complex was studied both visually and spectrophotometrically. The reagent could be used in either acid or alkaline medium. In alkaline solution (pH 9 to 10), it was sensitive to 1 part of iron in 200,000,000 parts of solution when observations were made in Nessler cylinders (50-cc., tall-form). In acid solution (pH 3.5 to 4.5), the sensitivity was 1 part in 30,000,000. The colored complexes (red in alkaline medium, blue in acid) obeyed Beer's law over the useful range of iron concentration. A variety of materials was analyzed with a high degree of accuracy. The number of interfering ions was found small. Analyses could be carried out in the presence of fluorides, phosphates, tartrates, citrates, oxalates, etc. Procedures for the use of the reagent are given.

**Determination of small amounts of molybdenum in plants and soils**, M. L. NICHOLS and L. H. ROGERS. (Cornell Univ.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 2, pp. 137-140, illus. 2).—Spectrographic, colorimetric, and polarographic procedures for the determination of small quantities of molybdenum in plants and soils were studied. It is concluded that, for the ordinary laboratory, the colorimetric procedure is superior if reasonable amounts of sample (1 gm. or more of soils, 10 gm. or more of air-dried plant material) are available. However, if only small quantities of sample are available (100 mg. of soil, 1 gm. of air-dried plant material), the spectrographic procedure is recommended. The polarographic procedure was found to have no particular advantages over the other two.

**A modification of the ethanolamine hydrolysis method for determination of methyl bromide**, R. D. CHISHOLM and L. KOBLITSKY. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 8, p. 538).—The modified method here described was designed for the sampling of the atmosphere of fumigation chambers during experiments on the behavior of methyl bromide as an insecticidal fumigant. It involved withdrawal by aspiration of a portion of the atmosphere of the chamber, passing it through a series of absorption tubes packed with sand wet with ethanolamine, and subsequent determination of the bromide ion by the Volhard method. In this way gas losses during sampling were avoided. In a

chamber exposed to the effect of wind, recovery of methyl bromide from a volume of 1,000 cu. ft. ranged from the equivalent of 96 to 100 percent of a 1-lb. charge (mean recovery 97 percent), 95 to 100 percent of a 2-lb. charge (mean recovery 97 percent), and 91 to 98 percent of a 4-lb. charge (mean recovery 95 percent). The samples were taken 15 min. after introduction of the fumigant. Making a calculated correction for normal rate of leakage and increased rate due to wind, the authors found the actual recoveries to be from 1 to 2 percent greater than those above indicated.

**Determination of starch in sweet potato products and other plant materials,** E. T. STEINER and J. D. GUTHRIE. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 12, pp. 736-739).—A polarimetric method was adapted for the determination of starch in sweetpotato products and other plant materials. By use of the specific and quantitative precipitation of starch as starch iodide and by the further use of developed uranyl acetate as a protein precipitant, the effect of substances which interfere with most methods for the determination of starch was largely eliminated. When the method was tested on samples containing large amounts of protein, pectin, inulin, and other interfering substances, the starch values obtained were closer to the true starch content than were those found by either the malt-diatase or Hopkins method. The addition of a number of different substances commonly found in biological materials did not significantly alter the starch values obtained with the proposed method. The procedure described appeared to be applicable to materials containing 10 percent or more starch on the moisture-free basis. The specific rotation for the conversion of polarimetric readings to starch was found to be 200.9 for the proposed method.

**Analysis of wood sugars,** J. F. SAEMAN, E. E. HARRIS, and A. A. KLINE. (U. S. D. A. et al.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 2, pp. 95-99, illus. 6).—It is noted that experimental work on wood saccharification requires determinations of reducing and fermentable sugars and of alcohol which will be dependable, simple, rapid, and capable of being carried out in large numbers. Two copper-reduction methods were used for the determination of reducing sugars—one an electrometric titration method and the other a micromethod. The electrometric titration method was used when it was desirable to have a sugar analysis in as short a time as possible, the micromethod when large numbers of determinations were made or when concentrations and quantities available were too low for the macro-methods. Fermentable sugars were estimated by determining the amount of sugar sorbed from a 1.5 mg. per cubic centimeter solution by a 5.0 percent yeast suspension. Alcohol was determined by the specific gravity method, using a Westphal balance with a thermostated container for the beer distillate. It was found that the error due to the effect of surface tension on the wire supporting the bob could be eliminated by the addition of a very small quantity of a wetting agent.

**Microdetermination of hydroxyl content of sugars and glycosides,** B. E. CHRISTENSEN and R. A. CLARKE. (Oreg. State Col.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 4, p. 265).—A method which had been found successful for numerous alcohols, phenols, and polyhydroxy compounds, and consisted essentially in esterifying with acetic anhydride in pyridine solution in a sealed tube and titrating the acid liberated on contact of the reaction mixture with water, was adapted for use with sugars and glycosides by the use of a larger volume of pyridine to bring the sugars into solution and by increasing the time allowed for the esterification.

**Microdetermination of acetyl groups in acetates of sugars and glycosides,** R. CLARKE and B. E. CHRISTENSEN. (Oreg. State Col.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 5, pp. 334-335, illus. 1).—A 5- to 10-mg. sample of the acetate was weighed out in a small glass boat and placed in a 25-cc. Erlen-

meyer flask. The sample was then dissolved in 95 percent ethanol, 2 to 5 cc., depending upon the solubility of the acetate, and warmed if necessary to obtain solution. Four cc. of 0.045 N sodium hydroxide (carbonate-free) were added from a microburet. The flasks were stoppered and shaken mechanically or intermittently by hand for 4 to 24 hr. at 20° C. The excess alkali was neutralized with dilute sulfuric acid (0.05 N) using phenolphthalein indicator. These conditions appeared satisfactory in all tests except those applied to the reducing monosaccharides. The deacetylation of glucose penta-acetate at 20° gave high results even when 0.015 N sodium hydroxide was used, an observation taken to indicate that oxidation accompanied the hydrolysis. The slower hydrolysis occurring at 0° gave more nearly normal results.

**Determining chlorophyll, carotene, and xanthophyll in plants,** R. B. GRIFFITH and R. N. JEFFREY. (Ky. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 7, pp. 438-440).—A method for the determination of chlorophylls a and b, carotene, and total xanthophyll from a single ether solution is described. This method is considered to be adaptable to any spectrophotometer of good resolving power provided preparations are available for determination of absorption constants for the instrument to be used. The pigments were extracted from the plant material with acetone and transferred to ether, and chlorophyll was determined from the light absorption at the wave lengths of the chlorophyll a and b maxima in the red end of the spectrum. Carotene and xanthophyll were separated in the unsaponified ether solution by means of the flowing chromatographic technic and then determined spectrophotometrically. Evidence of the reproducibility of results which may be expected from this method is presented. The results of single determinations were found to seldom vary more, with respect to each pigment determined, than 5 percent from the average of those given by four similar samples.

**Determining the hydroxyl content of certain organic compounds: Macro- and semimicromethods,** C. L. OGG, W. L. PORTER and C. O. WILLITS. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 6, pp. 394-397, illus. 3).—A modification of macroprocedures for determining the hydroxyl content of hydroxylated fatty acids and alcohols is described, an internal indicator having been used. For colored solutions a potentiometric method was developed. A semimicro-procedure using an internal indicator is also presented. An acetylating solution of 1 volume of acetic anhydride in 3 volumes of pyridine and a hot-water hydrolysis were used.

**Errors in the Zeisel methoxyl values for pectin due to retained alcohol,** E. F. JANSEN, S. W. WAISBROT, and E. RIETZ. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 8, pp. 523-524).—Retained ethanol caused the methoxyl content of pectins, as measured by the Zeisel method, to be as much as 20 percent higher than saponification values. This ethanol cannot be removed by the usual drying technics, even the Abderhalden drier procedure reducing the apparent Zeisel methoxyl content only slightly, but can be removed by humidification followed by drying. Acetone rather than ethanol precipitation results in good agreement between the two methods of analysis. Retained isopropyl alcohol can be removed by drying at 100° C. The humidification, above mentioned, was accomplished by placing the pectin samples in a desiccator containing water instead of a drying agent, toluene being placed on the water surface to prevent mold growth. The required humidification was attained either with or without a slow stream of air bubbled through the water.

**Analysis of the organic acids of orange juice,** W. B. SINCLAIR, E. T. BARTHOLOMEW, and R. C. RAMSEY. (Calif. Citrus Expt. Sta.). (*Plant Physiol.*, 20 (1945), No. 1, pp. 3-18, illus. 4).—The acid constituents of orange juice, as determined by titrating the juice directly with standard NaOH to a phenolphthalein end point, were

equivalent to the percentages determined by the lead acetate method. The total free acids determined from the points of inflection on the titration curves were significantly lower than those reported both for the phenolphthalein titration and for the lead acetate method. When juice samples were titrated, with phenolphthalein as indicator, the end points ranged from pH 8.25 to 8.45. The potentiometric values were taken to represent more accurately the total acidity. The concentration of malic acid in various juice samples differed only slightly as compared with the changes in the citric acid content. With one exception, the samples studied had a malic acid content of from 1.40 to 1.77 mg. per milliliter.

"Apparently, there is a definite relation between the free acid-combined acid balance and the pH of the juice. The amount of combined acids in the juice is remarkably uniform; this indicates that the free-acid concentration is the chief variable. With a decrease in the value of

total free acid

total free and combined acids  
a corresponding rise in pH occurs."

**Determination of sesamin.** M. JACOBSON, F. ACREE, JR., and H. L. HALLER. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 3, pp. 166-167, *illus. 1*).—A method for the quantitative determination of sesamin in sesame oil is based upon measurement of the greenish-yellow color produced by sesamin when it is allowed to react with a mixture of perchloric acid and hydrogen peroxide. The standard error of the final result was found to be practically constant, amounting to about  $\pm 0.05$  percent of sesamin when the result of a single determination on an unknown is read from a curve established from 10 replicates.

**Determination of wax in cotton fiber: A new alcohol extraction method.** C. M. CONRAD. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 12, pp. 745-748, *illus. 1*).—A new technic for the determination of the wax of cotton fiber consists of a two-step process in which the wax is first extracted with hot 95 percent ethyl alcohol and then transferred to chloroform through a phase-separation process, in order to eliminate sugars, mineral constituents, and other nonwaxy constituents removed at the same time by the alcohol. The wax is extracted from cotton fiber more rapidly by hot alcohol than by chloroform, the most rapid and adequate of a considerable number of common wax solvents previously studied. The wax thus determined contains a negligible amount of mineral impurities and is less contaminated with sugars than that determined in the usual Soxhlet extraction.

**Adsorption analysis of colorless compounds: Method and application to the resolution of stearic and oleic acids.** H. J. DUTTON. (U. S. D. A.). (*Jour. Phys. Chem.*, 48 (1944), No. 4, pp. 179-186, *illus. 4*).—The authors describe an adsorption analysis and separation technic made applicable to colorless compounds by the use of a highly sensitive differential refractometer modified for measurement of changes in the refractive index of percolates from adsorption columns during continuous flow. The resolution of stearic and oleic acids was studied as an example of the application of this general method. Advantages and limitations of the method are discussed. As development of the column is provided for in the modified method, and the size of the adsorption column is not restricted, the new technic is applicable to large-scale preparative as well as qualitative and quantitative analytical procedures. Furthermore, the observed readings from this system are directly proportional to the difference between the refractive indices of the solution and the solvent ( $\Delta n$ ), and hence are proportional to the concentration where a single solute is involved.

**Determination of sulfur dioxide in dehydrated foods.** A. N. PRATER, C. M. JOHNSON, M. F. POOL, and G. MACKINNEY. (U. S. D. A. coop. Univ. Calif.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 3, pp. 153-157, *illus. 2*).—In principle, the method described consists in extracting the sulfur dioxide from the

finely ground sample with a weak aqueous sodium hydroxide solution, titrating for total reducing substances with iodine, treating a second aliquot with acetone after adjustment of the pH value from 2 to 3, and then determining the reducing power for the iodine solution used of the reducing substances other than sulfur dioxide by a second iodine titration. The reliability of the method was established by recovery of added sulfur dioxide and by comparison with distillation and polarographic methods.

**Determination of total sulfur in feeds: Modified nitric and perchloric acid digestion procedure,** R. J. EVANS and J. L. ST. JOHN. (Wash. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 10, pp. 630-631).—A method of determining the total sulfur content of feeds and similar substances by destroying the organic matter and oxidizing the sulfur compounds to sulfates by digestion with nitric and perchloric acids is described. The sample is dissolved and partially oxidized by heating with concentrated nitric acid on a steam bath for 24 hr. The most important modification is the more complete oxidation of the sulfur compounds to sulfates, which is accomplished by gentle boiling with perchloric acid for about 15 hr. The results obtained agree with those by the Parr bomb method.

**Separation of cholesterol from degreas,** L. YODER, O. R. SWEENEY, and L. K. ARNOLD. (Iowa Expt. Sta.). (*Indus. and Engin. Chem.*, 37 (1945), No. 4, pp. 374-377, illus. 4).—Wool fat (degreas) was saponified in 52.5-lb. batches by sodium hydroxide, and the unsaponifiable material was extracted from the wet soaps by gravity separation with ethylene dichloride. Cholesterol of 97 percent digonin precipitability was prepared from the unsaponifiable extract in 4-lb. yields per batch by a pilot process based on the formation of the oxalic acid addition product insoluble in ethylene dichloride solutions. Byproducts obtained per batch were 37 lb. of fatty acids, 14 lb. of oily unsaponifiable material, and 9 lb. of ischolesterol wax.

**Some color tests for rotenone not specific,** H. L. HALLER. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 4, p. 277).—The author reports experiments indicating that neither the evanescent blue color produced by treating rotenone with nitric acid and then with ammonia, nor the red color formed when the compound is treated with alcoholic potassium hydroxide containing sodium nitrite and then acidified with sulfuric acid can be regarded as entirely specific for rotenone or rotenoid compounds. From the results reported, it is concluded that "considerable caution should be taken in interpreting the color obtained in both these tests when they are applied to plant material other than *Derris*, *Lonchocarpus*, and *Tephrosia*. Rotenone should be reported as present in plants only when it has been definitely isolated and characterized."

**Colorimetric analysis of xanthone spray residues,** C. C. CASSIL and J. W. HANSEN. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 1, pp. 35-37, illus. 2).—A colorimetric method for the determination of xanthone spray residues consists in adding a measured quantity of toluene to a sample of apples or apple plugs in a glass jar and shaking for 5 min. The resulting solution of xanthone and apple waxes is filtered and an aliquot of the filtrate taken for analysis. The xanthone is reduced to xanthidrol by refluxing with sodium amalgam in toluene and methanol. After removal of the methanol by a water extraction, an aliquot of the supernatant toluene solution is swirled in concentrated hydrochloric acid, effecting an equilibrium transfer of the xanthidrol to the acid layer to give a yellow color, which is measured photometrically.

**The effect of light on the stability of the Carr-Price color in the determination of vitamin A,** M. J. CALDWELL and D. B. PARRISH. (Kans. Expt. Sta.). (*Jour. Biol. Chem.*, 158 (1945), No. 1, pp. 181-186, illus. 1).—Standard solutions of vitamin A were studied under carefully controlled conditions in various photometers where the intensities of the light illumination were determined or regulated. Graphic repre-

sentations of the results illustrate the marked influence of the light intensity upon the rate of fading of the characteristic blue color of the reaction. Loss of color ranged from 7.8 percent in the Evelyn photometer to as high as 89.4 percent when a 200-watt bulb was used. In the Coleman photometer, reduction of the incident light from 100 to 13 decreased the fading from 39 to 18.2 percent for a 60-sec. reading interval.

Exposure of the vitamin A solution to strong light (for 2 min.) prior to the addition of the antimony trichloride (which causes formation of the blue color) did not affect the subsequent color production.

The influence of illumination on the accuracy of the determination and its effect on the kinetics of the Carr-Price reaction is discussed.

**Determination of vitamin A in dehydrated eggs,** W. G. SCHRENK, D. S. CHAPIN, and R. M. CONRAD. (Kans. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 10, pp. 632-634, illus. 1).—A spectro-chemical method for the determination of vitamin A in dehydrated eggs is described. The procedure involves careful control of analytical conditions, followed by the use of a correction factor required because of the absorption of ultraviolet radiation by the carotenoid pigments present. The correction had to be so defined as to include the effects of isomerization of the pigments caused by the analytical process, and was determined on the basis of the two principal pigments present, luteol and zeaxanthol. The absorption spectra of these two pigments, in absolute ether, and the specific absorption coefficients at their wave lengths of maximum and minimum absorption are presented.

**Chromatographic determination of carotene in alfalfa,** L. W. CHARKEY and H. S. WILGUS, JR. (Colo. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 3, pp. 184-187, illus. 3).—The author reports, with experimental results indicating its accuracy, an adsorption-column method which avoids the oxidative losses of carotene generally encountered in freshly harvested plant tissues, as well as errors due to incomplete extraction and incomplete separation of carotenes from other pigments present. The method includes an enzyme inactivation and sample storage procedure, making possible the collection and preparation of large numbers of samples on fixed dates. The chromatographic technic was modified for the purpose at hand by converting the adsorption column to an adsorption filter which avoids losses of adsorbed carotene.

**Effects of beta-carotene isomerization on its absorption at 326 millimicrons,** W. G. SCHRENK, R. E. SILKER, and H. H. KING. (Kans. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 5, pp. 328-329, illus. 1).—The authors report observations indicating a straight-line relationship between the extent of the isomerization of  $\beta$ -carotene and its calculated optical density ratios. They hold that the isomerization of  $\beta$ -carotene, due in part to heating of the material under examination, is at least partly responsible for the wide range of correction values in use in the determination of vitamin A from its ultraviolet absorption. The correction required at 326 m $\mu$  for  $\beta$ -carotene in a specified commercial light-petroleum solvent was calculated on the basis of spectrophotometer data and shown to be a linear function of the percentage isomerization.

**The vitamin B<sub>6</sub> group, III-IV, VI-VII** (*Jour. Biol. Chem.*, 157 (1945), No. 2, pp. 475-505; 158 (1945), No. 2, pp. 491-503).

III. *The vitamin activity of pyridoxal and pyridoxamine for various organisms,* E. E. Snell and A. N. Rannefeld (pp. 475-489).—Preliminary studies by Snell (E. S. R., 93, p. 660) on the activities of pyridoxal (I) and pyridoxamine (II) as growth factors for micro-organisms have been extended.

Pyridoxine, as well as (I), (II), and several related derivatives including the isomeric amine and aldehyde, the 5-formyl derivative, and 4-pyridoxic acid and its

lactone, were tested with the following organisms: *Streptococcus faecalis* R, *Lactobacillus casei*, and *Saccharomyces carlsbergensis*. Rats, yeasts, molds, and bacteria served to test the relative activities of (I), (II), and pyridoxine. Results showed that these three compounds had approximately equal activity on a molecular basis for rats, *S. carlsbergensis*, and *Neurospora sitophila*. It was observed that for a large group of lactic acid bacteria, the activities of (I) and (II) varied from a few fold to several thousand fold that of pyridoxine. Autoclaving the medium containing (I) and (II) produced changes which could be detected by the use of different test organisms. Pyridoxal and pyridoxamine were destroyed by light, and were found to be labile when heated in a dilute water solution containing dissolved air.

The implications of some of the results are discussed.

IV. *Evidence for the occurrence of pyridoxamine and pyridoxal in natural products*, E. E. Snell (pp. 491-505).—Based upon the findings that pyridoxal (I), pyridoxamine (II), and pyridoxine (III) have equal growth activities for yeast (see above), a differential test has been devised. *L. casei* was used for the pyridoxal standard, *Streptococcus faecalis* for (II), and *Saccharomyces carlsbergensis* for (III). Natural compounds, yeast extract, liver extract, rice bran concentrate, and powdered dehydrated grass juice were tested for their content of these three derivatives by subjecting them to various chemical treatments.

Results showed that pyridoxal and the pyridoxal fraction of natural materials are inactivated in a comparable fashion by incubation with acetone in alkali, incubation with sodium cyanide and ammonium chloride, or autoclaving with hydrolyzed casein. They remain undamaged by treatment with nitrous acid.

Pyridoxamine and the pyridoxamine fraction of the products tested are completely inactivated by nitrous acid. Autoclaving with  $\alpha$ -ketoglutaric acid decreases the activity of (II) and increases the activity of (I). This is interpreted by the author as a conversion of (II) to (I).

"It is concluded that pyridoxal and pyridoxamine occur naturally, that they constitute a considerable portion of the total vitamin B<sub>6</sub> present in many natural materials, and that the proportions in which the three compounds occur differ markedly with different materials. The presence of these compounds satisfactorily explains 'pseudopyridoxine' activity."

VI. *The comparative stability of pyridoxine, pyridoxamine, and pyridoxal*, E. Cunningham and E. E. Snell (pp. 491-495).—Experiments were made on the effect of light, acids, alkali, and oxidizing agents on pyridoxine, pyridoxamine, and pyridoxal.

Results showed that upon exposure to direct sunlight, diffused daylight, or artificial light all three compounds were rapidly inactivated. Greatest loss of activity occurred with exposure to direct sunlight and in neutral or alkali solutions. Pyridoxamine showed the greatest sensitivity, being unstable in direct sunlight in 0.1 N acid solution while pyridoxine and pyridoxal were comparatively stable in acid solution. Oxidizing agents (manganese dioxide (in acid) and potassium permanganate) rapidly destroyed all three compounds. Heating at 100° C. with 5 N H<sub>2</sub>SO<sub>4</sub> or HCl did not alter the activity of pyridoxine, pyridoxal, or pyridoxamine, while HNO<sub>3</sub> caused rapid destruction under similar conditions. Pyridoxal alone was slightly inactivated when heated 1 hr. with 5 N NaOH.

VII. *Replacement of vitamin B<sub>6</sub> for some microorganisms by d(—)-alanine and an unidentified factor from casein*, E. E. Snell (pp. 497-503).—An enzymatic digest of vitamin-free casein was found to contain a substance which, together with *dl*-alanine, permitted growth of *L. casei* in the absence of vitamin B<sub>6</sub>. This substance differs from B<sub>6</sub> as it is destroyed by acid or alkaline hydrolysis, is not destroyed by light, and is not readily adsorbed from aqueous solutions by charcoal.

When optimal levels of this substance were added to the vitamin B<sub>6</sub>-free medium, the growth response of *L. casei* to alanine could be calculated. It was noted that

under these circumstances *d*(—)-alanine promoted growth, while *l*(+)-alanine was almost inactive showing less than 1 percent of the activity of the *d*-form.

Alanine alone could replace vitamin B<sub>6</sub> for *Streptococcus faecalis* R. In this respect *l*(+)-alanine was less than one-sixth as active as *d*(—)-alanine. When the growth response of the same organism to the optical antipodes of alanine was determined in an alanine-free medium which contained vitamin B<sub>6</sub>, it is found that *l*(+)-alanine was most active, while *d*(—)-alanine showed considerably less activity. The author suggests that both optical forms of alanine are required for growth of these organisms in the absence of vitamin B<sub>6</sub>, each serving different functions within the organism.

A short discussion of these results is included.

**The response of *Lactobacillus casei* and *Streptococcus faecalis* to vitamin B<sub>6</sub> and thymine.** K. KRUEGER and W. H. PETERSON. (Wis. Expt. Sta.). (*Jour. Biol. Chem.*, 158 (1945), No. 1, pp. 145-156, illus. 3).—*L. casei* 7409 and *S. faecalis* 8043 (*S. lactis* R.) were used to test the vitamin B<sub>6</sub> (norit eluate factor) potency of various preparations.

Material isolated from yeast or liver showed the same B<sub>6</sub> potency for both organisms. It was found that thymine could replace B<sub>6</sub> completely in the nutrition of *L. casei* and to a lesser extent with *S. faecalis*. As little as 1 µg. of free thymine in a test sample could erroneously influence the growth response to a marked degree.

Both hydrolyzed casein and synthetic amino acid media were used for the *L. casei* assays. At the 0.5 percent level, the hydrolyzed casein medium did not give optimum response to vitamin B<sub>6</sub>, as supplementation with alanine or leucine, isoleucine, and threonine resulted in an approximately 10 percent increase in titer with the various levels of B<sub>6</sub> used, while leaving the blank unaffected.

The effect of these variables upon the accuracy of the assay with either organism is discussed. Twenty-five references are included.

**Growth stimulants for microbiological biotin assay.** V. R. WILLIAMS and E. A. FIEGER. (La. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 2, pp. 127-130, illus. 3).—The microbiological determination of biotin (using *Lactobacillus casei*) was investigated from the standpoint of growth stimulants. The lipid nature of such interfering factors in rice polish was established by comparing extracts that had been treated by filtration, ether-extraction, enzyme digestion, etc. Methods for obviating the stimulating effect were devised. Various supplements to the basal medium were tested, but none was found successful enough to justify recommendation. Lecithin, mineral oil, oleic acid, whole rice oil, and the unsaponifiable fraction of rice oil were compared as to extent of stimulation produced. In tubes showing high acid and cell production in the presence of basal medium and rice oil without added pure biotin, no evidence of biotin synthesis could be demonstrated.

**Chemical determination and urinary excretion of the metabolite N<sup>1</sup>-methylnicotinamide.** M. HOCHBERG, D. MELNICK, and B. L. OSER (*Jour. Biol. Chem.*, 158 (1945), No. 1, pp. 265-278, illus. 3).—A method is described in detail for the chemical determination of N<sup>1</sup>-methylnicotinamide in urine. The steps involved include direct adsorption of the metabolite on an activated zeolite column, elution with potassium chloride, treatment of the eluate with alkali, development of the fluorescence to maximal intensity in butanol, and comparison of the butanol solution in a fluorometer with a standard similarly treated. Correction for the blank fluorescence is made prior to alkalization. Quantitative recovery of the added N<sup>1</sup>-methylnicotinamide chloride is routinely obtained only when the urine aliquot used is a 6 min. sample or less. The simplified procedure is such that only 1 zeolite column is necessary and 15 urine samples may be tested in 1 day.

Eight normal subjects, subsisting on an adequate diet containing 23 mg. of nicotinic acid (or amide) per day, excreted in 24 hr. from 3.1 to 8.0 mg. of N<sup>1</sup>-methylnicotina-

mide, calculated as nicotinamide. Their average basal excretion value amounted to 24 percent of the dietary intake. Extra excretion of the metabolite following oral postprandial dosage with 50 to 200 mg. of nicotinamide occurred and was approximately 20 percent. An appreciable variation in the values obtained at a given dose level was observed, but the responses of each subject were fairly consistent at different levels of intake. The advantages of the present method are discussed.

**Determination of riboflavin in low-potency foods and feeds,** S. H. RUBIN, E. DE RITTER, R. L. SCHUMAN, and J. C. BAUERNFEIND (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 3, pp. 136-140, illus. 1).—A modification of the fluorometric method of Hodson and Norris (*E. S. R.*, 83, p. 151) is described in detail. The principal changes are: (1) "Extraction in a more dilute acid solution with the aid of a blender; (2) optional use of clarase digestion at pH 4.5; (3) optional use of permanganate treatment at pH 4.5; (4) a riboflavin recovery step when permanganate is used; (5) double reduction of the riboflavin at pH 4.5 instead of 7 to 7.5; and (6) use of the minimum quantity of sodium hydrosulfite during the second reduction of the riboflavin. Two steps require careful adjustment—the back-titration with dilute hydrogen peroxide after permanganate oxidation, and the second reduction of riboflavin by dilute sodium hydrosulfite."

A number of foods including rice, poultry mash, meat, breakfast foods, and a variety of flour or bread products have been assayed. Comparisons are made with other chemical methods and a microbiological method. The authors report that "results by this method showed better agreement with the microbiological assay than did results by fluorometric procedures employing Florisil adsorption."

**Fluorometric determination of riboflavin in eggs,** W. J. PETERSON, R. S. DEARSTYNE, R. E. COMSTOCK, and V. WELDON. (*N. C. Expt. Sta.*). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 6, pp. 370-371).—Stable emulsions which interfered in the fluorometric determination of riboflavin in egg yolks can be clarified by mixing the extract in a Waring blender with a small amount of chloroform. Average riboflavin values for all eggs studied were (micrograms per gram): Yolk, 4.1; white, 2.7; entire egg, 3.2. Variations from day to day in the riboflavin content of eggs from the same bird were extremely small. The difference in the riboflavin content of eggs from different birds on the same ration was large and highly significant. The average ratio of riboflavin in yolks to riboflavin in whites was 1.53. The standard deviation of the ratio was 0.48.

**Use of *Lactobacillus arabinosus* 17-5 for microassay of pantothenic acid,** E. H. HOAG, H. P. SARETT, and V. H. CHELDELIN. (*Oreg. State Col.*). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 1, pp. 60-62, illus. 2).—A rapid microbiological assay method for pantothenic acid used *L. arabinosus* as the test organism. With the growth medium used, assay values with good recoveries of added pantothenic acid could be obtained turbidimetrically after 14 hours' growth, or titrimetrically after 24 to 30 hr. The response to pantothenic acid in the effective assay range (0.01 to 0.08  $\mu$ g. of pantothenic acid) is greater and more rapid for this organism than for *L. casei*.

Good agreement between pantothenic acid values of foodstuffs as determined by the two organisms was obtained. Assay values of yeast concentrates by the chick method are higher than those obtained microbiologically, however.

**Determination of gamma-tocopherol in vegetable oils,** G. S. FISHER. (*U. S. D. A.*). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 4, pp. 224-227, illus. 2).—The assumption that the use of an alcohol as solvent is necessary to the production of a red color in the oxidation of the tocopherols by nitric acid was found to hold only for  $\alpha$ -tocopherol. Red solutions were formed when either  $\beta$ - or  $\gamma$ -tocopherol was oxidized by nitric acid in solution in acetic acid. The  $\alpha$ -tocopherol gave only a slightly yellow solution when treated in this way. The intensity

both of the red color obtained by the oxidation of  $\gamma$ -tocophorol and of the yellow color produced by like treatment of  $\alpha$ -tocophorol was proportional to the concentration of the respective tocophorol. It was, therefore, possible to determine  $\gamma$ -tocophorol in the presence of  $\alpha$ -tocophorol by use of a photoelectric colorimeter and the principle of differential spectral separation. The details of a method of determining  $\gamma$ -tocophorol by oxidation with nitric acid in the presence of acetic acid, followed by photometric estimation of the red color produced, are presented, together with the results of its application to several vegetable oils.

**Purification of solvents for absorption spectroscopy: An adsorption method.** M. M. GRAFF, R. T. O'CONNOR, and E. L. SKAU. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 16 (1944), No. 9, pp. 556-557, illus. 1).—A simple, rapid method for removing ultraviolet-absorbing impurities from hydrocarbon solvents by selective adsorption on silica gel columns is described. Solvents suitable for use in absorption spectrum measurements were prepared by this method from commercial samples of cyclohexane, *n*-heptane, iso-octane, and two specified commercial light-petroleum solvents. In general, hydrocarbon solvents, both synthetic and commercial, which were subjected to exhaustive chemical and physical purification were noticeably improved by this adsorptive treatment. The advantages of the adsorption method over the usual methods were speed, simplicity of technic, and high yield of purified solvent.

**Apple sirup by ion exchange process.** R. E. BUCK and H. H. MOTTERN. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 7, pp. 635-639, illus. 6).—The removal of most of the malic acid from apple juice by anion adsorption avoided the bitter aftertaste of calcium malate formed by liming the original juice in the preparation of apple sirup. Anion adsorption also removed arsenic from spray residue. Lead was almost completely removed in the final step of liming and was not a serious problem. Three methods of treatment were tested. From the standpoint of flavor the simplest treatment with a single anion exchanger was the most practical. It removed about 80 to 90 percent of the acid and produced a palatable sirup with little flavor other than that of sweetness. A variable quantity of arsenic was removed by the single treatment. To ensure more complete removal when it becomes necessary, a two-step (cation-anion) or a three-step (anion-cation-anion) exchanger treatment must be used. As much as 96 percent of the arsenic content was removed by the three-step method, and a smaller amount was eliminated by the two-step method. In addition, the cation exchanger removed about 90 percent of the ash.

**Changes in stored dried eggs: Source of fluorescence.** H. S. OLCOTT and H. J. DUTTON. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 11, pp. 1119-1121, illus. 1).—The authors note that the fluorescence of 10-percent salt extracts of dried eggs is currently used as a simple criterion of palatability. This fluorescence, the source of which has not been recognized, appears to be due to the brown reaction products of glucose and the free amino groups of proteins. Similar fluorescing brown products also result from the interaction of simple amines and aldehydes. These can be used as model systems for the study of the glucose-protein reaction.

**Vapor pressure of water adsorbed on dehydrated eggs.** B. MAKOWER. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 10, pp. 1018-1022, illus. 4).—Equilibrium pressure of water vapor over spray-dried whole eggs was determined at six temperatures varying from 17.1° to 70° C. and at moisture contents ranging from 0.5 to 5.5 percent. The results agreed well with similar data on eggs dried from the frozen state and with other published data. The results were analyzed by a graphical method, and from this analysis was derived the isosteric heat of adsorption of water on dried eggs at various moisture levels. The ratio of the isosteric heat to the latent heat of condensation of water vapor increases from 1.1 to 2.1 as

the moisture content decreases from 5.5 to 0.5 percent. It was also shown that the adsorption isotherms can be represented, within certain limits, by the Brunauer, Emmett, and Teller theory of adsorption of gases on solids.

**La cura de la vainilla [Vanilla curing]**, F. E. ARANA (*Puerto Rico Sta. Cir.* 25 (1945), *Span. ed.*, pp. 22+, *illus.* 9).—The English edition of this circular has been noted (E. S. R., 94, p. 8).

**Quantitative saccharification of wood and cellulose**, J. F. SAEMAN, J. L. BUBL, and E. E. HARRIS. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 1, pp. 35–37).—The authors describe a rapid analytical technic developed for the hydrolysis of cellulosic materials. The method involves treatment of the material with 72-percent sulfuric acid for 45 min. at 30° C., followed by a secondary hydrolysis for 1 hr. in a 15-lb. autoclave or for 4.5 hr. at the boiling point. Data presented show how the yield of reducing sugar varies with the conditions used. A table shows the "potential reducing sugar" content of 15 species of wood and the variation occurring within a species.

**Fermentation of wood sugars to ethyl alcohol**, R. H. LEONARD and G. J. HAJNY (*Indus. and Engin. Chem.*, 37 (1945), No. 4, pp. 390–395, *illus.* 1).—Fermentation of neutralized wood-sugar liquors was difficult except under special conditions. Acid sugar liquors, which had been treated with lime to a pH of 5 and then heated to 138° C. for a short time before filtering, gave a preparation that fermented anaerobically in 14 to 20 hr. with 2 percent by volume of distiller's yeast. The addition of reducing agents was useful for production of easily fermented wood-sugar preparations.

**Thermodynamics of producer gas combustion: Application to internal combustion engines**, A. P. OLESON and R. WIEBE. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 7, pp. 653–660, *illus.* 7).—The composition and heats of combustion of producer gas derived from various raw materials are given. A nomograph is presented for calculating the heats of combustion of producer gas mixtures containing hydrogen, carbon monoxide, and methane. The theoretical air-fuel ratios of producer gas are compared with those of other fuels used in internal combustion engines, and attention is called to their importance in connection with carburetor design. The heat of combustion of a mixture of producer gas with theoretical air was found considerably lower than that of gasoline or alcohol; and lower power output must be expected from such a mixture run under identical conditions with the liquid fuels mentioned above. The thermodynamic properties of two typical producer gas mixtures were calculated, and the results shown on charts. A sample calculation gives temperatures and pressures at various points of the Otto cycle, as well as work, mean effective pressure, and efficiency. The effects of compression ratio and intake-manifold pressure on mean effective pressure and thermal efficiency are shown by charts. It is pointed out that extreme compression ratios are not so practicable for an Otto cycle engine as an increase in manifold pressure, since a relatively low supercharge pressure gives a power output equivalent to that of gasoline. It is noted that it would be possible to use such a fuel in a Diesel gas engine.

**Cryptostegia leaf rubber**, S. R. HOOVER, T. J. DIETZ, J. NAGESKI, and J. W. WHITE, JR. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 9, pp. 803–809, *illus.* 4).—Investigating the leaves of *C. grandiflora* as a possible emergency source of rubber, supplementary to the latex rubber obtained from the stems of the vine, the authors found the leaf rubber to be of two distinct types. From 85 to 90 percent was a rubber of relatively low degree of polymerization, occurring in the chlorenchyma cells. From 10 to 15 percent was a latex rubber of a better quality, found in latex ducts. Isolation of the leaf rubber by a combination of fermentation and chemical extraction, and the characterization of vulcanizates are described. Extensive experiments on the microbiological phase of the process led to an anaerobic

fermentation by *Clostridium roseum* in which more than 60 percent of the dry weight of the leaves was digested and the leaves were well digested and disintegrated after a 2-day incubation. Passage over a vibrating 80-mesh screen separated a liquid containing the cell protoplasts, carrying the greater part of the rubber, from a bagasse of cuticle, veins, and small stems. An alkali cook process and a benzene extraction method for the recovery of the rubber from the cell-contents thus separated are described, together with preparation and testing of vulcanized blends of the leaf rubber with GR-S.

**Artificial bristles from proteins**, T. L. McMEEKIN, T. S. REID, R. C. WARNER, and R. W. JACKSON. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1944), No. 7, pp. 685-688, *illus.* 7).—The authors describe a method for producing coarse fibers from casein by extruding a heated mixture of casein and water through a suitable die. When the fiber was stretched and hardened, under tension, with quinone, a bristle material was obtained. This was tested in certain types of brushes.

**Textile fiber from casein: Factors affecting the tensile strength**, R. F. PETERSON, T. P. CALDWELL, N. J. HIPPI, R. HELLBACH, and R. W. JACKSON. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 5, pp. 492-496, *illus.* 1).—The authors report experiments on the preparation of fibers from acid-precipitated casein with a laboratory spinning machine, attention having been directed to the major operations of fiber production—namely, dissolving the casein, spinning, stretching, and hardening. A spinning solution containing 20 percent protein and having a pH of 9.2 was employed in most of the experiments. All fibers were given a final hardening treatment with formaldehyde. Stretching the tow issuing from the spinnerette, either in the precipitating bath or between godet wheels in air, gave a tensile strength of about 0.7 gm. per denier. Under these conditions of stretching, the addition of aluminum sulfate to the precipitating bath containing sulfuric acid and sodium sulfate did not affect the strength of the fiber. Such incorporation of aluminum sulfate had a marked effect in a subsequent operation involving simultaneous stretching and partial hardening with formaldehyde, however. When the latter process was operated at 85° C., a dry strength of 1 gm. per denier and a wet strength of 0.5 gm. per denier were obtained. It was found that comparative measurements of tensile strength of artificial protein fibers which will be exposed to moisture are best made after the fibers have been swollen in water and dried.

**Fermentation process for itaconic acid**, L. B. LOCKWOOD and G. E. WARD. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 4, pp. 405-406).—A fermentation process for the production of itaconic acid based on the cultivation of a superior strain of *Aspergillus terreus* (designated NRRL 1960) on the surface of glucose nutrient media, was developed and operated on a semipilot plant scale. Itaconic acid yielded in excess of 30 gm. per 100 gm. of glucose supplied were obtained in 12 days. The major portion of itaconic acid produced can be recovered by crystallization after concentrating and cooling the filtered liquors. The fermentation was resistant to contamination, since the nutrient medium was maintained at a low pH level throughout the culture period.

**Peanut protein hydrates: Preparation and properties**, R. S. BURNETT. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 9, pp. 861-864, *illus.* 2).—The authors describe hydrated preparations of the peanut proteins said to be capable of binding increasing amounts of water, from 38 to about 70 percent by weight of the sol, as the pH value of the system was increased from 4.5 to 9.0. The presence of water in excess of that bound by the protein resulted in disintegration of the protein-water system. The protein hydrates were tacky and, at pH values near neutrality, had viscosity characteristics which made them suitable for use as adhesives, provided the protein used was isolated from the meal with a minimum of alteration by heat or alkali. Precipitated and filtered peanut protein curds were dewatered by warm-

ing until the curd particles coalesced and excluded unbound water. This reduction of the water content from 70–80 to about 40 percent greatly reduced drying costs in preparing isolated peanut protein. Similar hydrates can be prepared from isolated soybean protein.

**Peanut protein hydrates: Utilization as tacky and remoistening adhesives,** R. S. BURNETT, E. D. PARKER, and E. J. ROBERTS. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 10, pp. 980–982).—The authors prepared glues from peanut proteins obtained both from solvent-extracted and from hydraulically pressed meals. These products were found suitable for making gummed tape and paper and for making flexible glues of the type used by the set-up paper-box maker and the bookbinder. Preliminary investigations indicated that gummed tapes with relatively good adhesive strengths could be prepared from peanut protein glues. Peanut protein flexible glues were relatively free of difficulties encountered with certain other types because they could be applied cold and became tacky immediately. Readily soluble glues could be prepared from isoelectric peanut protein curds by neutralizing the curds before they were dried. Dewatering peanut protein curds to the water content required in the hydrate reduced drying costs and provided a glue of relatively uniform ash content. The characteristics of these peanut protein glues, particularly rewettability, tackiness, and flow properties, rendered them suitable for certain gluing purposes for which vegetable proteins had previously been considered unsuitable.

**A comparison of Sicilian and three American species of sumac for tanning sheepskin skivers,** I. D. CLARKE, C. W. MANN, and J. S. ROGERS. (U. S. D. A.). (*Jour. Amer. Leather Chem. Assoc.*, 41 (1946), No. 2, pp. 57–79).—Fifteen packs of sheepskin skivers were tanned with four lots of *Rhus copallina* leaves, two of *R. glabra* leaves, three of *R. glabra* leaflets, two of *R. typhina* leaves, two of *R. typhina* leaflets, and two of ground Sicilian sumac. Satisfactory commercial leather was produced by all, though some were so low in tannin that it was necessary to reduce the number of skivers in the pack below the normal 30 doz. None of the lots of domestic sumac gave leather quite equal to that produced by Sicilian sumac. The order of preference, as expressed by the tanner, was *R. coriaria* (Sicilian), *R. copallina*, *R. typhina*, and *R. glabra*.

**Recovery of 2,3-butylene glycol from fermentation liquors,** R. H. BLOM, D. L. REED, A. EFRON, and G. C. MUSTAKAS. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1944), No. 9, pp. 865–870, illus. 6).—A possible industrial source of butadiene is 2,3-butylene glycol, produced by the fermentation of cereal grains. The recovery of butylene glycol from a fermentation liquor is difficult because of its comparative high boiling point and the presence in the liquor of 2 parts of non-volatile solids to 1 part of glycol. This paper reports upon a recovery process in which a concentrated liquor is steam-stripped in a packed column at an elevated pressure. Experimental work underlying this step of the process is described.

**Liquid-vapor equilibrium in mixtures of 2,3-butylene glycol and water,** R. H. BLOM, G. C. MUSTAKAS, A. EFRON, and D. L. REED. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 9, pp. 870–872, illus. 3).—The authors made liquid-vapor equilibrium measurements for meso-2,3-butylene glycol-water system at pressures and concentrations covering the ranges to be encountered in the recovery of glycol from fermentation liquors. They prepared from these data a chart which shows vapor composition as a function of pressure for certain arbitrarily chosen liquid concentrations. The chart was found to have an accuracy sufficient for engineering design calculations.

**Continuous process for acetylation of 2,3-butylene glycol,** L. E. SCHNIEPP, J. W. DUNNING, and E. C. LATHROP. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1944), No. 9, pp. 872–877, illus. 4).—A practical continuous process for 2,3-butylene glycol diacetate consisted in feeding the glycol, along with a catalytic quan-

tity of sulfuric acid, into the top of a reaction column while introducing a continuous stream of glacial acetic acid into the base of the column. Temperatures of 140°–150° C. were maintained in the zone between the feeds. The column distillate, consisting of acetic acid, water, and traces of methyl ethyl ketone, was dehydrated in an auxiliary column, and the acetic acid returned to the esterification feed. The base product from the reaction column consisted of glycol diacetate, acetic acid, and sulfuric acid esters of glycol. This mixture was separated by vacuum fractional distillation, the acetic acid and sulfuric acid esters being returned to the esterification column as feed and catalyst, respectively. The glycol diacetate so produced was of high quality and suitable for conversion to butadiene by pyrolysis. 2,3-Butylene glycol diacetate was produced in 97 percent yield; 3 percent of the glycol was converted to methyl ethyl ketone, and the excess acetic acid was recovered quantitatively. This procedure was found applicable to the production of other high-boiling acetates.

**Conversion of 2,3-butylene glycol to 1,3-butadiene by pyrolysis of diacetate,** S. A. MORELL, H. H. GELLER, and E. C. LATHROP. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 9, pp. 877–884, illus. 2).—The conversion of 2,3-butylene glycol to butadiene by pyrolysis of its diacetate was studied over a wide range of temperatures and contact times. Yields of 82 percent of butadiene (purity, 99 percent) were obtained on one-pass pyrolyses in the temperature range 575° to 600° C. An additional 5 percent was secured by isolation and pyrolysis of the intermediates left in the pyrolysis liquors. Acetic acid recoveries of 99 percent were obtained under optimum conditions. Methyl vinyl carbonyl and crotyl acetates were identified as the intermediates of the reaction. The main byproducts were methyl ethyl ketone, methyl ethyl ketone enol-acetate (2-acetoxy-2-butene), and methyl acetyl acetone.

**Pilot-plant conversion of 2,3-butylene glycol diacetate to 1,3-butadiene,** L. E. SCHNIEPP, J. W. DUNNING, H. H. GELLER, S. A. MORELL, and E. C. LATHROP. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 9, pp. 884–889, illus. 5).—Pilot-plant studies of the process for producing 1,3-butadiene from 2,3-butylene glycol diacetate by pyrolysis showed an 88 percent yield. The process consisted in pyrolyzing the diacetate at 595° C. to obtain an 83 percent conversion to 99+ percent pure butadiene. The intermediate butenol acetates were separated from the acetic acid of the pyrolysis liquors and repyrolyzed to obtain the additional 5 percent of butadiene. Approximately 8 percent of useful byproducts were obtained. These consisted of methyl ethyl ketone, methyl ethyl ketone enol-acetate (2-acetoxy-2-butene), and methyl acetyl acetone, the latter two being hydrolyzable to methyl ethyl ketone and acetic acid. The over-all acetic acid recovery was 99 percent, and 0.8 percent of the initial diacetate was converted to vent gases. A proposed continuous process for production of butadiene from 2,3-butylene glycol is described briefly.

**Iron pentacarbonyl as antiknock agent in alcohol motor fuels,** I. PITESKY and R. WIEBE. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 6, pp. 577–579).—Iron pentacarbonyl was found an effective antiknock agent for ethyl alcohol fuels, but caution had to be observed when it was used in motor fuels, since the iron oxide deposit may seriously interfere with engine operation. The action of light changed iron pentacarbonyl to iron enneacarbonyl which was practically insoluble in hydrocarbon fuels. Iron enneacarbonyl, however, was soluble in ethyl alcohol, at least to the extent tested, and no obnoxious precipitate occurred in this fuel. Small quantities of oleic, palmitic, or stearic acids or of triethanolamine oleate were effective stabilizers for the iron pentacarbonyl in some hydrocarbon fuels. For solutions in anhydrous ethyl alcohol and in ethyl alcohol containing 5 percent water by volume, no stabilizer was necessary. If reasonable precautions were observed,

working with iron pentacarbonyl appeared no more dangerous from a health standpoint than the use of tetraethyl lead.

**Solubility of water in alcohol-hydrocarbon mixtures**, C. B. KRETSCHMER and R. WIEBE. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 11, pp. 1130-1132).—The solubility of water in mixtures of ethyl alcohol with paraffin hydrocarbons was found to decrease with increase in the molecular weight of the hydrocarbon. As this rule appears to hold also for naphthenes and olefins, and similar observations upon the aromatic hydrocarbons have been recorded, the more volatile gasolines may be said generally to have the higher water tolerances. With the exception of distillate fuels, the solubility of water in ethyl alcohol-hydrocarbon blends or, in general, in ethyl alcohol-gasoline blends is large enough so that if reasonable precautions are observed, no trouble from this source should be experienced. This has been found generally to hold for mixtures containing 10 percent or more of alcohol. Storage above water, required by law in some parts of the country, would be impossible because of the fuel loss due to dissolving out of the alcohol by the water. Unless higher alcohols are present in ethyl alcohol as a denaturant or in consequence of the method of production, it would not seem practical to add them in order to increase the solubility of water in blends. If necessary, this might be better accomplished by the further addition of ethyl alcohol.

**Evaluation of malts for production of alcohol from wheat**, C. B. THORNE, R. L. EMERSON, W. J. OLSON, and W. H. PETERSON. (Wis. Expt. Sta.). (*Indus. and Engin. Chem.*, 37 (1945), No. 11, pp. 1142-1144).—The authors find that knowledge of the amylase content of a malt is helpful but is not adequate for complete evaluation of the malt. Other factors also operate, and probably only a fermentation test can give an accurate evaluation. A possible method for evaluating malts for production of alcohol from wheat is to employ a 5 percent level of malt in a 36-hr. fermentation. If two fermentations are run, 24- and 72-hr. periods give both the rate of conversion and the final degree of conversion of the wheat starch to alcohol. In laboratory fermentations of wheat, malt in the amount of 8 percent of the total grain bill, as commonly used in industrial plants, was found to be in excess. Many malts at a 5 percent level gave maximum yields of alcohol in 36 hr. Under the conditions employed, the limiting factor in speed of fermentation appeared to be the action of the malt rather than the fermenting power of the yeast.

**Conversion of "percentage concentration" of mash or beer to gallonage**, E. M. BURDICK and J. CORMAN. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 4, p. 268).—Percentage concentration is the weight, in grams, of original grains contained in 100 cc. of final slurry. "Gallonage" is the volume, in U. S. gallons, of final slurry which contains one U. S. distillers' bushel of original grains. The authors point out that the relation between the two expressions of mash concentration is such that the percentage concentration multiplied by the gallonage is equal to the constant 671.04, so that either expression is obtainable by dividing the specified constant by the other.

## AGRICULTURAL METEROLOGY

**The sun makes the weather.—I, Measuring solar variation. II, Weather effects of solar variation**, C. G. ABBOT (*Sci. Mo.*, 62 (1946), Nos. 3, pp. 201-210, illus. 10; 4, pp. 341-348, illus. 3).—This is a semipopular account of the author's investigations of the past 25 yr. on three problems: "How much does the sun's heat that warms the earth change from time to time? How much do these heat changes affect the weather? Can sun-produced weather changes be predicted?"

**Reduction of radio interference from meteorological installations**, R. L. IVES (*Amer. Met. Soc. Bul.*, 27 (1946), No. 2, pp. 59-61, illus. 3).—Increasing electrifica-

tion of meteorological apparatus—accompanied by a greatly expanded use of radio equipment, often in the near vicinity—has created an interference situation that is rapidly becoming acute. Fortunately, its reduction to a very low level is in most cases both simple and inexpensive; general methods are here outlined. The installation of a relatively large number of spark absorbers and radio frequency filters indicates that the devices described are not only effective in reducing interference, but that they also protect the entire installation from break-downs due to line surges at various potentials and frequencies. It is recommended that manufacturers of meteorological equipment check their designs and make such modifications as are necessary to minimize radio interference.

**Field-type soil thermometers**, R. L. IVES (*Amer. Met. Soc. Bul.*, 27 (1946), No. 2, pp. 69-70, *illus.* 2).—Mounting an "industrial type" metallic thermometer in a mechanically rugged thermally insulated supporting and protecting frame produced a soil thermometer said to give considerable accuracy and to be immune to most forms of field damage. The apparatus is described and illustrated.

**Variation in physical properties and in atmospheric concentration of hail**, N. C. GERSON (*Amer. Met. Soc. Bul.*, 27 (1946), No. 2, pp. 47-53, *illus.* 1).—The author discusses the common range and frequency distribution of size in hail as reported for India, central Europe, and the United States; the shape, temperature, degree of wetness, and horizontal and vertical distribution of hail in the atmosphere; and the duration of hailstorms. There are 12 references.

**Thunderstorms and the freezing level**, N. R. BEERS (*Amer. Met. Soc. Bul.*, 27 (1946), No. 2, pp. 54-58, *illus.* 2).—The developments presented are thermodynamical in character. It is shown that phase changes from water to ice or snow produce large accelerations in ascending air provided the phase change occurs within a level of accumulation not too thick—i. e., if the phase change actually raises the temperature of the ascending air above that of its environment. It is believed that this discussion clarifies the problem of thunderstorm forecasting by emphasizing the importance of the freezing level. Observation and a dynamical theory of thunderstorm formation are, however, still required. Observations are needed of temperature, three-dimensional wind, water content, and impurities both within and without ascending columns and both before and after the cloud is formed. Controlled tests with supercooled water and air may afford information on the rate of phase changes; statistical studies should also illuminate the situation. "In fine the problem of thunderstorms and the freezing level is admittedly not yet completely solved; the writer's sole excuse for publication of these preliminary results is that they have been useful in making daily weather forecasts during the summer of 1945."

**Injury and death or recovery of trees in prairie climate**, F. W. ALBERTSON and J. E. WEAVER. (Univ. Nebr. et al.). (*Ecol. Monog.*, 15 (1945), No. 4, pp. 393-433, *illus.* 62).—This study—involving data from a wide range of sources—describes the effects of the greatest drought since the beginning of recorded weather history on forests and trees under a prairie climate. A major area of postclimax forest occurs along the Missouri River, where the red oak-linden community is the most mesic, black oak-shagbark hickory is intermediate, and bur oak-bitternut hickory is the most xeric. Communities of shrubs are often transitional from forest to prairie. In Nebraska, as elsewhere, all these forests suffered heavily from drought, especially when pastured. Decreases in size of individual trees and number of species and confinement to the most protected sites are marked northward, and especially westward where the climate becomes more arid. Along prairie streams westward from the Missouri River, forest communities rapidly disappear; farther westward, trees are largely confined to the banks of the larger streams, broad shallow ravines, and the vicinity of springs. Several years of decreasing precipitation initiated the 7 yr.

of drought; the 12 mo. following June 1943 had the driest weather ever recorded in the prairie region. The early effects were very impressive and widely reported as revealed in the literature (44 references).

Pre-drought data on mean annual precipitation, average weekly evaporation, and water content of soil from Nebraska, Kansas, and Colorado are presented. The chief cause of injury was lack of sufficient available water due to low precipitation but accentuated by one or more of several causes, such as competition for water by grasses, decreased rate of water infiltration and rapid run-off, drying up of streams and springs, rapid fall of the water table, low humidity, high evaporation, desiccating winds, and the inability of trees to accommodate their root systems to the rapidly changing environment. Experimental data on the harmful effects of competition with grass on both roots and shoots of trees are given in detail. Injury and death of woody plants by the drought often resulted from continuous adverse conditions over an extended period. Exposure of branches with reduced foliage to high insolation, great heat, and low humidity was a common cause of injury. Destruction in long-established timber claims was also high, and losses in windbreaks were nearly always heavy—with dust storms a contributory factor. Average losses of trees in Nebraska and Kansas were probably 50 to 60 percent by death, with severe to moderate injury in an additional 20 to 25 percent. The effects of drought on the radial growth of uninjured or least injured trees of various species in western Kansas are described. Trees retaining some life at the close of the drought usually remained alive temporarily unless already nearly dead or heavily infested by borers; recovery was principally through locally renewed growth within the crown. Sprouts developing from the bases of certain trees grew rapidly. Seedlings were not found in timber claims, windbreaks, or hedgerows in mixed prairie and only rarely in unpastured places east of the Missouri River. The findings from this monographic study are presented in great detail.

The agricultural climatology, vegetative cover, and crop ecology of the Ukraine and the Ukrainian climatic analogues in North America, M. Y. NUTTONSON (*U. S. Dept. Agr., Off. Foreign Agr. Relat., 1946, pp. 23+, illus. 1*).—This processed report—along lines similar to those previously noted (E. S. R., 93, p. 121)—represents an agroclimatic and crop-ecological approach by an agronomist to plant introduction and exchange of plant material between the Ukraine and North America; it is a direct offshoot from problems of the huge postwar agronomic plant introduction tasks, but its background is also an outgrowth of some of the nonemergency experiences where careful varietal field trials of introduced plant material have been possible. From a purely regional viewpoint there is often need for crop diversification and improvement, as well as for economy in time, effort, and cost of varietal field trials. The particular object of this contribution is to organize, define, and analyze the various distinct agroclimatic conditions in different parts of the Ukraine and to compare them with similar conditions in North America in order to ascertain the "climatic analogs" of the two areas.

Climatology of Norway and its climate parallels in North America, M. Y. NUTTONSON (*U. S. Dept. Agr., Off. Foreign Agr. Relat., 1945, pp. 6+, illus. 1*).—This study of Norway follows essentially the same approach as that followed for other European countries and previously noted (see preceding entry).

Kansas weather, 1945, S. D. FLORA (*Kans. Acad. Sci. Trans., 48 (1946), No. 4, pp. 394-408, illus. 13*).—In addition to data on the severe windstorms, hail, and overflows in streams of the State for the year, the author summarizes the weather data of 1945 by months.

The 1945 crop season in North Dakota, H. L. WALSTER ET AL. (*North Dakota Sta. Bimo. Bul., 8 (1946), No. 3, pp. 3-9*).—The growing season of 1945 in the State differed in so many ways from the usual conditions likely to occur over an average of

a long period of years that it seemed wise to publish rather detailed discussions. These include meteorological and crop conditions throughout the State; seeding dates at Fargo, Dickinson, and on the upland and irrigation stations at Williston; the crop season at Dickinson, Edgeley, Langdon, and Williston; and seasonal conditions at Minot and Hettinger.

**Report on the phenological observations in the British Isles from December 1944 to October 1945**, H. C. GUNTON (*Roy. Met. Soc. [London], Quart. Jour.*, 72 (1946), *Sup.*, pp. 43, *illus.* 4).—A further report (*E. S. R.*, 93, p. 121).

**Climate and insect life**, C. B. WILLIAMS (*Nature [London]*, 157 (1946), *No.* 3982, pp. 214–215, *illus.* 1).—A brief general statement as to the factors involved in the bioclimatics of insect life and the present state of the problems concerned, as suggested at a joint meeting of the Royal Meteorological Society and the Royal Entomological Society in London on June 20, 1945.

## SOILS—FERTILIZERS

**The rôle of clay minerals in the formation of soil structure**, J. B. PETERSON. (Iowa Expt. Sta.). (*Soil Sci.*, 61 (1946), *No.* 3, pp. 247–256, *illus.* 5).—In experiments upon measurement of the relative capacity of kaolinite and montmorillonite to form water-stable aggregates under the influence of cyclic wetting and drying, the kaolinite was found to be very inert as a binding agent, having little effect on aggregation. Montmorillonite formed gel-like globules which varied in resistance to dispersion in water according to the conditions of the experiment. The difference in behavior of the two clays was attributed to the greater surface, hydration, and charge of the montmorillonite in comparison with the kaolinite. Kaolinite had no apparent effect on the state of aggregation that developed in a puddled Tama soil. Montmorillonite increased markedly the proportion of the mixture resistant to wet-sieving when the clay mineral was added in a quantity sufficient to constitute it the predominating component. When mixtures of sand and either clay treated with various quantities of ground alfalfa were incubated for 1 mo. before puddling and then exposed to cyclic wetting and drying, the alfalfa had no effect on the proportion of the material resistant to dispersion in water. Hydrous ferric oxide had no effect on the aggregation of kaolinite and sand. When quantities of this oxide equivalent to 1.5 percent of the dry weight of the mixture were added, the amount of montmorillonite gel remaining on the screens decreased, possibly through the mechanism of mutual flocculation. Small additions of sand to mixtures of kaolinite and montmorillonite increased the resistance of the mixtures to dispersion in water. Larger proportions of sand had a reverse effect.

**Mineralogy of some soils from Denmark, Western Australia**, D. CARROLL (*Soil Sci.*, 60 (1945), *No.* 6, pp. 413–426, *illus.* 1).—A disease of stock, affecting especially dairy cows and sheep, was found to be confined to certain land holdings, adjacent properties being not only free from the disorder but capable of curing it when the affected animals were transferred to them. Locally known as “Denmark wasting disease” or enzootic marasmus, the trouble was traced to cobalt deficiency. A detailed examination of the soils concerned, their mineralogical composition, and their geological origins, is here reported. Two soil series derived from dolerite and schists, an area designated alluvial and wash, and laterite boulder areas referred to as “various” parent rock origins were free from the cobalt deficiency disorder. Three soils derived from gneiss materials and one originating from gneiss, quartzite, and transported sand showed the deficiency, as did also a transported sand and a sand derived from sillimanite schist.

**Some effects of freezing and thawing on the aggregation and permeability of dispersed soils**, R. GARDNER. (Colo. Expt. Sta.). (*Soil Sci.*, 60 (1945), *No.* 6,

pp. 437-443, illus. 2).—Compaction and dehydration of semidispersed soils between the faces of adjacent ice crystals produced a stable flaky soil structure in soils with a high percentage of replaceable calcium and an unstable flaky soil structure in soils high in replaceable sodium. Freezing and thawing did not restore permeability to impermeable sodium-saturated soils. Replacing the sodium ions in sodium-saturated soils with calcium ions without freezing did not restore permeability, but freezing after calcium chloride was added to replace the sodium ions did so. It is concluded that freezing and thawing may be utilized to good advantage in cold climates as aids in restoring structure and permeability in the process of reclaiming soils that have been injured by sodium salts.

**Increase made in soil testing,** R. COWART (*Miss. Farm Res. [Mississippi Sta.]*, 9 (1946), No. 1, p. 6).—A soil testing service recently instituted received about 800 samples during the first year and a larger number during the first half of its second year, July 1, 1945, to January 1, 1946. Under conditions of excessive rainfall, the farmer is advised to delay sampling until the soil is no longer waterlogged. Soil dry enough for cultivating is considered to be probably in the best state for sampling.

**Comparison of four methods of soil moisture measurement,** C. S. SLATER and J. C. BRYANT. (U. S. D. A. coop. Md. Expt. Sta.). (*Soil Sci.*, 61 (1946), No. 2, pp. 131-155, illus. 7).—The authors compared, under field conditions, the behavior of tensiometers (E. S. R., 79, p. 159), resistance blocks (E. S. R., 82, p. 307), and gravimetric plugs. The performances of the instruments were judged by moisture determinations on soil samples that were taken at random within a restricted area around each instrument installation.

The three instruments were found to differ with respect to the accuracy with which they measured soil moisture, the ranges of moisture in which the instruments were sensitive, and their efficiencies in differentiating soil moisture levels. On a silt loam soil, the plugs and blocks were superior to the tensiometers with respect to errors of estimate and range of operation but were insensitive to moisture changes in a range of higher moisture contents where the tensiometers gave their best performance. On a silt loam soil the plugs were better than the blocks with respect to errors of estimate, efficiencies of differentiation, and location of their sensitive ranges on an available moisture scale. On a very sandy soil the blocks appeared to be better than the plugs in all respects, although the performance of neither instrument was satisfactory throughout the available moisture range.

"The results of the experiment as a whole indicate clearly that no one instrument is 'best' in its present state of development. The choice of method for measuring soil moisture should be based on differences in the conditions of measurement as well as on instrument characteristics. It is the opinion of the writers that tensiometers are decidedly limited in usefulness, that under a majority of soil conditions gravimetric plugs are best adapted to accurate measurement, and that resistance blocks are best adapted to semiquantitative measurements of the variable field moisture of large areas under conditions that do not require the improved accuracy that can be obtained by temperature corrections."

**Changes in construction of soil moisture tensiometers for field use,** A. S. HUNTER and O. J. KELLEY. (U. S. D. A.). (*Soil Sci.*, 61 (1946), No. 3, pp. 215-217, illus. 1).—Tensiometers of the vacuum-gauge type were found too sluggish in their response and to present difficulties in maintenance. Mercury-manometer tensiometers, though very useful for following changes in soil moisture content within their range, had to be made from 3 to 4 ft. high, with the result that cultivating implements could not pass over them. Removal and replacement of the instruments at each cultivation was considered not only to be too laborious and time-consuming but also to have nonmeasurable effects both upon roots near the tensiometer cup and upon moisture equilibria. The channel iron support carrying the glass manometer tubing and its scale was therefore hinged directly over the mercury reservoir, and

a short length of a flexible tubing was inserted between the copper capillary tubing leading to the cup and the manometer tubing. A short bar rigidly attached to the side of the upper part of the channel iron support and capable of being locked in the vertical position by a cotter pin passing through it and the lower part of the support completed the mechanism, permitting the support to be laid over level with the ground. A coil in the copper tubing at the top of the instrument permitted a movement of the glass manometer capillary sufficient to allow it to be raised from the mercury container. The mercury had to be run back into its reservoir before the frame of the instrument was folded over, and the instrument reset when replaced in operating position.

**The integrated soil moisture stress upon a root system in a large container of saline soil.** C. H. WADLEIGH. (U. S. D. A. coop. 11 western States et al.). (*Soil Sci.*, 61 (1946), No. 3, pp. 225-238, illus. 8).—A mathematical method for evaluating the variations in energy content of the soil moisture being absorbed by a plant grown in a large container of saline soil is presented. The method takes into account variability in salt distribution within the soil, variations in moisture distribution of the soil at a given time, and variation in total moisture content with time. A discussion of the errors involved is included.

**Effect of moisture content on the dissolved and exchangeable ions of soils of arid regions.** R. F. REITEMEIER. (U. S. D. A. coop. 11 western States et al.). (*Soil Sci.*, 61 (1946), No. 3, pp. 195-214, illus. 7).—Dissolved ions of six soils were determined at field moisture content, saturation percentage, 200 percent, and 500 percent. The ions included Ca, Mg, Na, K,  $\text{NH}_4$ ,  $\text{CO}_3\text{-HCO}_3$ ,  $\text{SO}_4$ , Cl,  $\text{NO}_3$ , and  $\text{PO}_4$ . The soils contained varying quantities of soluble salts, alkaline earth carbonates, and gypsum. The exchangeable base status at each moisture content was determined by ammonium acetate extraction and calculations based on cation-exchange equilibria.

With the exception of sulfate in one soil, all soluble ion contents in all soils changed to some degree on dilution. Sodium, K,  $\text{NH}_4$ ,  $\text{CO}_3\text{-HCO}_3$ ,  $\text{PO}_4$ , and  $\text{SO}_4$  (with the exception noted) increased in all soils with increasing moisture content. Calcium and magnesium increased in four soils, passed through maxima in one soil, and decreased continuously in one. The increases in these eight ions are explained by ion exchanges and solution of solid compounds on the basis of additional amounts of water. The decreases in Ca and Mg were found to result from a cation valence dilution effect whereby, on dilution, soluble Ca and Mg replace exchangeable Na, K, and  $\text{NH}_4$  from the soil colloids. Chloride and nitrate decreased continuously in all soils; the average reduction in the two ions was 28 and 23 percent, respectively. Possible explanations of the decreased concentrations of these ions are suggested. Exchangeable sodium decreased continuously on dilution, by from 32 to 58 percent. The ratio of exchangeable calcium to magnesium in the two gypsiferous soils increased greatly on dilution.

It is recommended that the soluble salts of arid soils be determined at a moisture content near that at which the results are to be interpreted. In soils having appreciable contents of mixed soluble salts, the determined exchangeable-base status was found to apply only to the moisture content at which the soluble salts are determined. The theoretical and experimental aspects of the various cation and anion phenomena led to the conclusion that the soil solution cannot be homogeneous throughout its entire mass and generally is less concentrated near the soil colloidal particles.

**Microorganisms and soil aggregation.—II, Influence of bacterial polysaccharides on soil structure.** J. P. MARTIN. (Idaho Expt. Sta.). (*Soil Sci.*, 61 (1946), No. 2, pp. 157-166, illus. 1).—The present paper deals with the effects of the polysaccharides produced by six bacterial strains in addition to the one organism found an effective soil aggregating agent, and discussed in the first paper (E. S. R., 94, p. 20) of the series.

Six bacterial polysaccharides, three fructosans and three dextrans, were prepared

in quantity and their influence on soil aggregation and slaking was determined. The effectiveness of the different preparations varied but was very marked in all cases. The polysaccharides alone had a greater influence than the casein or lignin with which they were compared. In combination with lignin and casein, they influenced soil structure quite as beneficially as when used alone. The bacterial polysaccharides, in general, were attacked to a limited extent by micro-organisms. At least one and usually several microbes were capable of utilizing each, however.

**Dynamics of wind erosion, III-V, W. S. CHEPIL** (*Soil Sci.*, 60 (1945), No. 6, pp. 475-480, illus. 3; 61 (1946), Nos. 2, pp. 167-177, illus. 5; 3, pp. 257-263, illus. 1).—Continuing this series (E. S. R., 94, p. 594), paper 3 is concerned specifically with the relationship between the velocity of a wind and the rate of removal of the soil, paper 4 with five forms of wind erosion, and paper 5 with cumulative intensity of soil movement.

III. *The transport capacity of the wind* (pp. 475-480).—Equations given in an introductory analysis of the problem show that a decrease of 10° C. in the air temperature will increase the density of the air (and concomitantly, the force of a wind) to an extent depending upon the original temperature, but only from 2.5 to 4 percent; that an increase of 10 mm. of mercury in the air pressure will increase its density only by about 1.3 percent; and that changes in air humidity will seldom affect erosive force to a degree in excess of 3 percent. The effect of small changes in velocity, however, was found to have a much greater effect upon erosivity.

The rate of movement of the soil in saltation, in suspension, and in surface creep was shown to vary as the cube of the drag velocity of the wind, the experiments in which this relationship was determined having been carried out in a portable field wind tunnel provided with six Pitot tubes and a specially designed multiple alcohol manometer for simultaneous readings of wind velocity at various heights. In open-field measurements, wide variations in the degree of gustiness of the wind made any determination of the relationship between wind velocity and soil movement very difficult. The relation between the velocity,  $v$ , at any height,  $z$ , and the drag

velocity,  $V'$ , was found to conform to the equation:  $v_z = 5.75 V' * \log \frac{z}{k}$ , in which

$k$  is the height at which the projected curves indicate the velocity to be zero. Since the velocity and the log-height have a straight-line relationship,  $V' *$  determines the slope of the velocity distribution curves.

IV. *The translocating and abrasive action of the wind* (pp. 167-177).—It is shown that arable soils are affected by five forms of wind erosion—effluxion, extrusion, detrusion, efflation, and abrasion. All, or some, of these forms may affect the soil simultaneously, but none of the other forms occurs on any appreciable scale without effluxion. Therefore, prevention and control of wind erosion should be based mainly on prevention of erosion by effluxion.

Effluxion is defined as removal of soil grains ranging from 0.1 to 0.5 mm. in diameter, initiated and maintained by the direct pressure of the wind. The removal is almost entirely by saltation, but a minor proportion of the soil may be removed in surface creep and some fine particles may be picked up directly by the wind and carried away in true suspension.

V. *Cumulative intensity of soil drifting across eroding fields* (pp. 257-263).—The steadily increasing amounts of erosive particles, the cumulative degree of abrasion, and the gradual decrease in surface roughness along the direction of the wind were found to be the main causes for the gradual increase in the rate of soil movement with distance away from the windward edge of eroding fields. The data indicate that there was much sorting of the soil particles by the wind in accordance with their sizes, the coarser particles tending to remain nearer the windward edge, the finer tending to accumulate nearer the leeward. Causes for the variations in the rate

of increase of soil flow on different soil types and the relationship between these variations and the strip-farming method of soil-drifting control are given.

**Evidences of the effect of erosion on the organic matter and erodibility of Honeoye soil,** G. R. FREE. (U. S. D. A. coop. [N. Y.] Cornell Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 3, pp. 207-217, illus. 3).—Soil loss, runoff, and organic matter data which show evidences of the effect of erosion on the organic matter and erodibility of the highly productive Honeoye soil at Marcellus, N. Y., are presented.

Marked and significant differences in erodibility were found under a uniform treatment following practices which permitted great differences in the amount of erosion. The percentage of organic matter was found to have dropped about 0.002 percent per ton of soil eroded. When the relationship shown by data from land slopes of 9 percent and 4 percent which had not suffered excessive erosion in the past was extended to a 17-percent slope, it was found that the effect of land slope per se upon soil and water losses during the summer period accounted for only about one-eighth of the measured soil losses and about one-third of the measured surface runoff. The remainder could only be attributed to the effects of past erosion. Length of slope was found to be a major factor determining the degree of the erosion on the 17-percent slope which had suffered excessive erosion in the past. The effect of length of slope was less on the 9-percent slope and tended to disappear entirely on the 5-percent slope for the range of lengths of slope included in the study.

**Straw mulch for soil improvement,** R. E. STEPHENSON and C. E. SCHUSTER. (Oreg. Expt. Sta.). (*Soil Sci.*, 61 (1946), No. 3, pp. 219-224).—The authors report pot experiments on soils subjected for 5 yr. to (1) a 6-in. mulch of wheat straw; (2) volunteer growth sod; and (3) scraping sufficient to prevent all growth.

Growth of sunflower as an indicator plant in soil taken from the top 2 in. under a straw mulch was appreciably greater than in soil taken from sod or a scraped plot. The straw-mulched soil maintained its lead in promoting plant growth after liberal fertilization of all the soils to correct nutrient deficiencies. The straw-mulched soil contained the most acid-soluble potassium, was richest in humus, and had much the highest proportion of aggregates larger than 1.0 mm. diameter.

**Influence of fertilizers on the yield and composition of certain crops and on the soil,** J. E. GREAVES and D. W. PITTMAN. (Utah State Agr. Col.). (*Soil Sci.*, 61 (1946), No. 3, pp. 239-246).—Commercial fertilizers and manures carrying soluble nitrogen and phosphorus materially increased the yields of potatoes, sugar beets, wheat, and barley on a highly calcareous soil under irrigation. The percentages of phosphorus were increased in all crops, and nitrogen in all crops except alfalfa. Ammonium sulfate in the fertilizers slightly increased the sulfur content of the alfalfa. All fertilizers were without effect on the other constituents of the crops.

The composition of first-, second-, and third-crop alfalfa produced on this soil differed. The protein, sulfur, and phosphorus contents of first-crop alfalfa were lower than those of either second- or third-crop alfalfa, and second-crop alfalfa was lower in these constituents than third-crop alfalfa. Alfalfa produced on this soil responded readily to phosphorus fertilizers, which brought about increased yields and higher percentages of phosphorus in the plants. This soil was high in total phosphorus but did not meet the growing needs of the alfalfa plants. It is concluded that the nutritive value of alfalfa, with reference to protein and phosphorus content, was highest for the third crop and lowest for the first crop. Alfalfa grown on soil to which phosphorus fertilizers have been added would probably have a higher nutritive value than similar alfalfa grown on this soil without fertilizers.

**The agrobiologic test for normality in fertilizer experiments and variety comparisons.—I, Varieties,** O. W. WILLCOX (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 3, pp. 218-224, illus. 1).—A variety  $\times$  nitrogen fertilizer field experiment by Tolman with sugar beets (E. S. R., 89, p. 540) is cited as an example showing all

the characteristics of a perfectly normal soil for crop increase. The characteristics of normality are that the experimental yield curves of two or more varieties must show full homology with the curves of the standard yield diagram based on the Mitscherlich-Baule normal yield equation  $y = A(1 - 10^{-0.3012x})$ , and fulfill the condition that the spread between two homologous values of  $y$  for any two values of  $A$  must increase as  $x$  increases while the ratios of the yields of the varieties remain constant. Where these conditions are fulfilled, the comparison of yielding abilities is virtually mathematically exact. In the contrary case, abnormality of soil conditions or faulty experimental technic will be indicated. The degree of departure from normality can be measured by reference to the nearest standard curve.

**Soil-plant relations.**—II, **Balanced fertilizer use through soil tests for potassium and phosphorus**, R. H. BRAY. (Ill. Expt. Sta.). (*Soil Sci.*, 60 (1945), No. 6, pp. 463-473, illus. 1).—In the second paper of this series (E. S. R., 92, p. 341), the author reports experiments leading to the following conclusions:

The quantity of a fertilizer needed to achieve balanced fertility at the maximum yield level depends on the soil supplies and the crop being grown. Supplies of the available forms of a nutrient vary from soil to soil, causing a corresponding variation in the fertilizer requirement. These soil supplies can be measured directly with soil tests. The soil test value can be substituted for  $b_1$  in the modified Mitscherlich equation:  $\text{Log } (A - y) = \text{log } A - (c_1b_1 + cx)$ . The values of all of these terms except  $c$  and  $x$  have been previously determined for different crops, and the value of  $x$  is approximately known for certain cases on the experiment fields for the rotation as a whole. This permits the calculation of  $c$ , and by using the  $c$  values obtained the approximate fertilizer requirements for each soil test value for phosphorus and potassium have been calculated. These fertilizer requirement values are used in practice in the form of a rotation requirement, which is so applied as to favor the crops with the lowest  $c_1$  values (the crops most responsive to the nutrient added). When both phosphate and potash fertilizers are used in these quantities during the rotation they balance the soil forms and make possible a balanced fertility program as far as these two nutrients are concerned. "The old idea of a certain ratio of phosphate and potash being needed for a certain crop is not recognized in this plan except insofar as small amounts are used by placement methods for the initial stimulation of the plant."

Where the fertilizer requirement is lower than the quantity ultimately removed by crops, a gradual decrease in the available soil supplies will occur unless the rate of supply from the less available soil forms is sufficient to make up for this difference. This may be checked by a continued soil-testing program measuring the balance in the soil resulting from crop removals and possible leaching loss, on the one hand, and fertilizer additions and release from less available forms, on the other.

"These fertilizer requirements for phosphorus and potassium as determined by the soil tests are not considered recommendations except as they are recommended with a knowledge of the favorableness of the other factors in crop production."

**Potassium needs of New Jersey soils**, F. E. BEAR, A. L. PRINCE, and J. L. MALCOLM (*New Jersey Stas. Bul.* 721 (1945), pp. 19, several illus.).—This subject is dealt with under the captions: Plow depth acre of average soil contains 35,000 lb. potassium; from 80 to 160 lb. potassium in year's produce of average acre; potassium in interior of soil particles unavailable for current use; loam soils have high capacity to store potassium for plant use; potassium-storage capacity of sandy soils very low; soil potassium moves into plants more readily than soil calcium; plants tend to absorb more potassium than they require; percentage potassium in plants lowered by liming land; Collington soils naturally high in exchange potassium; available potassium kept at high level in well-managed land; sandy soils require frequent applications of potassium; extra potassium required for crops grown on acid soils;

potassium-deficiency symptoms often observed on New Jersey crops; and potassium an essential constituent of New Jersey fertilizers.

Although devoted mainly to the problems involved in assuring adequate potassic nutrition of crop plants, the bulletin notes also the fact that "plants tend to absorb much larger amounts of K than they need, the K content of alfalfa having been made to vary between 1.15 and 3.30 percent of the dry weight of hay without sacrificing yields. The sum of the Ca, Mg, and K in alfalfa is nearly constant, no matter what the content of the individual elements. Thus as the K content rises the contents of Ca and Mg decrease, and vice versa. Excessive absorption of K by plants is objectionable, not only because of the relatively high cost of K in comparison with that of Ca but also because the Ca need of animals and man is much greater than their need for K. Excessive absorption of K by plants can be partly overcome by liming the land liberally and by adding K fertilizers as needed rather than in very large doses at planting time. To prevent excessive absorption of K by alfalfa, the element should probably be applied as a top-dressing after the first crop of the season has been removed, rather than in late fall or early spring. Since plants tend to absorb more K than they need, cropped soils often quickly develop K deficiencies, and constant attention must be paid to replenishing their K supply."

**Relation between potash in soils and that extracted by plants, E. H. STEWART and N. J. VOLK. (Ala. Expt. Sta.). (*Soil Sci.*, 61 (1946), No. 2, pp. 125-129).—**Continuous cropping of 10 Alabama soils with a series of different crops quickly depleted the readily available potassium to the extent that the soils would not support plant growth even though adequate amounts of plant-food nutrients with the exception of potassium were supplied. The plants utilized nonexchangeable potassium heavily, but the amount of nonexchangeable potassium consumed bore no relation to the total potassium extracted by the crops, the total potassium in the soil, or the decrease in exchangeable potassium that resulted from cropping. An average of two-thirds of the potassium used by the plants came from forms nonexchangeable at the beginning of the test, and the amount of nonexchangeable potassium removed from the different soils varied between 39 and 87 percent of the total amount of potassium consumed by the plants. The authors found no close relationship between the potassium removed by the crops and the exchangeable potassium in the soil, removed from the soil, or remaining in the soil after cropping. Neither the exchange capacity of the soil nor the percentage potassium saturation showed a definite relationship to the quantity of potassium extracted by the plants. The variability of the capacity of different soils to release potassium from the nonexchangeable forms for plant consumption appeared to be a dominant factor in the nutrition of plants, and the magnitude of this factor was difficult to measure through the use of chemical soil tests.

**Phosphate adsorption by Illinois soils, T. KURTZ, E. E. DETURK, and R. H. BRAY. (Ill. Expt. Sta.). (*Soil Sci.*, 61 (1946), No. 2, pp. 111-124, illus. 3).—**Samples of the soil under examination were brought into contact with phosphate solutions of known concentration, and the phosphate remaining in solution after 10 min., after from 35 to 90 days, and after 3 yr. was determined. Adsorption curves so obtained for various soils and at various ratios were of similar shape and could be formulated in an equation of the Freundlich type. The forms in which the phosphate was adsorbed were studied by determining the ease with which the phosphate could be removed by water and other extracting solutions.

Extractions of stored samples of soils to which phosphate had been added 3 yr. before recovered over 90 percent of the added phosphate. In these extractions, three fractions were determined, namely water-soluble, adsorbed (that is, removed by 1 N  $\text{NH}_4\text{F}$ ), and easily acid-soluble, were determined. These results showed that with additional time there was not only a gradual increase in the amount of phosphate adsorbed but also a gradual change in the status of the adsorbed phosphate. This

was shown by decreases in the amounts of phosphate which could be removed by water in successive extractions and by an increase in the easily acid-soluble fraction. The bulk of the added phosphate, however, was retained in the adsorbed form from which it was displaced by the fluoride ion in a neutral solution.

The phosphate-replacing abilities of several different anions were studied. An analogy between anion and cation adsorption is developed and discussed. The experiments reported indicate that the phosphate taken up by the soil is held against leaching loss but remains in a form such that it can be utilized by plants. The work also "gives evidence that so-called 'phosphate-fixation' is not a serious problem in Illinois soils, and that phosphate fixation, therefore, has no justification as an argument against the use of soluble phosphate fertilizers."

**Retention of phosphates by soils, III-IV, F. L. DAVIS.** (La. Expt. Sta.). (*Soil Sci.*, 60 (1945), No. 6, pp. 481-489, illus. 1; 61 (1946), No. 2, pp. 179-190, illus. 5).—This is a continuation of a series previously noted (E. S. R., 94, p. 25).

III. *Nature of phosphate retention of virgin Hammond very fine sandy loam treated with  $\text{Ca}(\text{OH})_2$  and  $\text{H}_3\text{PO}_4$*  (pp. 481-489).—When small quantities of phosphorus in the form of phosphoric acid were added to suspensions of a soil in calcium hydroxide solution, the calcium and hydroxyl ions governed the extent of reversion of the phosphate; that is, the hydroxy-apatite was probably formed and the phosphate was not adsorbed by the soil as anions at pH values above 5.0 except at very low calcium concentrations. When larger quantities of phosphoric acid were added to soils under the same experimental conditions, some of the phosphorus was reverted to primary or secondary calcium phosphates which were adsorbed by the soil as anions and thereby produced an increase in the cation-exchange capacity. The smaller quantity of calcium hydroxide added, the larger was the increase in cation-exchange capacity. When large quantities of excess calcium hydroxide were present, a small portion of the added phosphorus was converted by carbonation and equilibration with air into the calcium carbonate-form of the tertiary calcium phosphate and adsorbed by the soil as such. Some of the water-insoluble phosphate retained by the soil may be held in the form of a double layer or a soil micelle-calcium-phosphate linkage.

IV. *Solubility of phosphates retained by virgin Hammond very fine sandy loam treated with  $\text{Ca}(\text{OH})_2$  and  $\text{H}_3\text{PO}_4$*  (pp. 179-190).—The data given show the effects of the treatments on water-soluble phosphorus and the quantities of phosphorus removed from the soil by successive extractions with carbonic acid, 0.002 N  $\text{H}_2\text{SO}_4$ , and 0.1 N  $\text{H}_2\text{SO}_4$  in relation to soil reaction. The differential solubility of the phosphorus resulting from treating the soil with  $\text{H}_3\text{PO}_4$  is compared to that obtained for similar soil samples treated with monocalcium phosphate.

The quantities of soluble phosphorus obtained by successive extractions of the soil treated with 1.08 mM  $\text{H}_3\text{PO}_4$  per 100 gm. soil were significantly less than those obtained from the samples to which phosphorus was added in the form of monocalcium phosphate. The largest difference for the two forms was that obtained by extraction with carbonated water. At all soil reactions below pH 6.5, the amount of phosphorus soluble in  $\text{CO}_2$ -saturated water in the  $\text{H}_3\text{PO}_4$ -treated series was uniformly low; but at soil reactions above pH 7.0, it approached that obtained from the soil treated with monocalcium phosphate. At soil reactions below pH 6.5, the phosphorus added as  $\text{H}_3\text{PO}_4$  became much less soluble in carbonic acid than that added in the form of monocalcium phosphate.

**Manufacture of concentrated superphosphate: Effect of mixing and curing conditions on conversion, G. L. BRIDGER, R. B. BURT, and W. W. CERF** (*Indus. and Engin. Chem.*, 37 (1945), No. 9, pp. 829-841, illus. 8).—Concentrated superphosphate was made in the TVA plant by mixing 78 percent phosphoric acid with finely ground rock phosphate, curing in large piles for about 12 weeks, grinding, screening, and bagging. Data on the conversion of rock phosphate  $\text{P}_2\text{O}_5$  to available

P<sub>2</sub>O<sub>5</sub> for plant superphosphate made from Tennessee and Florida rock phosphate were obtained for a period of several years and compared with corresponding data for control superphosphates prepared in the laboratory. The conversion of the plant superphosphate was lower than that of the control. This behavior was due to differences in thoroughness of mixing, temperature of mixing, and temperature of curing. The effect on conversion of reactant temperature over the range 32° to 200° F. and of curing temperatures from 80° to 190° was determined in laboratory experiments on Tennessee rock phosphate; both low mixing temperatures and low curing temperatures favor high conversion for superphosphate made with acid stronger than 70 percent H<sub>3</sub>PO<sub>4</sub>. By improving thoroughness of mixing, lowering reactant temperature, and lowering curing temperature, considerable increase in conversion can be obtained.

**Liquid and solid sources of nitrogen for cotton production, 1943-45, J. PITNER and F. E. EDWARDS** (*Miss. Farm Res. [Mississippi Sta.]*, 9 (1946), No. 1, pp. 1, 6).—The two commercially supplied solution fertilizers contained (1) ammonia equivalent to 24.6 percent of nitrogen and (2) both ammonium and nitrate nitrogen, the total of both forms being 40.6 percent. With cotton as the test crop, the solution containing ammonia alone produced no increase in yield in the first of the 3 yr. of the test, and increases distinctly less than those given by calcium cyanamide, ammonium sulfate, or sodium nitrate in the second and third years. The second solution, tested only in the first year, gave an increase in yield greater than that produced by the cyanamide or sodium nitrate but less than that given by ammonium sulfate.

**High manure losses on Colorado farms may be reduced, experiment shows, R. GARDNER and D. W. ROBERTSON** (*Colo. Farm Bul. [Colorado Sta.]*, 7 (1945), No. 6, pp. 10-12, illus. 2).—Losses of plant nutrients from manure were greatly reduced by spreading the fresh manure in the field and plowing under immediately rather than keeping the manure in storage.

**Supplements to high-analysis fertilizers with special reference to sulfur, calcium, magnesium, and limestone, N. J. VOLK, J. W. TIMMORE, and D. T. MEADOWS.** (*Ala. Expt. Sta.*). (*Soil Sci.*, 60 (1945), No. 6, pp. 427-435).—Experiments designed to test the need for supplementing high-analysis fertilizers with sulfur, calcium, magnesium, and minor elements showed the following results: The quantities of sulfur brought down in rain in the rural districts in Alabama are small and are probably insufficient for the normal growth of common agricultural crops. The efficiency of gypsum and elemental sulfur in increasing the yields of plant material differed but little. The sulfur concentration of the plant tissue was increased more readily through the use of elemental sulfur as a supplement than through the use of gypsum if the sulfur was given a chance to oxidize before a crop was planted. Lime increased the yield of plant material but caused a decrease in the sulfur concentration in the tissue. Sulfur, calcium, and magnesium in some form were necessary supplements to high analysis fertilizers. Minor elements in low-grade materials also appeared to be important. Lime was necessary as a supplement for neutralizing the acidity of high-analysis fertilizers in order to obtain maximum yields of crops. Lime added in quantities equivalent to the acidity of the fertilizer applied was sufficient to maintain the pH of the soil at a constant level. The concentration of any particular cation in the exchange material after 9 yr. of fertilizer treatment was higher in soils to which the cation was added than in those to which it was not added. In general, the use of high-analysis fertilizers relatively free of the usual impurities found in low-grade materials hastened the development of nutritional problems involving calcium, magnesium, sulfur, acidity, and minor elements.

## AGRICULTURAL BOTANY

**Electrokinetic studies on bacterial surfaces.—I, The effects of surface-active agents of the electrophoretic mobilities of bacteria, M. T. DYAR and E. J. ORDAL**

(*Jour. Bact.*, 51 (1946), No. 2, pp. 149-167, illus. 8).—The experimental work reported is exploratory in nature and represents an attempt to establish a method of characterizing bacterial surfaces. A variety of bacteria were treated with an anionic and a cationic surface-active agent, giving concentration-mobility curves which are distinctive for the various bacterial species. The changes in mobility occurring on treatment with such agents must depend on the chemical nature of the agent and that of the cell surface. The selection of sodium tetradecyl sulfate and cetyl pyridinium chloride for this study "was somewhat fortuitous, and it is to be expected that more distinctive concentration-mobility curves will be obtained by the use of surface-active agents of different structures or by the use of other polar molecules." The method described will prove of value in determining the chemical nature of substances present at the cell surface only if the presence of these substances is characteristically reflected in the electrokinetic behavior of bacteria in the presence of surface-active agents or other reagents. A beginning has been made in determining the electrokinetic behavior of particles of known composition in the presence of varying concentrations of surface-active agents. Striking differences have been observed in the electrophoretic behavior of substances such as hydrocarbons, protein, phospholipid, cholesterol, and inert surfaces in the presence of surface-active agents.

Further observations on the nuclear material of the bacterial cell, G. KNAYSIS. (Cornell Univ.). (*Jour. Bact.*, 51 (1946), No. 2, pp. 177-180, illus. 4).—In further studies (E. S. R., 89, p. 421), microcultures of *Bacillus cereus* (strain C<sub>3</sub>) were subjected to the Feulgen reaction at various stages of development. In very young cultures, the only Feulgen-positive differentiated structures were the cytoplasmic membrane and its extensions. At a later stage, cells grown aerobically formed lipoprotein inclusions—also Feulgen-positive. Forespores and young endospores stained homogeneously by the Feulgen technic, but mature spores exhibited a positive granule or rod. Whether this granule indicates differentiation or is due to shrinkage of the protoplasm during maturation is undetermined. The findings show that in this strain the nuclear material is diffuse both in the vegetative cell and in the young endospore, with a possible differentiation of a nucleus during maturation of the spore.

On the process of sporulation in a strain of *Bacillus cereus*, G. KNAYSIS. (Cornell Univ.). (*Jour. Bact.*, 51 (1946), No. 2, pp. 187-197, illus. 18).—*B. cereus* (strain C<sub>6</sub>) forms endospores by condensation of the protoplasm; the cytological processes involved are described. When very young sporangia are transferred—together with vegetative cells—into a fresh medium, the spores fail to germinate, and the sporangium and inclusions are preserved until the new culture reaches the sporulation stage. The form and size of the endospore and its position in the sporangium vary; its orientation seems to depend on the difference between its width and that of the sporangium; if the latter is much wider, the endospore tends to be oblique to the long axis of the sporangium. The number of endospores in a sporangium also varies. There is a tendency, however, in sporangia containing more than one spore for them to be separated—often incompletely—into monosporous sporangia. More often, a large cell forms a spore; this is followed by the formation of a partition, and another spore is usually formed in the newly delimited half of the cell. Only in a certain type of cells is sporulation preceded by enlargement of the sporangium. Sometimes midjet endospores are formed.

Utilization of certain rare sugars by microorganisms, C. M. McCLOSKEY and J. R. PORTER (*Soc. Expt. Biol. and Med. Proc.*, 60 (1945), No. 2, pp. 269-271).—The authors tested 13 rare sugars, including turanose, tagatose, neolactose, primeverose, vicianose,  $\beta\beta$ -trehalose, three methylated glucoses, and the Schardinger dextrans, for their utilization by 18 bacterial species and 4 yeasts. Some of these sugars

appear to be of value for differentiating certain members of the enteric group of bacteria.

**A study of the effect of growth substrate on the respiration of *Azotobacter*,** J. O. HARRIS. (Kans. Expt. Sta.). (*Jour. Biol. Chem.*, 162 (1946), No. 1, pp. 11-20, illus. 4).—The organic compound serving as growth substrate for *Azotobacter* markedly influences the subsequent respiratory activities of the resulting cells as measured by  $O_2$  uptake and reduction of methylene blue in the presence of a number of common respiratory substrates. When placed under favorable conditions, the cells are capable of adapting their respiratory system to the utilization of new compounds in a relatively short time—usually less than 2 hr.

**The effect of riboflavin analogues upon the utilization of riboflavin and flavin adenine dinucleotide by *Lactobacillus casei*,** H. P. SARETT. (Oreg. State Col.). (*Jour. Biol. Chem.*, 162 (1946), No. 1, pp. 87-97, illus. 1).—Isoriboflavin and 1-ribitylamino-2-amino-4,5-dimethylbenzene possess little riboflavinlike activity by themselves but are able to stimulate the utilization of riboflavin and flavin adenine dinucleotide (FAD) by *L. casei*. In the presence of alloxan the riboflavinlike activity of the ribitylamino compound was markedly increased. The diaminophenazine analog of riboflavin competitively inhibited the utilization of riboflavin and FAD to the same extent. Lumiflavin can either inhibit or stimulate the use of riboflavin or FAD by *L. casei*, depending on the relative amounts of lumiflavin present. The inhibition by lumiflavin is much greater when FAD is supplied as a growth factor in place of riboflavin. The findings suggest that riboflavin may be attached to an apoenzyme before it is converted to riboflavin phosphate or to FAD. *L. casei* utilizes riboflavin, riboflavin phosphate, and FAD equally well for growth and acid production. FAD is hydrolyzed to riboflavin phosphate by weak acid and to riboflavin by enzymatic digestion.

**The function of pyridoxin derivatives: A comparison of natural and synthetic codecarboxylase,** W. W. UMBREIT, W. D. BELLAMY, and I. C. GUNSALUS. (Cornell Univ.). (*Arch. Biochem.*, 7 (1945), No. 1, pp. 185-199, illus. 4).—The preparation of tyrosine decarboxylase from *Streptococcus faecalis* (strain R) in a cell-free state and the resolution of this enzyme into apoenzyme and coenzyme is described. The latter is identified as a derivative of pyridoxal, and a procedure is given for the chemical conversion of pyridoxal into the coenzyme in approximately 5 percent yield. An assay system for codecarboxylase or for pyridoxal is described, the method employing tyrosine decarboxylase apoenzyme obtained from cells of *S. faecalis* grown in a medium deficient in the vitamin  $B_6$  group.

**On the function of pyridoxine in lactic acid bacteria,** C. M. LYMAN, O. MOSELEY, S. WOOD, B. BUTLER, and F. HALE. (Tex. Expt. Sta.). (*Jour. Biol. Chem.*, 162 (1946), No. 1, pp. 173-174).—The results of an experiment showing the relationship of both pyridoxine and  $CO_2$  to the amino acid requirements of *Streptococcus faecalis* R and *Lactobacillus arabinosus* are presented. From the data obtained—since  $CO_2$  is not required for the growth of the organisms in a medium containing all the amino acids—it is deemed probable that  $CO_2$  is required specifically for amino acid synthesis. Likewise—since neither pyridoxin nor its derivatives are required for rapid growth where all the amino acids are present, but are required in a medium where certain of them are omitted—it seems probable that some form of pyridoxine is involved in an enzyme system which carries out amino acid synthesis in these organisms.

**The amino acid requirements of *Streptococcus faecalis* and the use of this organism for the determination of threonine in natural products,** I. T. GREENHUT, B. S. SCHWEIGERT, and C. A. ELVEHJEM. (Wis. Expt. Sta.). (*Jour. Biol. Chem.*, 162 (1946), No. 1, pp. 69-76, illus. 1).—Leucine, threonine, glutamic acid, asparagine, lysine, valine, isoleucine, methionine, arginine, histidine, serine, tryptophan, and

cystine were required and alanine, tyrosine, phenylalanine, and glycine were found to be stimulatory to *S. faecalis*. It has been used for the assay of threonine in natural materials; suitable recovery experiments and a study of methods of hydrolysis established the validity of this assay. The following values were obtained: Animal tissue protein 4.1 to 4.7, casein 3.7, lactalbumin 5.0, soybean oil meal 3.9, and whole corn 4.4 percent threonine in the protein (calculated to 16 percent N). The values are also expressed for each sample on the basis of the percentage of threonine N of the total N.

**Pléomorphism du *Penicillium notatum* et potentialité antibiotique**, H. VILU, J. COMANDON, P. DE FONBRUNE, and M. M. JANOT (*Compt. Rend. Acad. Sci. [Paris]*, 222 (1946), No. 7, pp. 406-408).—The authors conclude from data presented that, as in the dermatophytes, *P. notatum* possesses a pleomorphism, reversible with difficulty, which may be accompanied by a reduction or even suppression of its bacteriostatic activity. Single spore cultures appear indispensable in obtaining strains of high antibiotic potentiality.

**Studies to determine if antibiosis occurs among Rhizobia.—I, Between *Rhizobium meliloti* and *Rhizobium trifolii***, L. W. ERDMAN (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 3, pp. 251-258).—In greenhouse tests with alfalfa and red clover in which single-strain cultures of the alfalfa and red clover nodule bacteria were compared with so-called combination cultures, the over-all results were significantly in favor of the latter. There was no evidence in the alfalfa tests of any inhibition of nitrogen fixation when the alfalfa bacteria were grown in the same culture with the red clover strains, thus no antibiosis or antagonism was found. In the red clover test the over-all comparisons gave no evidence one way or the other. Nitrogen fixation with four of the red clover strains gave some indication that the combination red clover plus alfalfa cultures were better than the red clover bacteria alone; there was no evidence of antibiosis with these four single-strain red clover cultures. Antibiosis was demonstrated, however, with one red clover strain and with a composite red clover plus alfalfa bacteria inoculant which included this particular red clover strain.

**The nature of the antibacterial agent from *Anemone pulsatilla***, H. BAER, M. HOLDEN, and B. C. SEGAL (*Jour. Biol. Chem.*, 162 (1946), No. 1, pp. 65-68).—The antibacterial agent of *A. pulsatilla* is shown to be protoanemonin.

**Inheritance in a bread mold**, L. R. WALDRON (*North Dakota Sta. Bimo. Bul.*, 8 (1946), No. 3, pp. 22, 39).—A popular account of the inheritance and nutritive requirements of a bread mold, *Neurospora*.

**Some Oedogoniaceae and Zygnemataceae from Texas and Louisiana**, C. E. TAFT. (Ohio State Univ.). (*Amer. Micros. Soc. Trans.*, 65 (1916), No. 1, pp. 18-26, illus. 10).—The records of these groups of fresh-water algae here presented are from 215 collections.

**Notes on the grasses, sedges, and rushes of the Great Swamp (New Jersey)**, W. F. RAPP, JR., and J. L. C. RAPP (*Bul. Torrey Bot. Club*, 73 (1946), No. 2, pp. 203-204).—Notes on collections made by the authors in the summer of 1944.

**A catalog of the vascular plants of Maryland**, J. B. S. NORTON and R. G. BROWN. (Md. Expt. Sta.). (*Castanea*, 11 (1946), No. 1, pp. 1-50).—The present list includes 82 Pteridophytes and 2,334 Spermatophytes, making a total of 2,416 species, forms, and varieties known to grow without cultivation in Maryland.

**Additions to the revised catalogue of Ohio vascular plants, XIII**, C. H. JONES. (Ohio State Univ.). (*Ohio Jour. Sci.*, 45 (1945), No. 4, pp. 162-166).—An annotated list of further additions (E. S. R., 92, p. 181) to the State Herbarium.

**Wild flowers of Mississippi**, F. S. BATSON and G. W. JOHNSTON (*Mississippi Sta. Bul.* 417 (1945), pp. 60+, illus. 65).—"This bulletin has been prepared to help nature lovers and gardeners identify wild flowers of the State and to encourage

their use in landscape plantings." Although relatively few (62) of the native herbaceous plants are listed, many of the species that are more desirable for cultivation have been included and are described and illustrated.

**The genus *Palafoxia* in Texas**, V. L. CORV. (Tex. Expt. Sta.). (*Rhodora*, 48 (1946), No. 568, pp. 84-86).—The annual plant *P. riograndensis* n. sp. is described.

**Catalogus florae Domingensis (Catalogo de la flora Dominicana)**.—I, **Spermatophyta**, R. M. MOSCOSO (*New York: Univ. Santo Domingo*, 1943, pp. 732+, illus. 5).

**Las plantas medicinales de México [Medicinal plants of Mexico]**, M. MARTINEZ (*Mexico: Ediciones Botas*, 1944, 3. ed., pp. 630, about 400 illus.).—This manual—copiously illustrated and with many colored plates—considers in part 1 those plants of known botanical classification, the properties of which have been scientifically and more or less extensively studied, and in part 2 those botanically known but whose properties have been studied incompletely or not at all; lists in part 3 the plants not yet botanically identified but which are in popular use as "home remedies;" and in part 4 considers briefly and without illustrations the plants of Yucatan mentioned in the work of "El Julio" entitled "Medicina Doméstica," published in 1834.

**Trees for the Aleutians**, D. BRUCE and A. COURT (*Geog. Rev.*, 35 (1945), No. 3, pp. 418-423).—Thousands of trees have been planted in the originally treeless Aleutians as a byproduct of the war. The reasons that have been advanced for the original absence of trees on the islands are two, viz, either the present climate is too severe or the trees have not yet spread so far since the last ice age. Weather statistics from a score of Army weather stations since the start of the war have indicated 130 to 190 days from frost to frost—far longer than for many heavily forested regions. For the full year 1944 precipitation ranged from 27 to 52 in.; for the 4 summer months, 7 to 15 in. It is probable that many Aleutian sites receive more sunshine than some forested regions of southeastern Alaska in the same latitude. It is not believed that, in general, the high winds or the available N, P, K, and Ca are limiting factors for tree growth. Furthermore, there is evidence to be found on Kodiak Island of the advance of the forest during the memory of older residents. Natural establishment of new foci of tree propagation removed from the present forest limit requires not only favorable conditions at the site but also recurrent means of transporting seeds or seed-bearing branches and uprooted trees. The prevailing winds are westerly, and 500 miles of ocean lie between Asia and the westernmost islands. Occasional winds blow from the northeast, but the rugged Alaska Peninsula offers few footholds for tree seedlings and ocean currents are erratic. The Army's efforts may finally answer the question whether or not the Aleutians can support the continued growth of trees.

**Additional introduced plants in the Aleutian Islands**, E. H. WALKER (*Bul. Torrey Bot. Club*, 73 (1946), No. 2, pp. 204-205).—The author records some introductions additional to those noted by Bruce and Court (see preceding entry).

**Istoricheskaiâ geografiâ rastenii: Istoriâ flor zemnogo shara [Historical geography of plants: History of the world floras]**, E. V. VUL'F (*Moskva (Moscow): Akad. Nauk S. S. S. R.*, 1944, pp. 545+, illus. 64).

**The role of plants in geography**, G. F. CARTER (*Geog. Rev.*, 36 (1946), No. 1, pp. 121-131).—Giving consideration to the economic plants of the earth in their regional setting, the author in this address discusses the corn regions of the Americas, relationships between corn areas, application to settlement problems, the danger of plant standardization, and regions and complexes of useful plants. Historically, plant distributional studies have long been associated with geography; plant geography—and especially economic plant geography—is based on field study, with observations of soil, slope, climate, and culture supplying the necessary data for

meaningful distributional studies. As a field, plant geography is considered as valid a study as any other systematic branch of geography; in its broadest sense—and not only in its domestic plant aspects—it is vital to a comprehensive regional approach and is especially important to regional planning. The historical approach to economic plant geography gives not only greater depth to an understanding of the problems involved but aids in judging the validity of apparent environmental limitations. Finally, from an over-all view of the past and present trends in economic plant geography, the danger of suffering a tragic loss through the continuing and accelerating destruction of useful plants becomes clear.

**A seven-year quantitative study of succession in grassland,** J. E. WEAVER and W. E. BRUNER. (Univ. Nebr. et al.). (*Ecol. Monog.*, 15 (1945), No. 3, pp. 297–319, illus. 17).—The nature and rate of succession in a 23-year-old native pasture under complete protection from grazing were studied quantitatively near Lincoln, Nebr., during 1937–43. The pasture was of the little bluestem-Kentucky bluegrass type before the great drought of 1934–36, but was dominated by sand dropseed and side-oats grama after the high mortality of the less xeric grasses. As determined by stem counts, 14 species of grasses and sedges, 19 native forbs, and 13 ruderals constituted the total vegetation in 43 one-meter quadrats in 1937; this later increased to 58. Drought occurred each season until 1942, but growth conditions were favorable in the spring and early summer of 1938 and 1941; excellent growth occurred in 1943–44. Soil sampling revealed that the vegetation depended chiefly on current rainfall. The most marked change in quadrats dominated by sand dropseed was a steady increase in number of stems of the dominant until near the end of the drought; such conditions were followed by gradual decreases when the more mesic grasses regained their vigor—as shown by the detailed data presented. Near the end of 1940, sand dropseed still dominated in many places. After 8 yr.—and especially 3 consecutive good years—climax conditions had almost been attained, and in only a few places was sand dropseed still abundant. The bluestems and side-oats grama dominated except in parts of lowlands where bluegrass formed a dense sod; there was no bare soil. All the weedy annuals had disappeared; aster and goldenrod were also absent or greatly subdued. An understory of various minor prairie grasses, bluegrass, and forbs was rapidly developing. Under the dense stand of prairie grasses there was a good mulch of fallen debris, but the absence of certain species of prairie grasses and forbs, common in adjacent climax prairie, as well as the lack of various community relationships indicated that succession was still incomplete.

**A change from grassland to forest vegetation in the "Big Barrens" of Kentucky,** B. B. MCINTEER. (Univ. Ky.). (*Amer. Midland Nat.*, 35 (1946), No. 1, pp. 276–282, illus. 1).—The pioneers found vast regions of grassland in some parts of Kentucky; the early settlers gave the name "Barrens" to the region, thinking that the absence of trees signified land of low productivity. The "Big Barrens" formed a narrow crescent corresponding to that part of the State having karst lands, covering an area of 5,000 to 6,000 sq. miles. It appears that the treeless condition had been brought about by a severe drought followed by invasion of prairie-plant species, and that thereafter the grasses remained because of the combined influence of the unusual conditions in the earth's crust, extremes in some climatic factors, and the frequent fires. After settlement by the whites a young forest growth sprang up all over that part which shortly before had been covered with prairie vegetation. There are 16 references.

**Investigation of plant-growth substances (auxins) in sewage products,** C. A. CHAPLIN and C. J. REGAN (*Jour. Soc. Chem. Indus., Trans and Commun.*, 64 (1945), No. 12, pp. 331–332).—In order to ascertain whether the auxin content (if any) of sewage products would be likely to play a role in their use as fertilizers, a

number of the normal sewage wastes of London were examined. The findings indicate that most of these products contain auxins in small but measurable quantities; also that—although crude and digested sludges in the wet state may both contain auxins of an order relatively high to the total solid content—most of these growth factors are decomposed during normal drying of the sludges.

**Influence of sulfonamides and para-aminobenzoic acid on the growth of *Lupinus albus*.** D. I. MACHT (*Soc. Expt. Biol. and Med. Proc.*, 60 (1945), No. 2, pp. 217-220).—Of the three aminobenzoic acids, the meta isomer proved the most toxic and the para isomer the least so. The latter exerted a diphasic effect on root growth; very weak solutions were growth-promoting, whereas stronger concentrations were growth-inhibitory. Sulfanilamide and six other sulfonamides exerted a similar action. Combinations of sulfanilamide and para-aminobenzoic acid in every case exerted not an antagonistic but a synergistic or potentiated depression on growth of this legume.

**Tuméfaction des racines et mito-inhibition sous l'influence du camphre** [Tumefaction of roots and mitoinhibition under the influence of camphor], G. DLYSSON (*Compt. Rend. Acad. Sci. [Paris]*, 221 (1945), No. 19, pp. 568-570).—In the experiments reported, camphor exercised a "mitoclasique" action on onion roots at an optimum concentration of 0.020 to 0.030 percent without provoking abnormalities in cell size. At lower concentrations—0.015 to 0.012 percent—it caused the formation of subterminal enlargements morphologically resembling those obtained with colchicine; in this case, the mitoclasique action had practically disappeared. Consequently, the two effects on the roots are considered to have been induced by different doses of the active principle, the two responses being parallel but apparently independent.

**The nitrate nutrition of plants: A general survey of the occurrence and assimilation of nitrate.** H. BURSTRÖM (*Lantbr. Högsk. Ånn. [Uppsala]*, 13 (1945), pp. 86).—This survey considers the presence of nitrate in plants, the seat of nitrate assimilation, products of the reduction of nitrate, the enzyme chemistry of its reduction, the influence of heavy metals on its assimilation, the connection with carbohydrate assimilation, and the theories of nitrate assimilation. The bibliography covers nearly 10 pages.

**Plant nutrition and the hydrogen ion.—V, Relative effectiveness of coarsely ground and finely pulverized limestone.** W. A. ALBRECHT. (Mo. Expt. Sta.). (*Soil Sci.*, 61 (1946), No. 3, pp. 265-271, illus. 1).—In continuation (E. S. R., 88, p. 604), use of 10-mesh or 100-mesh pulverized limestone,  $\text{CaSO}_4$ , and  $\text{Ca}(\text{Cl})_2$  as Ca fertilizers for establishing sweetclover revealed the smaller applications of the 10-mesh limestone to be relatively most effective as measured by corn yields. In heavier rates of application (2 tons per acre), the 10-mesh limestone was more effective than the 100-mesh materials alone, or than these combined with P and K fertilizers. These findings support the view that the soil need not be a uniform medium as to degree of acidity or distribution of all the essential plant nutrients; rather, it may be a mixture representing a heterogeneous collection of foci of each of these in the mineral or rock forms weathering slowly in contact with acid clay. Plant growth may then represent the summation of root contacts with all these different fertility centers as the roots move to and get from them all that is needed for maximum productivity. According to this idea, both the very soluble and the less soluble nutrients applied in granular form would maintain this seemingly beneficial heterogeneity of fertility sources for better plant growth than would any practice aiming to blend the soil to the uniformity of nutrient solutions. This concept points to possible trouble in saturating the clay with Ca only, which would displace other essential elements. It also suggests an economy in limestone use when this fertilizer stone will serve without the extra cost of finer grinding.

**On the solubility of boron compounds in the plant**, E. V. BOBKO and T. D. PRIADILSICHIKOVA (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 48 (1945), No. 5, pp. 358-359*).—When plant materials (lupine and buckwheat used) were extracted with hot water by the "periodic method of extraction," the greater part of the B passed into solution; under the experimental conditions, however, one-tenth to two-tenths could not be so transferred. The principal mineral elements in the plant formed the following increasing sequence of solubility in hot water—P, Ca, B, K.

**La pourriture de la betterave gelée—mécanisme de la synthèse de la fructosane** [Decay in frozen beets—mechanism of fructosan synthesis], H. BELVAL and B. DELAPORTE (*Compt. Rend. Acad. Sci. [Paris], 221 (1945), No. 20, pp. 592-593*).

**A field method for estimating rubber content in live roots of rubber plants**, M. S. NAVASHIN and A. F. CHEREDNICHENKO (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 48 (1945), No. 4, pp. 289-292, illus. 2*).—In the authors' simplified method—applicable to mass selection under field conditions—the equipment is limited to a test tube with a strip of printed text fastened to it and a glass rod. A drop of latex is taken from a surface wound made by cutting off the end of the root (e. g., of kok-saghyz); the drop is allowed to fall freely into the test tube, which has first been filled with water to a marked point. After stirring, the printed text is observed through the diluted latex—if it is readable, the root is rejected; if it is not, the root is considered deserving of propagation.

**On the synthesis of rubber in plants—filling of laticiferous vessels with foreign latex**, A. A. PROKOFIEV (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 48 (1945), No. 7, pp. 520-523, illus. 1*).—With the idea of clearing up a number of points concerning the synthesis of rubber and the physiological role played by the laticiferous system it seemed reasonable to attempt filling the laticiferous system of one species with the latex of another. This was accomplished by grafting together plants sharply differing in the shape of their latex globules, the common dandelion, kok-saghyz, and krym-saghyz being used for the purpose. During the first year of life of the graft no mixing of the latexes was observed, but in the second year transport of the latex from the stock into the scion was noted during the latter part of the growing season. A method was also worked out whereby, through tapping the roots of one of either component of the graft, the laticiferous system of the one could be filled with the latex of the other. This transport is believed explainable through the migration of liquids in the transpiration stream by which the latex is carried along. The possibilities of the method in studies of the physiological role of latex are suggested.

**The metabolism of starving leaves.—VI, Nitrogen balance sheet and changes in organic acid content during starvation of oat leaves**, D. H. CRUICKSHANK and J. G. WOOD (*Austral. Jour. Expt. Biol. and Med. Sci., 23 (1945), No. 3, pp. 243-247*).—In this paper (E. S. R., 92, p. 187), a balance sheet of changes in the amounts of nitrogenous substances in oats leaves during starvation is presented for two experiments. Determinations of protein, peptides, residual amino acids, glutamine, asparagine, arginine, ammonia, nitrate, purines, betaine and choline, and basic nitrogen were made—all expressed in terms of their N contents; up to onset of browning of the leaves, the amounts of these substances accounted for 95 to 100 percent of the total N. No change in the amounts of nitrate N, betaine and choline N, and purine N could be detected during the starvation period, the major changes involving redistribution of the N of protein, peptides, amino acids, amides, and ammonia. With onset of browning, a loss of total N occurred and the substances estimated accounted for only 75 to 80 percent of the total N in the leaves. Malic and citric acids increased during starvation; the evidence suggested that part of these acids was derived from

nitrogenous sources (probably amides) but that no simple relationship exists between the amides and acids.

**On the correlation between the reaction of flowering to the nitrogenous food and the photoperiodic reaction of the plant,** M. C. CAJLACHJAN (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 48 (1945), No. 5, pp. 360-364, illus. 4*).—According to studies by the author and other workers, plants may, in general, be placed in three groups according to their flowering reactions to nitrogenous nutrition: (1) N-negative plants which bloom earlier with complete elimination or low dosages of N, (2) N-positive plants which bloom earlier with normal or increased dosages of N, and (3) N-neutral plants which bloom at the same time irrespective of the N dosage or on a variety of soils. There also exists a correlation between the photoperiodic and flowering reactions to mineral nutrition. It became evident, however, that, although the N and photoperiodic groups for the most part coincide, there are certain deviations from this regularity. In the experiments here reported, all the N-negative plants were in the long-day group. The N-positive plants of low N threshold formed an intermediate or transitional group containing both long- and short-day plants. All the N-positive plants of high N-threshold were short-day plants. Finally, the N-neutral group included both short- and long-day species. Two other relationships of the blooming reaction v. N nutrition depended on the length of the growing period of a variety and on the earliness or lateness of varieties within the same species. The greater the length of the growing period—as controlled by the light regime—the greater were the differences in development rate as correlated with the N nutrition. Certain suggestions are made with respect to the evolution of these reactions.

**Effect of day-length upon salt-resistance in cotton,** V. A. NOVIKOV (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 48 (1945), No. 6, pp. 444-446*).—The author's studies led to the conclusions that when cotton is cultivated under short day its salt resistance is reduced; its susceptibility to short day heightens with increases in salinity; its increased reactivity to the short day under saline conditions is correlated with exhaustion; and the reduced salt resistance with short day depends on the reduced accumulation of organic substances within the plant. It is suggested that the salt resistance of the plant will increase along with its photosynthetic activity.

## GENETICS

**Five years of colchicine research,** J. M. KRYTIE and S. J. WELLENSIEK (*Bibliog. Genet., 14 (1942), No. 1, pp. 132*).—The literature (385 references) on induction of polyploidy in higher plants by the action of colchicine is discussed in detail, and the other effects of colchicine on both plants and animals are reviewed. The species treated with colchicine—243 species in 137 genera—are tabulated, and the amphidiploids produced—40 species crosses on 11 genera and 3 genus crosses—are listed. Some 47 substances with more or less similar action are also tabulated; thus far permanent polyploidy is said to have been induced only with growth substances and acunaphthene.

**Self- and cross-fertility relationships in *Lotus corniculatus* L. and *Lotus tenuis* Wald. et Kit.,** G. A. TOME and I. J. JOHNSON. (Iowa Expt. Sta.). (*Jour. Amer. Soc. Agron., 37 (1945), No. 12, pp. 1011-1023, illus. 2*).—Both the broad-leaf (*L. corniculatus*) and narrow-leaf (*L. tenuis*) types of birdsfoot trefoil had a high degree of self-sterility as measured by percentage of pod set and number of seeds per pod in a greenhouse study. Chromosome numbers of  $n = 6$  for *L. tenuis* and  $n = 12$  for *L. corniculatus* were verified. Crosses between the two species gave no seed set, yet a high percentage of pod set was obtained with *L. tenuis* as the female parent, and very low pod set with *L. corniculatus* as the female parent. Differences

in pod set with reciprocal crosses were explained on the basis of chromosome balance between the stylar tissue and the pollen tube. Crosses between an autotetraploid (4n) *L. tenuis* were produced by colchicine treatment, and *L. corniculatus* failed to produce viable seeds although pod development was normal.

**"Long husk" sterility in maize**, W. R. SINGLETON. (Conn. [New Haven] Expt. Sta.). (*Jour. Hered.*, 37 (1946), No. 1, pp. 29-30, illus. 1).—A brief comment is made upon an inbred line of sweet corn, Connecticut 95, that is incapable of maintaining itself under open-pollination field conditions because of the extremely long husks. These may prevent the silks emerging in time to be pollinated, or the silks themselves may be incapable of enduring long enough to become pollinated.

**Tetraploidy in flax**, J. G. ROSS and J. W. BOYES (*Canad. Jour. Res.*, 24 (1946), No. 1, Sect. C, pp. 4-6, illus. 1).—Tetraploid forms of Redwing flax and the  $F_1$  of Bison  $\times$  Redwing were obtained most easily by treatment of the epicotyl of seedlings with colchicine in lanolin emulsion. Their seeds were considerably larger than those of the diploid; but, because of their lower fertility and later maturity, yield and quality were definitely inferior.

**Potato breeding methods.—III, A suggested procedure for potato breeding**, F. A. KRANTZ (*Minnesota Sta. Tech. Bul.* 173 (1945), pp. 24).—Recent information on potato breeding (E. S. R., 61, p. 722), particularly since the formation of the National Potato Breeding Program in 1929, is summarized with discussion of the indicated procedures for potato improvement. Literature cited includes 52 titles.

Characteristics of the potato that seem to influence the method of breeding include asexual propagation, ease of selfing and crossing, influence of sexual reproduction on tuber yield, partial elimination of pollen sterility through the pollen, relation of stainable pollen in female parents to proportion of sterile to fertile pollen plants in sexual progenies, and effects of selfing and crossing. Breeding procedures are suggested for development of better pollen parents, utilization of these fertile pollen plants in crosses to obtain sterile and fertile pollen plants with the desired characters, and further crosses between selected sterile and fertile pollen plants of enough genetic diversity in origin to give an opportunity to obtain sterile pollen and shy blooming selections of high-yielding ability with an improved combination of characters.

**Further studies on southern stem blight resistance in tomato lines and varieties**, J. L. BOWERS and J. T. PRESLEY (*Miss. Farm Res. [Mississippi Sta.]*, 9 (1946), No. 1, pp. 1, 8).—Of 42 lines and selections of tomatoes tested in the spring of 1945 for resistance to stem blight, two species (*Lycopersicon pimpinellifolium* and *L. hirsutum*) showed some degree of resistance. The VBL 42-23 line obtained from a cross of *L. pimpinellifolium* and *L. esculentum* showed the highest degree of tolerance based on survivors of two inoculations. Good records were made also by certain other VBL (U. S. D. A. Regional Vegetable Breeding Laboratory) lines. Tests conducted in the fall of 1945 with plants about 4 weeks of age and with plants ready for transplanting into the field showed the older plants to possess a much higher degree of resistance. The highest survival in the young group was 43.7 percent and in the older group 87.5 percent. The results of all the trials suggested marked progress in the development of tomatoes possessing resistance to southern stem blight.

**The behavior of the self-compatibility factor and its relation to breeding methods in *Trifolium repens***, S. S. ARWOOD. (U. S. D. A. et al.). (*Jour. Amer. Soc. Agron.*, 37 (1945), No. 12, pp. 991-1004).—Results of investigations on the behavior of the  $S_1$  gene in white clover are summarized. In a heterozygous  $S_1S_2$  plant, the two types of gametes were produced in about equal numbers at least following macrosporogenesis, but when pollen from such a plant was placed on a stigma bearing two other alleles,  $S_1$  pollen functioned to produce less than one quarter of the resultant progeny. When a heterozygous  $S_1S_2$  plant was crossed as male onto a

self-incompatible plant bearing  $S_s$ ,  $S_s$  pollen was inhibited completely, despite association with  $S_f$ . In a heterozygous  $S_f S_s$  plant used as female, the  $S_f$  functioned as a partly dominant factor when all pollen normally would have been inhibited ( $S_s S_s$ ) permitting some seed set, but the oppositional effect was not disturbed by  $S_f$  when only part of the pollen was inhibited ( $S_s S_s$ ). Homozygous  $S_f S_f$  individuals were obtained in expected frequencies following selfing or intercrossing of heterozygous  $S_f$  plants, and they were detected easily by a progeny test. Such homozygous plants might prove useful in breeding operations, since the few tested so far have imparted considerable vigor and good seed setting ability to their  $F_1$  progenies.

**A mottled-leaf character in winter squash—inherited as a dominant mendelian character**, D. H. SCOTT and M. E. REINER. (U. S. D. A.). (*Jour. Hered.*, 37 (1946), No. 1, pp. 27-28, illus. 1).—Mottled leaf, a distinctive vegetative character in the winter squash (*Cucurbita maxima*), was found to be inherited as a single dominant gene that may have value as a marker for use in linkage studies.

**Maternal inheritance of variegation in common wheat**, W. K. PAO and H. W. LI (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 1, pp. 90-94).—A yellow-striped plant, found in a common wheat (Mo 101) variety, proved to be a case of maternal inheritance. Variegated plants always segregated into normal green, variegated, and pure yellow in different proportions in the subsequent generation. Pure-breeding, truly variegated lines were never isolated.

**Fertilization in *Ulmus* with special reference to hybridization procedure**, L. P. V. JOHNSON (*Canad. Jour. Res.*, 24 (1946), No. 1, Sect. C, pp. 1-3).—Germination tests on fruits derived from open-, self-, and crosspollinations made in *Ulmus* during four seasons strongly indicate a high degree of self sterility, possibly due to protogyny. It is suggested that a hybridization procedure involving the crosspollination of nonemasculated flowers is feasible in many species of the genus, especially under conditions that permit large-scale crossing and the growing of fairly extensive populations from which selfed seedlings may be eliminated.

**Genetic purity in animal colonies**, F. B. HUNT. (Cornell Univ.). (*Ann. N. Y. Acad. Sci.*, 46 (1945), Art. 1, pp. 5-21, illus. 1).—Differences in form, physiology, and viability among litter mates are noted. Important differences may occur between breeds as a result of multiple factor differences which may be cumulative. The effects of inbreeding in reducing heterozygosity and increasing uniformity are noted.

**Evidence of genes for female sterility in dairy cows**, P. W. GREGORY, W. M. REGAN, and S. W. MEAD. (Univ. Calif.). (*Genetics*, 30 (1945), No. 6, pp. 506-517, illus. 1). A qualitative analysis of female fertility and sterility was made for all Jerseys and Holsteins of the California Experiment Station herd that have reached the age of reproduction during the past 25 yr. The Jerseys numbered 266 cows sired by 16 bulls; the Holsteins, 94 cows sired by 2 bulls. Only a few of the bulls produced sufficient progeny for an adequate genetic analysis, but the use of sire-daughter matings permitted a Mendelian analysis for genes conditioning female sterility.

The female sterility transmitted by each of the bulls tested followed a single autosomal recessive factor with a sex-limited pattern of inheritance. It was not determined whether the original bulls carried the same or different genes for female sterility. Judging from the evidence, the original population of Jersey and Holstein cows carried a gene for female sterility, the frequency value being approximately 0.1 or less. "All the sterile females observed could be accounted for by a specific gene for sterility. Judging from this and other studies, heredity plays a more important role in female sterility than is generally suspected."

**Artificial insemination of Australian Merino sheep** (Sydney: Australasian Med. Pub. Co., 1942, pp. 52, illus. 8).—Directions for the collection of semen from rams and its use for artificial insemination are described. In addition to a foreword by

G. B. S. FALKNER (pp. 5-7), there are included: Some Genetical Aspects of Artificial Insemination, by R. B. KELLEY (pp. 9-14); Field Methods—A, Artificial Insemination of Sheep (pp. 15-32) and B, Preliminary Trials at Haddon Rig (pp. 33-50), by W. GRANGER; and The Likely Utilization of Artificial Insemination in Sheep Breeding in Australia, by R. M. C. GUNN (pp. 51-52).

**The genetics, physiology, and economic importance of the multinipple trait in sheep**, R. W. PHILLIPS, R. G. SCHOTT, and D. A. SPENCER (*U. S. Dept. Agr., Tech. Bul. 909 (1945), pp. 16, illus. 8*).—A more comprehensive account of the information previously noted (E. S. R., 95, p. 42).

**Prenatal development of the sheep**, W. W. GREEN and L. M. WINTERS (*Minnesota Sta. Tech. Bul. 169 (1945), pp. 36, illus. 57*).—The rate of fetal development of prenatal sheep is described and illustrated much as was done for the prenatal bovine (E. S. R., 88, p. 181), using fetuses of known age. Comparison was made with the different stages of bovine development.

**Relative growth in races of mice produced by selection**, J. W. MACARTHUR and L. P. CHIASSON (*Growth, 9 (1945), No. 4, pp. 303-315, illus. 2*).—"Selections for body weight in the house mouse produced small and large races which differ significantly in linear measurements, in relative length of the appendages (tail, ear, hind foot), and in litter size. For each appendage there proved to be two phases of relative growth, the first of tachy-heterauxesis—the second of brady-heterauxesis. The breaks between phases occur when the body is 40 to 70 mm. long, but are not synchronous for the three appendages. The difference in relative length of appendages between races, sexes, and ages are shown to depend primarily upon body size and the genetic factors controlling it. Length of each appendage is controlled by general body size factors, acting with or on characteristic specific rate determinants for heterauxesis. These determinants were not changed by the body size selections. The mice all form one allometric tribe, not differing in  $b$  or  $k$  constants."

**Evidence for normal segregation of species-specific antigens in the backcross of species hybrids in doves**, M. R. IRWIN and L. J. COLE. (Univ. Wis.). (*Genetics, 30 (1945), No. 6, pp. 487-495*).—When several hybrids from a cross of Senegal and ringdove were mated to ringdove, "the antigens specific to Senegal, as contrasted to ringdove, appeared to segregate at random in the first backcross generation; at least the segregation was not sufficiently at variance with expectation according to chance alone to be detected. Because the distribution of these cellular characters of Senegal appeared to be normal, it may be concluded that there was more or less normal assortment in the species hybrid parents of the nine or more chromosomes of Senegal carrying genes for antigens specific to the species. This in turn suggests that there was more or less normal pairing of these nine chromosomes of Senegal with partners in ringdove."

**The effects of low incubation temperatures on the expression of rose and duplex comb, crest, muffs, frizzled, naked neck, and triple spurs in the domestic fowl**, P. D. STURKIE. (Ala. Polytech. Inst.). (*Amer. Nat., 79 (1945), No. 782, pp. 286-288*).—In continuing the study of the effect of low temperatures on development of embryos (E. S. R., 90, p. 468), incubation for 2, 3, and 5 days was found to be effective on several characters, particularly crest, duplex comb, and muffs, which were shown by a Houdan ♂ homozygous for these characters mated with normal White Leghorn ♀♀. All the embryos produced from these matings and a homozygous frizzle ♂ mated with nonfrizzle ♀♀ showed the dominant characters except in the frizzled matings, where a few normal or questionable offspring were obtained.

**Biological actions of sex hormones**, H. BURROWS (*Cambridge, Eng.: Univ. Press, 1945, pp. 514+*).—This comprehensive manual is divided into six parts, dealing, respectively, with gonadotropins (pp. 1-95), gonadal hormones (pp. 96-151), androgens (pp. 152-250), estrogens (pp. 251-388), progestins (pp. 389-439), and sex hormones of the adrenal cortex (pp. 440-456).

**Induction of estrus in the ovariectomized golden hamster.** A. H. FRANK and R. M. FRAPS. (U. S. D. A.). (*Endocrinology*, 37 (1945), No. 5, pp. 357-361).—Estrus was regularly induced in the ovariectomized golden hamster by injection of 10 $\gamma$  of estrogen followed by injection in 24 to 48 hr. with injection of 0.05 to 0.5 mg. of progesterone. A single dose of estrogen alone over a wide range of dosages induced estrus in only a small percentage of the animals. Estrus response following estrogen-progesterone was of longer duration and resembled estrus in the normal ♀. Study was made with 93 ovariectomized hamsters.

**Response of chicks to pituitary gonadotropins and pregnant mare serum.** W. R. BRENLMAN (*Ind. Acad. Sci. Proc.*, 54 (1944), pp. 207-213).—Chicks kept without food or water during a test period of 12 to 96 hr. after hatching proved to be very responsive to pregnant mare serum and pituitary gonadotropins, both of which caused increased gonad weight. Three divided doses were more effective than a single dose. Only the combs of chicks composing 15- and 20-day series were increased in weight following the administration of pregnant mare serum, and higher doses were required in experiments of shorter duration. The 96-hr. test was about 30 to 40 times more sensitive than the longer assay. Follicular stimulating hormones were effective on chicks but showed no augmentation when combined with lutein hormone. Small doses of 0.2 rat units of follicle-stimulating hormone and 0.5 rat units of luteinizing hormone daily were ineffective in 15-day chick experiments. Good response only occurred at the relatively high dosages of 10 to 20 rat units. Both follicle-stimulating and luteinizing hormones increased comb growth in young and mature birds.

**Effects of FSH and LH upon the ovaries of immature chicks and low-producing hens.** A. V. NALBANDOV and L. E. CARD. (Univ. Ill.). (*Endocrinology*, 38 (1946), No. 2, pp. 71-78).—In these tests of gonadotropic hormones, female chicks were injected with one "hen unit" of FSH followed by LH at 30, 60, 90, 120, 150, and 180 days of age. Some increase in ovarian and oviducal weights resulted. No follicles of ovulatory size were produced before 180 days of age. It was found possible to produce follicles of ovulatory size and cause them to ovulate 8-22 days before their uninjected controls would commence to lay normally. In nonlaying hens FSH and LH caused the production and the ovulation of an average of 4.2 ova per hen following injection of LH. One hen of 7 began to lay and laid 5 eggs in 13 days. In low-producing hens FSH and LH treatment caused 6 of 7 hens to commence laying. In this group only 1 ovulation per hen was produced following the LH injection.

**Interruption of ovulation in the hen by subcutaneously administered non-specific substances.** R. M. FRAPS and B. H. NEFFER. (U. S. D. A.). (*Endocrinology*, 37 (1945), No. 6, pp. 407-411).—Experiments are reported in which hens in fair regular production were injected subcutaneously, in saline, with various nonspecific (hormone-free) substances which inhibited or interrupted ovulation. "Effective preparations include desiccated tissues (corpus luteum and ovarian residues of the cow; brain, muscle, and oviduct of the chicken), whole dried egg white, proteins (ovalbumin and casein) and peptone. At relatively high doses all of these substances bring about prompt and extensive follicular atresia, with cessation of ovulation. Control injections of saline and distilled water were of little or no effect. The effectiveness of ovalbumin, casein, and peptone indicates that the action of the dried tissue preparations and egg white may be attributed to their content of proteins or protein derivatives. Following the administration of some preparations at relatively low doses, ovulation was inhibited for at least 6 to 11 hr. beyond the time of its normal occurrence without evidence of the onset of atresia, suggesting that the nonspecific substances may act through the anterior pituitary gland or its gonadotrophins."

**The relation between ovulation frequency and the incidence of follicular atresia following surgical operations in the domestic hen, I. ROTHCHILD and R. M. FRAPS. (U. S. D. A.). (*Endocrinology*, 37 (1945), No. 6, pp. 415-430, illus. 2).—**The incidence of follicular atresia was studied in six groups of domestic hens subjected to one each of the following operations: Removal of the most recently ruptured follicle (111 birds), removal of the next older follicle (51 birds), removal of a follicle older than either of the first two (39 birds), sham ovarian operation (35 birds), operation on the right side of the body cavity (sham) (15 birds), and operation on the breast muscle (37 birds). It was found that in all the groups which were subjected to abdominal operations the incidence of atresia was inversely proportional to the frequency of ovulation preceding operation. The induction of atresia was found to be associated with the effects of abdominal operation per se, rather than with the removal of an ovarian element. Operations performed on the breast muscle, however, resulted in a negligible incidence of atresia. It was also found that, in birds of the same or similar ovulation frequencies, the incidence of atresia was directly related to the loss in body weight following operation. However, proportionately much greater increases in the incidence of atresia occurred in birds of similar body weight changes in relation to decreases in ovulation frequency than they did in birds of similar ovulation frequency in relation to increases in weight losses. A theoretical explanation of the relationship is offered which is based on the assumption that the induction of atresia is mediated through the pituitary gland.

**Capon production by the use of synthetic oestrogen (stilboestrol), D. J. G. BLACK and R. G. BOOTH (*Vet. Jour.*, 102 (1946), No. 2, pp. 41-44, illus. 2).—**Changes simulating caponizing were produced in 17-week-old cockerels by feeding 1 to 1.5 mg. of stilbestrol per day. The utilization of feed was improved by estrogen feeding to birds. However, optimal results were not obtained.

**Immunogenetic studies of cellular antigens: Individual differences between species hybrids, M. R. IRWIN and L. J. COLE. (Univ. Wis.). (*Genetics*, 30 (1945), No. 5, pp. 439-447).—**"Individual differences in antigenic content were observed among the cells of species hybrids of the cross of Senegal X ringdove. It was found that some of these differences could be explained by the segregation of at least a part of three separate antigenic characters (*d-1*, *d-2*, and *d-4*) peculiar to Pearlneck—as compared with ringdove—which are also shared by Pearlneck, in whole or in part, with Senegal. Differences in reactivity of reagents prepared from Pearlneck and Senegal antisera, respectively, showed that a part of the *d-2* substance of Pearlneck is shared by Pearlneck and Senegal, but a part is particular to Pearlneck."

## FIELD CROPS

**Forty-seven years of experimental work with grasses and legumes in Alaska, D. L. IRWIN (*Alaska Sta. Bul.* 12 (1945), pp. 48, illus. 1).—**Experimental data on grasses and legumes tested for pasture and hay at the several stations in Alaska since 1902 are summarized with notes on native grasses, descriptions of important cultivated grasses and legumes, hay and pasture mixtures, seedbed preparation and seeding, and harvesting the crop.

Native grasses found widely disseminated over Alaska, even far north of the Arctic Circle, make quick growth, mature early, and soon thereafter become tough and unpalatable. Their optimum harvesting stage for either hay or silage is when the head is just emerging from the boot or sheath. Cutting or pasturing native grasses, year after year, has quickly depleted the stand. Best results have been obtained by cutting or pasturing the same areas at 2- or 3-yr. intervals. Overgrazing the native grasses quickly kills the entire stand, and wind and water erosion is certain to result. None of the native legumes tried has been found satisfactory under cultivated conditions.

Tap-rooted alfalfas and clovers seeded alone usually winter-kill during the first winter. Occasionally they persist for several years, but vigor and stand is usually impaired. Legumes live over longer periods and produce heavier crops of hay or pasture when seeded on established grass meadows. Siberian alfalfa (*Medicago falcata*), perennial vetch, and white clover are the only legumes found consistently hardy over the entire area of Alaska. Annual vetches and Canadian field peas have made excellent hay or silage crops alone or when seeded in mixtures with oats or other small grains, and cut when the oats are at the soft-dough stage. This is the standard hay and silage crop in most of the farming districts.

Plants found best adapted to the south Alaska coast area are tall oatgrass, meadow fescue, meadow foxtail, smooth bromegrass, slender wheatgrass, timothy, redbud, creeping bent, and Kentucky bluegrass; and the perennial legumes Siberian alfalfa, alsike clover, perennial vetch, and white clover.

Cultivated grasses adapted to central Alaska, including upper Cook Inlet and as far north as the Alaska Mountain Range, are smooth bromegrass, Russian wild-rye, meadow fescue, meadow foxtail, slender wheatgrass, and sheep, Chewings, and creeping red fescues, Kentucky and Canada bluegrasses, and timothy. Legumes best adapted to this region are alsike clover, Siberian alfalfa, Russian red clover, perennial vetch, and white clover.

In the northern area, including the Tanana River Valley and as far north as the Yukon River, best-adapted grasses are smooth bromegrass, slender wheatgrass, western wheatgrass, tall meadow oatgrass, Kentucky bluegrass, and meadow, creeping, red, Chewings, and sheep fescues, and timothy. Legumes found best for the northern area are Siberian alfalfa, Russian and Siberian red clovers, alsike clover, white clover, and perennial vetch.

Broadcasting N fertilizer at 200 to 400 lb. of ammonium sulfate per acre or spreading manure at 6 to 8 tons per acre on grass meadows in spring at the beginning of the growing season has more than doubled the yield of hay or pasture. Applications of 100 lb. of nitrate fertilizer broadcast on the soil surface when legumes or grasses are seeded induces quick growth and secures a better stand. Larger yields of grass for hay or pasture are obtained if the land is cultivated with a spring-tooth harrow, or lightly disked every 2 yr.

**Successional trends on a conservatively grazed desert grassland range, H. S. ILASKALL.** (Univ. Ariz.). (*Jour. Amer. Soc. Agron.*, 37 (1945), No. 12, pp. 978-990, illus. 3). Successional changes resulting from conservative grazing on a formerly deteriorated desert grassland range near Oracle, Ariz., were compared with those on adjacent heavily grazed range by the line interception method. On the conserved area, under intensive land management since 1923, a partial reestablishment of climax grass species, as black grama and hairy grama, had resulted, accompanied by a reduction in the unpalatable desert shrubs burrowweed and snakeweed. Rothrock grama and red-three awn were the dominant grasses in the current sub-climax, and these grasses with other herbaceous species comprised a total herbaceous density of 1.80 percent. Burrowweed and mesquite formed a major portion of the total shrub density of 3.80 percent. Continuous heavy use on the overgrazed range had resulted in the establishment of a desert shrub community, with a total shrub density of 8.52 percent. Total density of herbaceous vegetation was 0.16 percent, in which the principal species were short-lived perennial grasses and weeds, with climax grasses occurring as widely scattered remnants.

**The effect of plowing under and the time of plowing under legumes on the conservation of nitrogen, J. W. TIDMORE and N. J. VOLK.** (Ala. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 37 (1945), No. 12, pp. 1005-1010).—Plowing soybeans under in the spring was superior to plowing them under in the fall, because yields of succeeding crops in rotation were greater and less N was lost by leaching during

winter. Plowing under soybeans or vetch for 9 yr. resulted in an increase of 60 percent in the organic matter content of the soil and an increase of 30 percent in its total N.

**Lime and phosphate were not enough** (*Dairy Res. Diges't* [Louisiana Sta.], 1 (1946), No. 1, p. 1).—In tests from areas near Bogalusa, La., barnyard manure and potash, or both, with lime and phosphorus, caused marked increases in pasture growth and nutritive value as compared to pasture herbage treated with only lime and phosphate.

**Pasture fertilization experiments at Reymann Memorial Farm**, F. W. SCHALLER, G. G. POHLMAN, H. O. HENDERSON, and R. A. ACKERMAN (*West Virginia Sta. Bul.* 324 (1945), pp. 24, illus. 5).—Pastures on Monongahela silt loam, seeded to Kentucky bluegrass, redbud, and white clover, and grazed 1931–41 with Ayrshire cows and heifers, were untreated or treated with lime and superphosphate; lime, superphosphate, and potassium chloride; and lime, superphosphate, potassium, and sodium nitrate. A marked increase in yield occurred on all treated pastures. Indications were that lime and superphosphate and potassium, lime, and superphosphate gave profitable yield increases. Nitrogen increased yields, but not more than enough to pay for cost of application. Liming and fertilizing increased the amount of clover and bluegrass in all pastures. Analyses of the herbage revealed marked increases in mineral and protein content as a result of liming and fertilization. Soil analyses showed a considerable residual effect in 1942 of lime and superphosphate applied in 1931 and 1933. Treated pastures also had a higher content of organic matter in 1941. There was good agreement between increases in yields as measured by days of grazing obtained, gain in weight, and yield of total digestible nutrients. See earlier notes (E. S. R., 78, p. 331).

**Improving pastures and grasslands for the Northeastern States at the United States Regional Pasture Research Laboratory** (*U. S. Dept. Agr., Misc. Pub.* 590 (1946), pp. 29+, illus. 13).—Activities of this laboratory described include its research program on pasture problems, especially establishment, fertilization, and management of pastures, chemical problems in pasture research, breeding of new varieties of grasses and legumes, and plant-disease problems of grasslands. Its publications on various phases of the work are listed, and mention is made of the laboratory staff, buildings, and equipment at State College, Pa.

**The effect of early spring flooding on certain forage crops**, J. L. BOLTON and R. E. MCKENZIE (*Sci. Agr.*, 26 (1946), No. 3, pp. 99–105, illus. 4).—Sweetclover, alfalfa, and crested wheatgrass could withstand only short periods of flooding in experiments at the Val Marie and Eastend Irrigation Projects near Swift Current, Sask., while brome, slender wheatgrass, and meadow fescue were able to stand fairly long periods. Timothy and reed canary grass endured the most flooding of the crops tested.

**Measured crop performance 1945: Corn hybrids, cotton, wheat, oats, barley, rye**, R. P. MOORE and G. K. MIDDLETON (*North Carolina Sta. Bul.* 354 (1946), pp. 54, illus. 4).—Field crop varieties outstanding in official tests in different localities of North Carolina in 1945 and over several years and variously recommended in 1946 for nine zones within the Mountain, Piedmont, and Coastal Plain sections (listed alphabetically) include the corn hybrids DeKalb 923, G94, G135, G714, and G717, 977M and 987M, N. C. T1, T11, T20, T23, and N. C. 1028, 1032, and 1111, S210, Tenn. 10 and 15, and U. S. 13 and 282; Coker 100 Wilt, 100, and 200 cotton; Davidson, Hooded 26, Randolph, Sunrise, and Tenn. 6 barley; Fulgrain, Fulwin, Lee, Lemont, Letoria, Stanton, and Victorgrain oats; and Carala, Fulcaster, Hardired, Nittany, Redhart, and Thorne wheat. Yields and other agronomic characters of these and other varieties are again (E. S. R., 92, p. 784) set forth in tables reporting results of individual tests and averages.

**Alfalfa in Missouri**, W. C. ETHERIDGE and C. A. HELM (*Missouri Sta. Bul.* 492 (1945), pp. 16, illus. 8).—Correct practices in growing alfalfa in Missouri discussed include selection of land—a fertile, deep, and well-drained soil, limed and fertilized if needed; good seed of an adapted variety, preferably of a common strain grown westward and northward of Missouri; thorough seedbed preparation; planting inoculated seed about August 15; cutting when new growth is 2 to 3 in. long; and cultivation of established stands, i. e., with a spring-tooth harrow fitted with half-round teeth. Comment is also made on merits of alfalfa-grass mixtures, relation of alfalfa to soil erosion, and diseases of alfalfa.

**The carotene content of alfalfa strains and hybrids with different degrees of resistance to leafhopper injury**, W. E. HAM and H. M. TYSDAL. (Nebr. Expt. Sta. coop. U. S. D. A.). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 1, pp. 68-74).—New growth of field-grown alfalfa was higher in carotene than more mature growth. Strains showing least yellowing after leafhopper attack were higher in carotene content than those which yellowed badly. In general, strains or hybrids having a high leaf percentage contained more carotene content than those with a lower leaf percentage. On the average, 77 percent of the carotene content of the plant was found in the leaves. Strains and hybrids differed inherently in carotene content.

**Chufas in Florida**, G. B. KILLINGER and W. E. STOKES (*Florida Sta. Bul.* 419 (1946), pp. 16, illus. 5).—The uses of chufas (*Cyperus esculentus*) for human food and hog feed, production practices, insects, pests, and diseases, and their place in Florida agriculture are discussed together with a report on spacing and fertilizing experiments 1934-35, 1943-44. Greatest increase in chufa yields can be expected from proper spacing of plants. On a Norfolk soil largest yields may be made by plants 12 in. apart in 2-ft. rows, or 6 in. apart in 3-ft. rows. Response of chufas to applications of fertilizers has been somewhat erratic. The hay (chufa tops) is low in protein but has an average quantity of other minerals, which apparently may be increased by fertilization. Chufas contain slightly more than half as much oil as peanuts and are relatively low in protein for a nut crop and low in Ca and Mg. Negro bugs may do considerable damage, resulting in lower yields if the chufas are not hogged off or harvested at maturity in the fall.

**Manure increased clover yield by eighty percent** (*Dairy Res. Digest [Louisiana Sta.]*, 4 (1946), No. 1, p. 1).—Highest average yields and percentages of protein and minerals were obtained on white-clover pasture at DeRidder, La., treated with phosphate and potassium chloride in combination with manure. Among unmanured plots, best results were secured when lime, phosphate, and potash were used. Thorough seedbed preparation, including plowing, disking, harrowing, and packing, proved better than the use of the disk in breaking the sod.

**Carotene content of the corn plant**, J. W. PORTER, F. M. STRONG, R. A. BRINK, and N. P. NEAL. (Wis. Expt. Sta.). (*Jour. Agr. Res. [U. S.]*, 72 (1946), No. 5, pp. 169-187, illus. 6).—Concentration of carotene in the leaf blades of corn plants was 20 to 50 times higher than in the remainder of the plant. Stalks, ears, and husks all have about the same concentration, at least in the early dent stage of growth. The concentration of carotene in leaves reached a peak at the pollen-shedding stage and then declined rapidly. Prevention of pollination by bagging the ear shoot did not prevent this drop. The total carotene content of the plant, however, remained relatively constant until near the end of the growing season, when it also fell sharply.

The optimum period for harvesting with respect to total yield of both carotene and silage was for most strains at the medium dent stage of maturity. Significant differences in carotene content between stocks, both inbred and hybrid, were found to exist, but were small relative to those associated with stage of plant development and with seasonal factors. Sweet corns, it was suggested, may retain a relatively

high carotene content as the season advances. The sun-red gene did not influence the carotene content of corn plants.

**Effect of certain summer and winter legume crops in improving corn yields in south Louisiana.** H. B. BROWN (*Louisiana Sta. Bul.* 396 (1945), pp. 36, illus. 6).—Soybeans planted in the row with corn made good growth, averaged 3,108 lb. of dry soybean hay per acre, and increased the soil organic matter 0.176 percent and total N 0.0088 percent. They lowered the corn grain yield 19.1 percent the first year, 33.6 the second, but increased it 12.7 percent the third, 51.7 the fourth, and 35.2 percent the fifth year. The weight of corn stover was decreased by soybeans the first year, but was increased in the later years. Corn and soybeans are grown more economically both on the same land rather than on separate acres. Grown separately, the average acre production was 20 bu. of corn and 3,089 lb. of dry bean hay, but grown in combination, it was 33.9 bu. of corn and 4,020 lb. of hay. With the same number of stalks per acre (both corn and soybeans), there was but little difference in yield between alternate-row and "every-row" planting, although alternate-row planting is better for harvesting both corn and hay. Varying the rate of soybean seeding 10, 15, and 20 lb. per acre in corn gave no consistent difference in corn production, either grain or stover, but a higher rate of seeding increased the weight of soybean hay. Turning under soybeans where they were grown alone increased corn production the next year by 55.6 percent, 162.3 at the end of the second rotation, and 98.1 percent at the end of the third. Land on which the soybeans were grown alone and cut for hay gave an increase in corn yields the following year of 22.9 percent, 74.3 the end of the second rotation, and 83.9 at the end of the third rotation.

In a search for a summer legume more satisfactory than soybeans, all legumes and treatments used increased corn yields, 150 lb. of sodium nitrate being best, surpassing Austrian winter peas, crotalaria, and velvet beans in order. In a winter legume experiment to find a legume that would make good winter growth in south Louisiana and ripen seed enough before corn planting to reproduce itself, crimson clover, hop clover, sour clover, Singletary peas, giant bur-clover, and 150 lb. of sodium nitrate all gave increases in corn yields, amounts ranging from 3.1 to 8.9 bu. per acre. Bur-clover gave the best increase and crimson clover next, and the sodium nitrate lower yields than any other treatment. One year's trial showed creole peas, local wild vetch, and narrow-leaf vetch to be unsatisfactory for the purpose. The main objection to volunteer winter legumes is that most of them must stand until late in the spring to ripen seed, which makes corn too late for best quality and highest yields.

**The relationship between predicted performance of double crosses of corn in one year with predicted and actual performance of double crosses in later years.** H. K. HAYES, E. H. RINKE, and Y. S. TSIANG. (*Minn. Expt. Sta.*). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 1, pp. 60-67).—Twelve inbred lines of corn were tested in single cross combinations 1940-41. Single cross data were used to predict the performance of double crosses for each year for date silked, plant and ear height, ear length, kernel rows, percentage moisture, and acre yield in bushels. Variability for each character in the predicted double cross was estimated from means of four single crosses averaged for each prediction. Forty-nine double crosses with a considerable range of estimated variability were tested as actual double crosses and rated for variability. Reliability of the prediction method of estimating the performance of the 49 double crosses was determined by correlating the performance of predicted double crosses in 1940 and 1941 with each other and with actual performance as double crosses in 1943-44.

Highly significant  $r$  values were obtained for all six characters when predicted performance based on 1940 data was correlated with predicted performance based on 1941 data and when predicted performance based on either 1940 or 1941 data

was correlated with actual performance of double crosses. The  $r$  values between predicted performance in 1940 and 1941 for date silked, plant height, and ear length were significantly higher in one of two comparisons than between predicted and actual performance and in both comparisons for percentage moisture and yield. The  $r$  values for ear height and kernel rows were not significantly different in any comparison. Highly significant relationships existed between predicted variability in 1940 with that of 1941 for all six characters. Significant although not highly important  $r$  values were obtained between predicted variability for moisture and estimated variability of the actual double crosses. The  $r$  value for predicted variability of plant height in 1941 and the actual variability in 1943-44 inclusive reached the 5 percent point. Variability relations of the other character studied were not significant.

**The 1945 Iowa corn yield test**, J. L. ROBINSON and F. REISS. (Coop. U. S. D. A., et al.). (*Iowa Sta. Bul.* P79 (1946), pp. 597-642, illus. 1).—The 324 section entries in the 12 fields of the 1945 test were grown cooperatively and in the same groupings (E. S. R., 93, p. 277). Agronomic data including yields and performance score are tabulated for each entry, results over several years are summarized, and test methods and seasonal conditions are described. The average acre yield for the 9 fields harvested, 71.76 bu., compared with the 11-yr. average of 71.08 bu., and the average stand was 86.8 percent in 1945. Lodging averaged 28.3 and dropped ears 0.8 percent compared with 16.3 and 1.1 percent, respective 11-yr. averages. The highest-performing (average) section entries with scores in 1945 in regular hybrid and experimental hybrid classes, respectively, were for the northern section (District 1 only) Iowa Hybrid 4316, Goldline 279; north-central section Iowa Hybrid 306, Iowa Hybrid 4397; south-central section 118-H (Holden), C 66 (Cornelius); and for the southern section ACE 43 and Maygold Exp. 5.

**Performance tests of corn varieties and hybrids, 1945**, J. S. BROOKS (*Oklahoma Sta. Bul.* 292 (1946), pp. 30, illus. 1).—Yields, maturity, grouping, percentage of stand, and for some tests percentage of lodging are reported again (E. S. R., 92, p. 785) for corn hybrids and open pollinated varieties totaling 139 grown in tests in 1945 at 8 locations. Average yields over several years are tabulated, and high-performing hybrids are listed.

**South Dakota corn performance tests, 1945**, K. F. MANKE (*South Dakota Sta. Cir.* 60 (1946), pp. 18, illus. 1).—Performance tests involving 96 corn hybrids and 12 open-pollinated varieties in different sections of South Dakota are reported on again (E. S. R., 93, p. 427). Tables show acre yields, moisture at harvest, and stands for each of 10 test fields in 1945 and temperature and precipitation data in each district for the 1945 corn-growing season.

**A study of factors determining safe drying temperatures for seed corn**, R. H. WILEMAN and A. J. ULLSTRUP. (Coop. U. S. D. A.). (*Indiana Sta. Bul.* 509 (1945), pp. 10, illus. 3).—Each of 268 150-ear samples of corn of various moisture contents, comprising inbred lines and single and double crosses, was divided into six 25-ear lots in tests 1937-41. Initial moisture was determined on one lot and the other five lots were dried in bins at 100°, 110°, 130°, and 140° F., respectively. The moisture content of corn placed in the drier was the prime factor in determining the safe air temperature for drying. Seed corn with an initial moisture content exceeding 25 percent should not be dried at air temperatures above 110°. Where the moisture content is 25 percent or below, 120° can be used with safety, and the extra 10° will reduce by one-fifth the time required to dry the corn to a moisture level necessary for safe storage. Relatively low germination (corrected by treatment with a seed disinfectant) was encountered in 1939 in certain test lots dried at the lower air temperatures (100° or 110°). It appeared due to seedling disease fungi tolerating the low drying temperatures but inhibited in development on seed dried at higher temperatures.

**The effects of plowing under hairy vetch on the yield of cotton and on Lufkin fine sandy loam, E. B. REYNOLDS and J. C. SMITH.** (Tex. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 1, pp. 13-21, illus. 1).—Yield of hairy vetch was increased about 54 percent by application of P and K, which had no effect on the N and P content of the vetch. Significantly larger cotton yields were produced on soil receiving P and K, with or without vetch, than on untreated soil or soil on which unfertilized vetch was plowed under. The quantity of nitrate N in the soil during the growing season of cotton was roughly proportional to the amount of N added in the treatments. Soil treated with P and vetch had a greater nitrifying power than that receiving other treatments. Addition of P and K, with or without vetch, greatly increased the quantity of available  $P_2O_5$  in the soil, although turning under unfertilized vetch apparently did not increase the availability of the native soil P. The nitrifying capacity of the soil and quantity of available  $P_2O_5$  were correlated more highly with the yield of cotton than was the quantity of nitrates in the soil.

**Nutritional factors affecting cotton rust, N. J. VOLK.** (Ala. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 1, pp. 6-12, illus. 5).—In fields that produced rusted cotton, soils were found to contain about one-half as much replaceable K as soils in fields that produced healthy cotton. Rust was eliminated by applying adequate quantities of K to the soil, but application of B, Cu, Zn, Mn, or Mg had no effect on rust. Sodium nitrate alleviated but did not eliminate rust in severe cases, believed due to the fact that Na may have partially substituted for K. High amounts of P increased severity of rust, probably by hastening maturity. Areas from which K was badly depleted by removal of several crops of peanuts produced severely rusted cotton. K was found to be more efficient when applied ahead of or at planting time than as a side dressing. High amounts of K, applied to cotton to prevent rust, retarded maturity of the cotton to the extent that boll weevil damage caused a decrease in yield.

**Cotton varieties in the hill section of Mississippi, 1945, J. F. O'KELLY** (*Mississippi Sta. Bul.* 426 (1945), pp. 7).—In tests previously referred to (E. S. R., 94, p. 846), varieties averaging about 500 lb. of lint per acre in five tests in 1945 were Hi-Bred 574 lb., Empire 547, Deltapine 540, Miller 532, Cleveland 54 517, Coker 100W-4 514, and Stoneville 5A 505 lb. Yields, acre value, and other agronomic data are tabulated for each test for 1945 and averages for the period 1941-45.

**The longevity of cottonseed as affected by climate and seed treatments, D. M. SIMPSON.** (U. S. D. A. coop. Tenn. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 1, pp. 32-45, illus. 1).—Cottonseed, fuzzy and acid-delinted, and untreated and treated with a fungicidal dust, was stored at eight stations in the Cotton Belt and tested for moisture content and viability at 6-mo. intervals over 7 yr. Duration of safe storage depended upon climatic conditions at the storage location and ranged from 1 to 2 yr. in the lower Coastal Plains to 5 to 6 yr. along the northern rim of the Cotton Belt. Seed stored at other places in the main Cotton Belt was intermediate between these extremes in moisture content and in rapidity of deterioration. Fuzzy seed was slightly lower in moisture content than acid-delinted seed and averaged slightly higher in germination. Seed treated with the fungicide was higher in germination than untreated seed, probably because of control of mucor and other fungi during the germination tests. The fungicide definitely was not injurious to the seed during storage. When samples of seed stored at Sacaton, Ariz., for 6 to 35 yr. were tested for germination, the oldest sample that contained viable seed had been in storage 25 yr. and contained 6 percent of viable seed.

**The evaluation of individual plant selections from a natural population of guayule (*Parthenium argentatum* Gray), H. K. KRAMER.** (U. S. D. A.). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 1, pp. 22-31).—The progenies of 42 guayule

plants individually selected from a natural population on the 02 Ranch in Texas were compared with a mass and a nonselected collection from the same location and with commercial strain 593 for percentage of aberrant and off-type plants, plant height and spread, percentages of rubber and resin, and date of first bloom. All progenies were from plants reproducing by facultative apomixis. Progenies showing introgression with mariola, *P. incanum*, had greater vigor, a lower percentage of rubber, and a later flowering habit than the better type progenies.

**Effect of plant spacing and time of planting on seed yield of kenaf (*Hibiscus cannabinus* L.),** J. C. CRANE and J. B. ACUÑA. (U. S. D. A. et al.). (*Jour. Amer. Soc. Agron.*, 37 (1945), No. 12, pp. 969-977, illus. 1).—Date and distance of planting of kenaf (E. S. R., 93, pp. 279, 429) under the conditions at the Cuban Agricultural Experiment Station had little influence on the degree of branching in either the *viridis* or *vulgaris* variety. Regardless of time of planting during the rainy season, flowering of kenaf does not take place at latitude 23° N. until September or October, when the length of the daily light period is shortened to about 12½ hr. Plantings for seed should be made during July or August, although in this experiment higher yields of seed per plant were obtained from July plantings. For high seed yields per unit area the crop should be drilled in rows 20 to 24 in. apart with 2 or 3 in. between plants in the row. For fiber, planting may be done from the beginning of the rainy season (April or May, depending upon local conditions) until July 15, but it is preferable to plant as early in this period as possible.

**Effect of plant spacing and time of planting on fiber yield of kenaf (*Hibiscus cannabinus* L.),** J. C. CRANE, J. B. ACUÑA, and R. E. ALONSO. (U. S. D. A. et al.). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 1, pp. 46-59, illus. 4).—Kenaf was planted at the Cuban Experiment Station during May, June, July, and August in 8-, 16-, and 24-in. rows at rates of 30, 15, and 10 lb. of seed per acre, respectively. With progressive delay in date of planting during the rainy season, ultimate plant height at blossoming time, weight per plant, and fiber produced per plant were successively smaller. As the distance between rows in any one planting was progressively widened, however, a concurrent increase occurred in the size and yield of fiber per plant. The acre yield of fiber from plants harvested during the flowering period decreased progressively as rows were wider, and also decreased as planting was successively later in the season. For maximum yield of kenaf fiber per unit area, the recommendation is that planting be done May 1 or earlier, in rows 8 in. apart, at the rate of 30 to 35 lb. of seed per acre.

**Morphological variation in *Poa pratensis* L. as related to subsequent breeding behavior,** D. C. SMITH and E. L. NIELSEN. (Wis. Expt. Sta. coop. U. S. D. A.). (*Jour. Amer. Soc. Agron.*, 37 (1945), No. 12, pp. 1033-1040, illus. 2).—Studies of the progeny behavior of 45 families of Kentucky bluegrass, representing selected strains and plants from pasture collections, were conducted for four generations in the field at Madison, Wis., and dealt with about 570 progenies, comprising 11,400 plants. Progenies from plants classified earlier as aberrant were generally higher in proportions of sexual or aberrant types than those from normal sister plants. Selection for normal or apomictic types and their propagation from seed did not appear to be highly effective in elimination of the tendency toward sexual reproduction. None of the families showed complete uniformity of type for two successive generations. Classification of sister plants for morphological similarities and differences evidently is not closely indicative of breeding behavior in subsequent generations when specific progenies are considered. Apomictic seed formation in Kentucky bluegrass appeared to be a relatively unpredictable character.

**Lespedeza culture and utilization,** R. MCKEE (U. S. Dept. Agr., Farmers' Bul. 1852, rev. (1946), pp. 14-†, illus. 4).—A revision of the publication noted earlier (E. S. R., 84, p. 754).

**Natural crossing and segregation in sericea lespedeza, *Lespedeza cuneata* (Dumont) G. Don, R. E. STITT. N. C. Expt. Sta., U. S. D. A., et al.).** (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 1, pp. 1-5, illus. 2).—Observation of selfed lines from a procumbent plant of *L. cuneata* indicated that the procumbent plants were homozygous. Natural crossing of procumbent plants with assurgent plants varied from 61.4 to 80.9 percent. Petaliferous flowers may naturally be either self- or cross-pollinated. Progeny from apetalous flowers indicated that they were always self-pollinated. Segregation in the  $F_2$  suggested a complex type of inheritance. Variation in segregation between  $F_2$  lines indicated that pollen from a number of assurgent lines was effective in bringing about natural crosses.

**Sow adapted varieties of spring oats, G. H. DUNGAN and O. T. BONNETT (Illinois Sta. Cir. 601 (1946), pp. 8).**—Clinton, Vicland, Boone, and Tama are the best oats varieties for northern Illinois, according to tests at Mt. Morris. Clinton, Tama, Vicland, Marion, and Vikota are the leading varieties of central Illinois, as shown by tests at Urbana. Boone, Tama, Columbia, Clinton, Marion, and Vicland are the highest yielding commercial varieties for southwestern Illinois, as indicated by tests at Alhambra. Outstanding characters of these and other varieties in the tests are described, and practices for growing oats in Illinois are recommended.

**Size of whole and cut seed and spacing in relation to potato yields, J. A. CHUCKA, A. HAWKINS, B. E. BROWN, and F. H. STEINMETZ. (Coop. U. S. D. A.). (Maine Sta. Bul. 439 (1945), pp. 33+, illus. 12).**—Effects of size of whole and cut seed pieces on potato yields were studied at Presque Isle, Maine, 1943-45. The lots of whole tubers used as seed had the size ranges: 1-1¼ in., 1¼-1½, 1½-1¾, and 1¾-1⅞. Cut seed used consisted of split large seconds (tubers 1½-1¾ in. cut into halves, and 1-oz., 1½-oz., and 2-oz. seed pieces cut from tubers 1⅞-2½ in. smallest diameter). The varieties were Green Mountain, Katahdin, and Sebago. Consistent increases in yield were obtained during each year with increasing size of whole and cut seed used. Yield increases resulting from use of larger seed sufficed to more than pay for the extra cost of seed and for extra harvesting costs associated with higher yields. The largest whole tubers (1¾-1⅞ in.) and the largest (2 oz.) cut seed pieces showed the greatest return per acre. As the size of whole or cut seed was increased, number of stalks and of tubers per hill increased. Number of tubers per hill was associated with and was largely responsible for increase in yield resulting from use of larger seed pieces. Since part of the yield increase from use of larger seed is in production of tubers smaller than 1⅞ in., use of large seed would appear more profitable to a seed grower than to a table-stock grower, because seed growers can sell profitably for seed purposes most tubers smaller than 1⅞ in. in diameter.

Effects of seed spacing on yields and on the distribution of the resulting tubers in various size classes were studied in several localities, 1936-42, in experiments involving 6-, 9-, and 12-in. spacings; 1,000, 1,250, and 1,500 lb. per acre of 8-16-16 fertilizers, and one to eight varieties of potatoes commonly grown in Maine. Total yields rose as seed spacing was decreased, and average size of tubers produced decreased as the spacing narrowed. Average size of tubers produced tended to rise somewhat with the amount of fertilizer applied. Effect of season, however, appeared more important than spacing or fertilizer rate in determining average size of tubers produced. A seed grower evidently could use profitably a close spacing (about 6 in.), but a table-stock grower should use spacing not less than 9 in. When planting varieties like Houma which tend to set a relatively large number of tubers per hill, a spacing somewhat greater than 9 in. is suggested. However, when planting varieties as Katahdin, Irish Cobbler, and Sequoia, use of a 9-in. spacing during seasons of high yields will insure against production of excessively large tubers which tend to be hollow.

**Potato production on northern Indiana muck soils, N. K. ELLIS (Indiana Sta. Bul. 505 (1945), pp. 16, illus. 6).**—Methods outlined for growing potatoes on muck

soil are based extensively on experiments at the Northern Indiana Muck Soils Experimental Farm. Optimum conditions include a soil with a reaction pH 5.0 to 5.6, a well-prepared seedbed, and from 750 to 1,000 lb. per acre of 0-9-27 fertilizer or any equivalent with a 1 P : 3 K ratio (up 1,500 lb. under favorable conditions) used with the most convenient method of application. Seed stock should be of a good variety, as Katahdin, 3-4 oz. in weight, cut only once and through the apical end, and planted 2 to 4 in. deep, about May 1 to 15, in 24- to 28-in. rows. Cultivation should not injure the feeding roots, yet enough soil must be loosened to throw a 4 to 5 in. hill over the potato row. A good potato spray is 6-6-100 bordeaux, in which 6 lb. each of copper sulphate and hydrated lime are mixed in 100 gal. of water. Four lb. of calcium arsenate may be added to this mixture for each 100 gal. of water when it is necessary to control Colorado potato and flea beetles. The crop should be harvested when mature, injury by digger, basket, crate, or sack avoided, and the tubers handled carefully in storage and grading. Storage for seed is best about 32° to 38° F., and for table stock usually not below 40°, and a relative humidity of 90 percent is desirable.

**Pre-harvest sampling of soybeans for yield and quality**, E. E. HOUSEMAN, C. R. WEBER, and W. T. FEDERER. (Coop. U. S. D. A.). (*Iowa Sta. Res. Bul.* 341 (1946), pp. 805-826, illus. 2).—In 1941, just prior to harvest, 67 fields of soybeans in eight east central Illinois counties were sampled for yield, percentages of protein and oil, and iodine number of the oil. Protein and oil percentages and iodine number of the oil could be estimated satisfactorily, but estimating yield appeared more uncertain pending accumulation of information on adjusting for harvesting losses and other factors which cause the sample average yield to be too large. Yield of seed per acre differed with method of planting (width of rows), indicating for the season studied that rows about 2 ft. apart should have been used. The iodine number of the oil was lower for fields with wide rows than for drilled fields, this being attributed to difference in date of planting rather than method of planting. Conclusions were that two subsampling units should be taken per field and that the optimum size of subsampling unit is approximately 7 sq. ft. Other investigations, e. g., by Cartter and Hopper (E. S. R., 87, p. 510), have shown that after the pods are fully distended there is little or no change in yield or chemical composition, indicating that production and quality can be estimated well in advance of harvest. See also an earlier study on wheat fields by King and Jebe (E. S. R., 84, p. 184).

**Varieties of winter wheat for Illinois**, G. H. DUNGAN and O. T. BONNETT (*Illinois Sta. Cir.* 596 (1945), pp. 4).—Winter wheat varieties recommended because of good yields, high quality of their grain for commercial use, availability of seed, and general desirability for the section indicated include Toturk, Pawnee, Wisconsin 2, and Marmin for northern Illinois; Pawnee, Tenmarq, Brill, Wisconsin 2, Prairie, and Fairfield for central Illinois; and Fulcaster, Fairfield, Clarkan, Wabash, Thorne, Goens, Trumbull, Fullbro, Prairie, and Fultz for southern Illinois. Acre yields, percentage of erect plants, and test weights are tabulated for these and other varieties in 1944-45 tests in the three sections of the State.

**Varieties of wheat for North Dakota**, T. E. STOA, L. R. WALDRON, R. H. HARRIS, and L. D. SIBBITT. (Coop. U. S. D. A.). (*North Dakota Sta. Bino. Bul.* 8 (1946), No. 3, pp. 10-20).—Behavior in experiments in recent years suggests Mida or Rival in the eastern part of the State where hard red spring varieties are grown, or Regent or Renown if a hardless early-ripening shorter-strawed variety is preferred. In central North Dakota, Rival, Pilot, Vesta, and Mida should yield best, Pilot, Vesta, and Regent being considered the most suitable if the crop is to be straight combined. Thatcher is preferred in extreme northwestern North Dakota. It lacks resistance to leaf rust, but this deficiency has generally been less serious in that area, and its yields have been satisfactory. Pilot and Vesta are also suited to

this area and thrive in other western counties, with Mida deserving consideration in the hessian fly area. Mindum is usually satisfactory in the durum growing areas unless rust is severe. Stewart affords rust protection and is recommended especially for the northern sections of the durum belt. Carleton is indicated where strong straw as well as high rust resistance is desired.

**Cadet—a new beardless wheat**, T. E. STOA (*North Dakota Sta. Bimo. Bul.*, 8 (1946), No. 3, pp. 21–22).—Cadet wheat, selected from a cross between Merit and Thatcher in cooperation with the U. S. Department of Agriculture and being distributed for increase in 1946, compares favorably with all other varieties of hard red spring wheat in resistance to stem and leaf rust. It is less resistant to stinking smut than Mida, Rival, Pilot, Regent, and Renown, being similar to Thatcher and Newthatch. It grows taller than other beardless wheats—as Thatcher, Regent, or Renown—but not as tall as Rival or Mida, does not shatter readily, has strong straw, and requires a few days longer to ripen. Because of its lateness Cadet is expected to find greatest usefulness in the more northern and northwestern sections of North Dakota, where ripening temperatures usually are not so high, and thus later varieties can more often realize their fullest yield. It is not high in test weight per bushel, somewhat resembling Thatcher and Regent. In milling and baking tests it has compared favorably with Thatcher and other wheats of good quality.

**Vahart wheat, a new variety for Virginia**, T. M. STARLING, S. A. WINGARD, and M. H. McVICKAR (*Virginia Sta. Bul.* 386 (1946), pp. 4, illus. 1).—Vahart, a head selection from Redhart, made in 1930 by T. B. Hutcheson, has proved to be one of the most resistant wheats to loose smut, although about as susceptible to leaf rust as other common varieties. It matures about 1 week later than Redhart, is slightly taller, and stands up as well or better. Vahart is as winter hardy as V. P. I. 131, Leap, or Forward, all of which it outyielded (average) at the station 1936–45 and the average of six localities in 1945.

**Further experiments with the Iowa air blast seed separator for the analysis of small-seeded grasses**, E. ÅBERG, R. H. PORTER, and W. A. ROBBINS (*Iowa Sta. Res. Bul.* 340 (1945), pp. 765–804, illus. 1).—Separation of immature, undeveloped, or empty florets from heavy (pure) seed of both redtop (*Agrostis alba*) and Kentucky bluegrass (*Poa pratensis*) (E. S. R., 79, p. 620) could be accomplished in a reasonably uniform manner by the use of the Iowa air blast seed separator (E. S. R., 84, p. 430). Some ergotized and smutted florets and other foreign material remain in the heavy fraction and must be removed by hand. The separator unit without the vernier scale on the valve dial can be set accurately to 0.5°. A valve equipped with the vernier can be adjusted accurately to 0.10°. The greater precision accompanies the finer adjustment. At any given dial reading a fairly uniform number of germinable seeds is removed with the light-weight fraction, but the valve opening may be so adjusted that the number of such seeds is relatively small and has little effect on the percentage of pure seed. The net result of this method of testing grass seeds is that the pure seed fractions are uniform, and the index value (purity  $\times$  germination) is greater than when immature and undeveloped florets difficult to classify are retained with the pure seed. Variance of the replicates increases more or less proportionately as the size of working sample of either redtop or bluegrass seed is reduced below 1 gm., and although the differences in percentage of purity of a given set of replicates may exceed that expected from homogeneous samples, the differences become greater among small subsamples than are permissible for practical application. Half-gram subsamples of redtop seed or even 0.25 gm. fractions may be substituted for gram samples to determine percentages of pure seed, crop seed, weed seed, and inert matter with an important reduction in time needed to complete the analysis. Tenth-gram subsamples of bluegrass seed, whether analyzed by the Iowa or binocular methods, are deemed too small for use currently in seed testing work.

**Commercial agricultural seeds, 1945**, G. P. STEINBAUER (*Maine Sta. Off. Insp. 198 (1945)*, pp. 66-86).—Percentages of purity, germination, weed seeds, and hard seeds (in legumes) and number of noxious seeds per pound are tabulated for 146 samples of farm crops seed collected from dealers in Maine during 1945.

**Final results of the Duvel buried seed experiment**, E. H. TOOLE and E. BROWN. (U. S. D. A.). (*Jour. Agr. Res. [U. S.]*, 72 (1946), No. 6, pp. 201-210, illus. 1).—The longevity of seeds buried in the soil under natural conditions was studied in an experiment begun in 1902 by J. W. T. Duvel at the Arlington Experiment Farm, Rosslyn, Va., and terminated in the fall of 1941. Results of germination tests made in 1932 and 1941 on these buried seed are compared with earlier results (E. S. R., 52, p. 726). Of 107 species buried in 1902, 71 grew after 1 yr., 61 after 3 yr., 68 after 6 yr., 68 after 10 yr., 51 after 16 yr., 51 after 20 yr., 44 after 30 yr., and 36 after 39 yr. The general tendency was for lower germination from seeds from the 8-in. depth than from the 22-in. depth, and for the highest germination from the 42-in. depth. The 16 species, representing 10 plant families, having the highest germination in 1941 (more than 15 percent from at least one depth) were *Abutilon theophrasti*, *Ambrosia artemisiifolia*, *Convolvulus sepium*, *Datura stramonium*, *Ipomoea lacunosa*, *Lespedeza intermedia*, *Nicotiana tabacum*, *Oenothera biennis*, *Onopordum acanthium*, *Phytolacca americana*, *Potentilla norvegica*, *Robinia pseudoacacia*, *Rudbeckia hirta*, *Solanum nigrum*, *Trifolium pratense*, and *Verbascum thapsus*. Of the 20 other species that showed some life after 39 yr., 18 species had not more than 6 percent of germination at either depth. See also other notes by Goss and Brown (E. S. R., 82, pp. 42, 182).

**Chemical weed control**, R. F. GOWDY (*Jour. Amer. Water Works Assoc.*, 38 (1946), No. 2, pp. 186-202).—A practical discussion of the use of chemicals in control of land weeds, emergent weeds, and aquatic weeds.

Land weeds and water-emergent weeds, the author concludes, are generally best controlled by the new 2,4-D compounds, but other chemicals have specific advantages for different purposes. Submerged aquatic weeds are generally best controlled with chlorinated hydrocarbons, employing higher doses than previously recommended (up to 50 gal. per acre), allowing much longer contact periods (up to 4 days) than formerly, and by observing necessary factors to avoid complaints of odors and tastes from consumers.

## HORTICULTURE

**Summary of State and Territorial plant quarantines affecting interstate shipments**, M. A. THOMPSON (*U. S. Dept. Agr., Misc. Pub. 80, rev. (1946)*, pp. 116).—This revision of an earlier publication (E. S. R., 63, p. 736) presents in a comparable manner brief summations of regulations prescribed by the various States, District of Columbia, Alaska, Hawaii, and Puerto Rico concerning the movement of nursery stock, fruits, vegetables, soil, and related materials.

**Fungicides and insecticides, 1945**, E. R. TOBEY (*Maine Sta. Off. Insp. 198 (1945)*, pp. 87-96).—In the usual manner (E. S. R., 92, p. 788) there are presented the results of analyses of 84 samples of materials collected by the State Department of Agriculture in the calendar year 1945, together with a reprint of the State law.

**Production of vegetable plants**, A. D. HIBBARD (*Missouri Sta. Cir. 308 (1946)*, pp. 16, illus. 8).—General information is presented on construction of plant frames, covers for frames, manure, electricity and stoves as sources of heat, containers for young plants, soils and their preparation, disease control in the beds, sowing seed, handling the frames and plants, growing of tomato and sweetpotato plants, etc.

**Four essentials for a good tomato crop**, S. A. McCORRY (*South Dakota Sta. Cir. 62 (1946)*, pp. 4, illus. 3).—Important considerations involved in the production of a good tomato crop are choice of adapted varieties, proper age and condition of

plants at time of transplanting to the field, and the use of a liquid fertilizer at the time of setting. Under South Dakota conditions Sioux, Stokesdale, Earliana, and John Baer have given consistently high yields. Maximum yields were obtained with 6- to 8-week-old plants in a vigorous status. A half-pint of a solution of 1 lb. of 4-12-4 fertilizer in 5 gal. of water poured on the soil around the freshly set plant increased yields materially.

**"Hormones" tested on greenhouse tomatoes,** R. E. NYLUND. (Minn. Expt. Sta.). (*Minn. Hort.*, 74 (1946), No. 3, p. 39).—Three so-called plant hormones were applied to the lower four blossom clusters of tomato plants growing in seven commercial greenhouses. For comparison, comparable clusters were treated with distilled water and certain others left unsprayed. The distilled water treatment was as effective as the chemical treatments, suggesting the possibility that the slight improvement in setting of the treated plants over the unsprayed checks was due to the accidental shaking of the plants as they were treated rather than to any chemical stimulus. Variety appeared important, with Potentate, the kind employed in the tests, capable apparently of setting a good crop under normal conditions.

**The pollination of tree fruits and nuts,** J. C. SNYDER (*Wash. State Col. Ext. Bul.*, 342 (1946), pp. 20, illus. 8).—Information is presented on the necessity of cross-pollination in fruits, role of insects in pollination, hand pollination of the apple including the collection, preservation, and handling of the pollen, methods of pollen application, and the use of bouquets of compatible bloom. In addition lists are presented of fruit and nut varieties grouped by species and arranged according to self-fruitfulness or self-unfruitfulness with suggestions as to adequate cross-pollenizers.

**The growth and composition of the tops of peach trees in sand culture in relation to nutrient-element balance,** D. S. BROWN (*West Virginia Sta. Bul.* 322 (1945), pp. 72, illus. 14).—Elberta peach trees were grown in sand cultures using 54 different treatments which included all possible combinations of N, P, and K provided at three concentrations (high, medium, and low) and of Ca provided at two levels (high and medium). The trees were harvested about 5 mo. after planting and their growth measured in terms of length and dry weight of shoots and in chemical composition.

N was the most important element in determining growth, with medium N most favorable. K and Ca were closely related and next to N in importance in affecting growth. With N in high or medium supply two treatments, namely, high K and medium Ca, and high Ca and medium K, were about equally effective.

Phosphorus was the least important of the four elements as a determinant of growth and there was no significant difference between high and medium P supply. Growth at low P level was greatly reduced. Acute deficiencies resulted under the conditions of a low supply of N, P, or K. Under the conditions of low K, growth improved with an increase in the Ca supply.

There were noted differences in the quantity of any given element in the leaves, shoots, and trunk, probably as a result of inherent differences in structure and function. Fundamentally it appeared that each element was antagonistic, at least potentially as to the accumulation of each of the others within the tops of the trees.

**Varieties of fruit for South Dakota,** S. A. McCORRY (*South Dakota Sta. Cir.* 61 (1946), pp. 4, illus. 1).—There are presented lists of desirable varieties arranged in order of their time of ripening and according to the geographical section of the State to which they are best adapted. In addition, brief suggestions are offered as to source of stock, selection of sites, protection from wind, and culture.

**Cherry and plum culture in Missouri,** T. J. TALBERT (*Missouri Sta. Cir.* 307 (1946), pp. 16, illus. 1).—General information is presented on site selection, pollination requirements, varieties, planting, preparation of the soil, planting operations, fertilizers, pruning, general cultural care, etc.

**Strawberry growing in Washington**, J. C. SNYDER (*Wash. State Col. Ext. Bul.* 246, rev. (1946), pp. 24, illus. 5).—Information is presented on the status and distribution of strawberry growing, selection of sites and soils, soil management, fertilization, planting, varieties, control of insect and fungus pests, etc.

**Utilization of nitrates by the coffee plant under different sunlight intensities**, T. TANADA. (Hawaii Expt. Sta.). (*Jour. Agr. Res. [U. S.]*, 72 (1946), No. 7, pp. 245–258, illus. 3).—Leaves of young coffee trees, 2–10 mo. old, were found to contain relatively large amounts of nitrate nitrogen as compared with other plants. Furthermore, the nitrate content varied widely during the growing season. Examination at two seasons, summer and winter, of plants grown in water cultures under three different sunlight intensities indicated that nitrate accumulation in the leaves of the coffee plant is a normal process, and that the amount stored is largely determined by the amount of solar energy available to the plant at that time. In the presence of excess nitrates, the excess is stored by the plant.

Under the conditions the coffee plant grew better without than with heavy shade. The number of leaves per plant decreased with an increase in shading while leaf size increased with shading. Unshaded plants had larger trunks and root systems than did shaded plants. Increases in shading resulted in increased total N, soluble N, insoluble N, ammonia N, amide N, nitrate N, alpha-amino N, peptide N, and hemicellulose; and in decreased dry matter, soluble sugars, and starch. K and Ca tended to increase with shading, and during the cooler season P also tended to increase with shading.

Severe K deficiency resulted in an increase in soluble N due principally to an increase in the basic N fraction. At the outset of K deficiency soluble sugars accumulated, but later declined to normal values.

Severe P deficiency caused abnormal increases in total N, ammonia N, amide N, nitrate N, basic N, alpha-amino N, and peptide N, apparently an indication of a serious breakdown in N metabolism.

**Leaf elongation and fruit growth of the Deglet Noor date in relation to soil-moisture deficiency**, W. W. ALDRICH, C. L. CRAWFORD, and D. C. MOORE. (U. S. D. A.). (*Jour. Agr. Res. [U. S.]*, 72 (1946), No. 5, pp. 189–200, illus. 3).—The effects of depleted soil moisture on the rate of leaf elongation and root development of date palms were determined. On adequately irrigated palms the rate of leaf elongation during the period from late May to October was found to be between 4 and 5 cm. per day. A prolonged decrease in rate of leaf elongation of 0.5 to 1 cm. or more per day below that of frequently irrigated palms during late May, June, July, and early August, when the fruits were enlarging, was always accompanied by a reduced rate of fruit growth. The rate of increase in dry weight of the fruits was not immediately reduced as much as that of fresh weight, so that the percentage water content of the fruits was temporarily reduced. Delayed effects of appreciable water deficits in the palm were manifested in late summer in a reduced rate of increase in fruit dry weight, in approximately 2 weeks' earlier softening of the fruits, and (during one season) in a premature dropping of the fruits. Appreciable water deficits in the palms for a single period in the summer did not greatly increase the shrivel of ripe fruits.

**Checking of fruits of the Deglet Noor date in relation to water deficit in the palm**, W. W. ALDRICH, J. R. FURR, C. L. CRAWFORD, and D. C. MOORE. (U. S. D. A., et al.). (*Jour. Agr. Res. [U. S.]*, 72 (1946), No. 6, pp. 211–231, illus. 9).—Studies were made of the amount of checking, a type of cracking, in both harvested fruits and in those attached to the palm in relation to the internal water supply of the fruit and to the water in the medium surrounding the fruit. Dates detached from the palm in the morning developed checking after 4-hr. immersion in water. Weekly repetition of this test showed that the period of susceptibility to checking

began in June and ended in August, when the fruit color had changed from yellowish green to pink. The termination of susceptibility to checking coincided with the time that total weight of water in the fruit stopped increasing and began to decrease. When sucrose solutions were substituted for water, dates decreased in weight but checked nearly as readily as those in water. Fruits collected in the morning and coated with paraffin checked as readily in air as did comparable fruits immersed in water.

Fruits on detached strands, exposed to air of relative humidities of 76, 95, and 100 percent, checked more when the cut end of the strand was placed in water than when not so treated, suggesting the importance of water movement as a cause of checking.

The rate of transpiration of fruits during July and August varied from a maximum of 30–60 mg. of water per fruit per hour at midday to a minimum of 5–20 mg. in the early morning. A lower rate of transpiration noted in fruits on palms with inadequate soil moisture indicated that water deficits in the palm reduced the rate of water movement from the plant to the fruit.

In irrigation plots it was observed that the water deficit brought about by soil moisture deficiency reduced the percentage of fruits that developed checking.

**Compositional changes in the date fruit during growth and ripening**, G. L. RYGG (*U. S. Dept. Agr., Tech. Bul. 910 (1946), pp. 51, illus. 16*).—Changes were followed in two varieties from 6 weeks after pollination to the end of harvest. After the main period of cell division the development is divided into three stages. The first is characterized by a rapid increase in fresh weight and reducing sugar content, high water content, low pH, and a low total sugar content; the second by reduced rate of growth, reduced rate of accumulation of sugar accompanied by hardening of the seed, a high water content, and low pH; the third by reduced rate of gain in fresh weight and reducing sugars but a rapidly increasing rate for sucrose, increasing pH, decrease in water content, and a change in color from green to red or yellow, depending on variety. The third stage continues until ripening begins. An abnormally high water content during and immediately prior to ripening appeared to be associated with inferior quality in the ripe dates. Inadequate irrigation early in the growing season appeared to be conducive to excessive water content later. Reduction in leaf-to-fruit-bunch ratio increased the water content and reduced the size of fruit but did not affect the total sugar content in percentage of dry weight. Maximum water in quantity per fruit coincided with maximum susceptibility to checking of the skin, which may later develop into blacknose and detract from the market value. No gain in dry weight occurred after ripening of the fruit was well under way.

**Cooperative rubber research in Costa Rica**, T. J. GRANT (*U. S. Dept. Agr., Agr. in Americas, 6 (1946), No. 3, pp. 47–50, illus. 4*).—This report on the activities of the Cooperative Rubber Research Station at Turrialba, Costa Rica, presents information on the establishment of the enterprise, its purposes, equipment, and something of the accomplishments.

**Tagua**, W. R. SCHREIBER (*U. S. Dept. Agr., Agr. in Americas, 6 (1946), No. 3, pp. 51–53, 58, illus. 3*).—Tagua palms are found growing naturally in many densely forested regions on the Pacific coastal plains of Ecuador and other tropical portions of the Western Hemisphere from Peru to Panama. The nuts are used in the manufacture of buttons and for carving into curios, chessmen, etc. The paper discusses methods of harvesting and handling the nuts, large quantities of which are exported annually.

**Effect of chloride on physical appearance and chemical composition of leaves of pecan and other native Oklahoma trees**, H. J. HARPER (*Oklahoma Sta. Tech. Bul. 23 (1946), pp. 30, illus. 10*).—The chloride content of pecan leaves collected in late August or early September was found to be a satisfactory indication as to the

chloride situation in the soil in which the trees were growing. Leaf analysis was a less laborious method than that of soil sampling. When the chloride content of the leaves exceeded 0.6 percent, the trees are in danger of serious damage. A brown margin on pecan leaves was a good indication of severe chloride injury and the affected trees die usually in one or two seasons. Many of the scorched leaves showed more than 1.0 percent of chloride.

Pecans and other native trees were more subject to chloride injury than were annual plants, due in part to the nature of the plants and in part to the fact that tree roots penetrate more deeply into the soil. Annual weeds contained actually more chloride in their leaves than did injured trees leaves yet made vigorous growth on areas where all trees were dead. The ash content of leaves did not vary with the chloride content nor was potash content reduced by the presence of excessive amounts of chloride. In many soils large pecan trees were more susceptible to chloride injury than were small trees which had shallower root systems.

**Walnut production in California**, L. D. BATCHELOR, O. L. BRAUCHER, and E. F. SEER (California Sta. Cir. 364 (1945), pp. 34, illus. 11).—This circular supersedes Bulletin 379 (E. S. R., 52, p. 344) and in a like manner presents information on climatic and soil requirements, varieties, propagation, planting, pruning, culture, irrigation, control of insect and fungus pests, harvesting, drying, marketing, etc.

**Flower gardening**, J. E. SMITH, JR. (Missouri Sta. Cir. 306 (1946), pp. 16, illus. 4).—General information is offered on soil and fertilizer requirements, seed sowing, species and varieties for various uses, planning and care of the flower garden, insect and disease control, development and care of the rose garden, etc.

**Growing garden roses**, E. C. VOLZ (Iowa Sta. Bul. P76 (1945), pp. 529-555, illus. 18).—General information is offered on types of roses for cold climates, locating and planning rose beds, desirable soils, planting stock, time and methods of planting, summer and winter care, control of insects and diseases, pruning, results of station variety tests with recommended varieties for Iowa planting, etc.

## FORESTRY

**Viability of pine seed after prolonged cold storage**, N. T. MIROV. (U. S. D. A. coop. Univ. Calif.). (Jour. Forestry, 44 (1946), No. 3, pp. 193-195).—A total of 33 samples of seeds of 19 species of pine which had been stored in airtight 5-gal. tin cans at 40° F. were, after varying durations of time, withdrawn and following a period of stratification tested for viability by placing the flats in a greenhouse. The highest germination percentage, 90, was recorded in a lot of *Pinus ponderosa* which had been stored for 11.5 yr. A total of 17 samples ranged above 50 percent in viability despite the fact that the seed had been held in storage for 5.5 yr. or more. The results as a whole gave evidence that pine seed can be preserved for a long time provided the seed is held in airtight containers placed in storage at about 40°.

**Natural reproduction of jack pine in Pennsylvania**, W. C. BRAMBLE. (Pa. State Col.). (Jour. Forestry, 44 (1946), No. 3, p. 204).—Jack pine was found reproducing in central Pennsylvania from seed released following a fire which destroyed a 15-year-old mixed plantation. In another planting 20-year-old jack pines were found to have attained a maximum d. b. h. of 6.7 in. and a height of 32 ft. The capacity for rapid growth and for reproduction after fires suggest the value of the species for certain situations in the State.

**Trees for reforestation in Indiana**, D. DENUYL (Indiana Sta. Cir. 306 (1945), pp. 11+, illus. 20).—General information is presented on desirable species, methods of planting, size and age of planting stock, location of sites, preparation of soil, protection from animals and fire, etc.

**Rainfall and increment of Monterey pine in the Australian Capital Territory**, M. R. O. MILLETT ([Austral.] Commonwealth Forestry Bur., Leaflet 56 (1944),

pp. 26, illus. 5).—The difficulties of correlating rainfall with the growth of a perennial and changing crop are discussed. The general character of the rainfall is first considered and then analyzed for successively shorter periods, viz, annual rainfall irrespective of season, monthly rainfall irrespective of season, "seasonally effective" rainfall, and distribution of rainfall in rate per hour classes, based on hourly and quarter-hourly analyses. The problem of the optimum rainfall intensity is noted. The part played by other climatic factors is discussed, and reference is made to the conclusions of other workers in this field. Of all the meteorological factors taken singly, rainfall plays by far the most important role. The increment and rainfall curves in this study corresponded as well as similar curves published by workers in other countries for this and other tree species. Nevertheless, it is thought that the problem of growth of forest trees in relation to climate will not be near a very satisfactory solution until much more of the environal complex is taken into account.

**Lean and ellipticity of stems of Monterey pine in the Australian Capital Territory,** M. R. O. MILLETT ([*Austral. Commonwealth Forestry Bur., Leaflet 60 (1944)*], pp. 10, illus. 2).—Measurements of the lean of the stems from 18 to 26 yr. of age are given for Monterey pine trees. The average lean at 18 yr. was 5.5° and varied by only 0.3° until 25 yr. when, as a result of very strong winds after heavy rains, it increased to 10.5°, many of the trees falling as a result of the severe leans. There was no significant difference in the leans of trees in the thinned v. control plots. The exaggeration of ellipticity of the stems as a result of these leans is discussed. The mean difference in the major and minor axes for the thinned trees increased from 0.45 in. in 1935 to 0.72 in. in 1942, whereas that for the controls decreased from 0.43 in. to 0.40 in. Notes are given on local prevailing winds causing the general lean of about 5° which must have developed during the life of the trees. The heavy rains and strong winds resulting in the severe lean and windfalls at the end of the experiment are discussed, and a comment is made on the practical importance of lean and ellipticity.

**Pollen shed of Monterey pine,** M. R. O. MILLETT ([*Austral. Commonwealth Forestry Bur., Leaflet 59 (1944)*], pp. 8, illus. 1).—The commencement, peak, and end of pollen shed of Monterey pine in two climatically different plantation areas in Australia are given and discussed. Air and soil temperatures associated with the first ripening of the ♂ flowers were the same in the two localities. The extension of the pollen season beyond the initial ripening was more closely related to sunshine, evaporation, and wind than to other meteorological factors.

**[Forestry studies]** (*U. S. Dept. Agr., Forest Serv., Caribbean Forester*, 7 (1946), No. 1, pp. 1–36, Span. trans., pp. 25–35, Fr. abs., pp. 35–36; pp. 57–69, illus. 3, Eng. trans., pp. 64–68, Fr. abs., pp. 68–69).—Included are two papers of significance to foresters: An Ecological Survey of the Polytechnic Institute Arboretum, by L. E. Gregory and I. Vélez; and El Cultivo del Eucalipto en la Sierra de Ecuador (The Planting of Eucalyptus in the Ecuador Sierra), by J. Marrero.

**Station establishes fence-post farm to determine best preservative treatments,** R. J. PRESTON (*Colo. Farm Bul. [Colorado Sta.]*, 7 (1945), No. 6, pp. 1, 5, 7, illus. 1).—A test conducted by the college from 1912 to 1936 showed that the life of Engelmann spruce and lodgepole pine posts can be prolonged greatly by proper treatment with water-gas tar. Brushing with crude oil had no preservative value. A new test started in 1943 is designed to determine the effect of various preservatives and methods of treatment on lodgepole pine and aspen in the hope that it will be possible for farmers to use native materials and save over the purchase of Idaho cedar and other costly species.

**Forest credit in the United States, 1930–1945,** R. C. WATROUS and F. C. BELL (*U. S. Dept. Agr., Libr. List 23 (1946)*, pp. 10).—A list of references grouped by years.

## DISEASES OF PLANTS

**The effect of colchicine and acenaphthene in combination with X-rays on plant tissue, III, M. LEVINE** (*Bul. Torrey Bot. Club*, 73 (1946), No. 2, pp. 167-183).—This report (E. S. R., 94, p. 777) deals with the combined effect of 0.01 percent aqueous solution of colchicine and X-irradiation on root tips of the onion varieties Yellow Globe and Brigham Yellow Globe; detailed results are presented. The cytological phenomena immediately following this combined treatment were more intensified clumping, fragmentation, and extrusion of chromosomes. There appeared to be some visible effects on the resting nuclei in that the chromatic material was distributed near the nuclear membrane, leaving a clear zone around the nucleoli. No division stages were found at 24 hr. after irradiation; 3 or 4 days after treatment, the cells that were irradiated only began to divide, while those receiving the combined treatment exhibited but few nuclear divisions. The nuclei became homogeneously stained; the meristem was interspersed with many highly vacuolated cells. These studies do not favor the view that the greatest number of cellular injuries occur when irradiations are made at the time when the metaphases are most abundant. Colchicine apparently sensitized the cells to X-rays at the time when nuclear reconstruction began; this occurred about 48 hr. after exposure to colchicine had started. Onion roots covered with acenaphthene crystals and exposed to a saturated solution of this chemical produced only small hypertrophies after 48 hr. and little or no gross visible changes after shorter exposures; the effects on nuclear and cell divisions, however, appeared similar to those produced by colchicine. The combination of acenaphthene and X-rays (at 900, 1,500, and 3,000 r.) followed closely the results with X-rays alone. "Colchicine tumors" are not considered analogous to animal neoplasia or to plant overgrowths induced by bacteria or growth substances.

The combination of an exposure of 900 r. with a treatment using 0.01 percent aqueous solution of colchicine for less than 72 hr., or 1,500 r. with 48 hr. of colchicine, proved the most effective for arresting growth of fundamental plant tissues such as the onion root tip. It is suggested that more intensive studies be made with this drug combined with X-rays on tumors of animals and man. The fact that some animal tumors and simple but normal plant structures exhibited delayed growth after such treatment renders it necessary to obtain a suitable concentration of colchicine followed by a selective dose of X-rays which will tend to inhibit and to destroy cancerous tissue without interfering with normal life processes of the host. There are 3.5 pages of references.

**On the effect of heteroauxin upon cells of diseased plant, K. SUKHORUKOV and D. STROGOV** (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 48 (1945), No. 3, pp. 210-212).—The author concludes from experiments with slices from the cortex of carrot roots that heteroauxin may cause a redistribution of the cell-division hormones in plant tissues. It is suggested that parasites may in a similar way modify the distribution of these hormones in the diseased plant by liberating auxins and thus creating conditions favorable to their nutrition and growth.

**Mikroelement och bristsjukdomar hos odlade växter (Minor elements and deficiency diseases in cultivated plants), K. LUNDELA** (*K. Lantbr. Akad. Tidskr.*, 84 (1945), No. 6, pp. 435-489; *Eng. abs.*, p. 485).—This contribution represents a compilation from the literature (over 3 pages of references—largely Swedish) on minor elements in plants. Section 1 takes up the 15 elements known to be necessary in plant nutrition; section 2 considers the different minor elements, with descriptions of the deficiency symptoms in crop plants; and section 3 deals with diagnostic and control matters.

**The effect of pH on fungistatic activity of dinitro-o-cresol, P. W. BRIAN** (*Jour. Soc. Chem. Indus., Trans. and Commun.*, 64 (1945), No. 11, pp. 315-316).—Using

*Fusarium graminearum* and *Trichoderma viride* as test fungi, the author presents results "showing that the fungistatic activity of dinitro-*o*-cresol (DNOC) solutions, adjusted to various pH values, is closely correlated with the concentration of undissociated DNOC. In fact, the fungistatic efficiency of aqueous DNOC solutions can be accounted for on the assumption that the DNOC anion has one-fortieth the toxicity of the undissociated molecule. It is suggested that the observed increases in insecticidal activity of DNOC-petroleum oil winter washes at low pH can also be accounted for by the increased concentration of undissociated DNOC, rather than by the increased concentration of DNOC in the oil phase. The concentration of DNOC in the oil phase is in fact an indirect measure of the concentration of undissociated DNOC."

**Molecular weights and other properties of viruses as determined by light absorption.** G. OSTER (*Science*, 103 (1946), No. 2671, pp. 306-308, illus. 3).—Virus solutions exhibit visible opalescence due to light scattered by the virus particles; this results in a decrease in light transmission. The light-scattering—and therefore light-absorptive—powers of solutions are very sensitive to changes in particle size, shape, and interaction. The method was used in studies with two virus preparations known to possess quite different particle sizes, viz, the influenza and tomato bushy stunt viruses. This technic was also followed in determining the isoelectric point from the point of maximum coagulation of virus (tobacco mosaic) particles; it was even possible to distinguish between the isoelectric points of this virus and many of its strains. The optical method is now being used to study irreversible polymerization and the formation of liquid crystals of tobacco mosaic virus; it seems to offer promise also in investigations of antibody-antigen reactions involving viruses as the antigens.

**De betekenis van de serologie voor het virusonderzoek [The value of serology for virus investigations],** E. VAN SLOTEREN ([Netherlands] *Lab. Bloembollen Onderzoek, Lisse*, No. 72 (1943), pp. 21+).

**The nutrition of phytopathogenic bacteria.—I, Minimal nutritive requirements of the genus *Xanthomonas*,** M. P. STARR (*Jour. Bact.*, 51 (1946), No. 2, pp. 131-143, illus. 3).—The minimum nutritive requirements of 113 isolates of plant-pathogenic bacteria representing 30 species and varieties of *Xanthomonas* were determined under conditions of controlled inoculum, carefully cleaned glassware, and pure components of the media. In this way it was learned that most—though not all—the species could grow to some extent in the simplest medium used, viz,  $\text{NH}_4\text{Cl}$ , glucose, and salts. Methionine, glutamic acid, and niacin in various combinations served to furnish the stimulative and essential growth factors necessary for prompt development of the more exacting species. Growth in these simple media offers promise of utility as a taxonomic character at the generic and specific levels. There are 36 references.

**Dispersion of small organisms: Distance dispersion rates of bacteria, spores, seeds, pollen, and insects—incidence rates of diseases and injuries,** D. O. WORRENBERGER (*Amer. Midland Nat.*, 35 (1946), No. 1, pp. 1-152, illus. 47).—The distance dispersed by organisms has not only great scientific interest, but is also very important in planning control measures; this double significance offers a challenge for quantitative research. The present paper was prepared in an attempt to meet this challenge, at least in part. Following introductory statements—including terms, conceptions, and methods used in the study, the author considers in part 1 the dispersion and incidence rates—horizontal dispersion of inanimate objects, viruses, plants, and insects and vertical dispersion of micro-organisms and insects. In part 2, generalizations, he discusses dispersion-distance in relation to dispersion-time reciprocity and differential, direction of dispersal, factors influencing dispersion, migration of small organisms, agencies or means of dispersal, density levels at the

source, sampling characteristics, dispersions for control measures, considerations of vertical and horizontal dispersion, vertical dispersions and generalizations, and vertical strata. An appendix presents regression formulas used for determining the calculated or curve values used in the figures. About nine pages of references and a subject index complete the monograph.

**The relation of soil temperature to the development of armillaria root rot,** D. E. BRISS. (Calif. Citrus Expt. Sta.). (*Phytopathology*, 36 (1946), No. 4, pp. 302-318, illus. 8). Plants were grown for 181 to 438 days in the greenhouse in five soil-temperature tanks at controlled temperatures from 7° to 38° C.; air temperatures ranged mostly between 21° and 27°. The optimums for root growth in group A plants—Lovell peach, casuarina, California peppertree, geranium, and Royal apricot—were 10° to 17°; those for group B plants—Koethen and Homosassa sweet orange, Standard sour orange, Sampson tangelo, and rose—were 17° to 31°. Top growth of citrus was retarded at 10° to 12°, the new leaves being small and very chlorotic; largest top growth occurred at 27° to 31°. The minimum for root growth was 12°; the maximum, slightly below 38°. Top growth of peaches and apricots was greatest at a soil temperature of 31° and least at 10°; that for geraniums was greatest at 17° and least at 31°. Top growth of peppertrees was retarded at 10° but was vigorous and nearly equal at 15° to 30°. The growth rate of roses increased from 8° to 28°; that for casuarina was retarded at 7° and most rapid at 27°.

Rhizomorphs of *Armillaria mellea* grew most rapidly in sterile deep nutrient agar at 19.7° and 24°. Slight growth occurred at 5° and 31°, but none at 36°. The fungus remained viable in woody inoculum in soil held at controlled temperatures of 7° to 28° for 181 to 438 days. The greatest development of rhizomorphs in nonsterile soil was evident at the lowest experimental temperature. Pathogenesis in artificially inoculated test plants was observed at 7° to 25°; the optimum range in plants of group A was 15° to 25° and that for group B 10° to 18°. The greatest resistance was shown by all plants at the temperatures most favorable to root growth. The upper critical temperature for pathogenesis in all susceptibles was tentatively placed at 26°. In southern California the prevalence of this root rot throughout the coastal region and its supposed absence in the inland desert areas are apparently related to differences in soil temperature. In the coastal region, pathogenesis in group A plants would develop most rapidly from spring to fall; in group B plants, most rapidly from late fall until spring.

**Further studies on the Erysiphaceae of China,** F. L. TAI (*Bul. Torrey Bot. Club*, 73 (1946), No. 2, pp. 108-130, illus. 13).—A careful comparative study of available collections of most species of these powdery mildew fungi thus far reported from China led the author to believe it advisable to keep the collective species *Erysiphe dichoraeum*, *E. polygoni*, and *Microsphaera alni* as emended by Salmon. Climatic conditions were found to affect the morphological characters of *Uncinula delavayi* at Kunming. As a result of this study several species were reduced to synonymy. *U. koelreuteriae* is transferred to the genus *Typhlochaeta*, and one variety of *Erysiphe*, two species of *Microsphaera*, and one variety and one species of *Uncinula* are described as new.

**Some resupinate polypores from the region of the Great Lakes,** XVI, D. V. BAXTER (*Mich. Acad. Sci., Arts, and Letters, Papers*, 30 (1944), pp. 175-192, illus. 56).—It is believed that no systematic attempt has previously been made to compare the reactions (on similar substrata) of a large group of isolates from many different species of resupinate polypores collected from widely separated localities of North America and found on a great variety of woods. The present paper is based on a large number of species and races obtained in culture from the Michigan collections; each isolate was placed on red gum and white pine blocks regardless of the kind of wood originally attacked, and the macroscopic effects on these test

woods were noted and records of the mycelial growth on malt extract in petri dish cultures secured. Distinctions that can be made among many species and races of the white resupinate polypores in such cultures were recorded in key form in the previous paper of the series (E. S. R., 92, p. 674); the key there presented is continued in this paper, which deals with the light- and dark-colored species of the group. The comparative appearances of the fungi in petri dish cultures are illustrated.

**A new bean mosaic in Idaho**, L. L. DEAN and C. W. HUNGERFORD. (Idaho Expt. Sta. et al.). (*Phytopathology*, 36 (1946), No. 4, pp. 324-326).—The authors report from Idaho a new virus causing symptoms resembling those of common mosaic but differing in its ability to infect certain varieties immune to the common form. The University of Idaho Great Northern selections 1, 56, 59, 81, and 123 and Idaho Refugee and U. S. No. 5 all proved resistant to the new strain; Great Northern U. I. 15, Red Mexican U. I. 3, Red Mexican U. I. 34, Michelite, Robust, Red Kidney, Bountiful, and Burtner were susceptible. Richards and Burkholder have reported a similar new bean virus in New York State (E. S. R., 90, p. 649).

**Sporidial fusion in *Ustilago maydis***, D. H. BOWMAN. (U. S. D. A. coop. Univ. Wis. and Ohio Expt. Sta.). (*Jour. Agr. Res. [U. S.]*, 72 (1946), No. 7, pp. 233-243, illus. 2).—Sporidial fusions in cultures of the corn smut fungus were markedly influenced by temperature and the nutritive value of the media; they were sufficiently numerous to be readily detected after 20 hr. at 24° C. in distilled water and after 15 to 20 hr. at 20° to 24° in 1-percent malt-extract solution. Initiation of the binucleate phase followed no fixed method but resulted from the fusion of any two compatible haploid cells—sporidial or hyphal. In no case were the binucleate hyphae seen to revert to sporidial production. The end cells of binucleate hyphae each uniformly contained a single pair of nuclei. The protoplasmic contents of older binucleate cells and of fused sporidia appeared to be in various stages of disintegration. In some cases the cell contents were apparently normal; in others they were either partly disintegrated or entirely lacking. The rapidly growing apical cells of binucleate hyphae and young sporidia had a pronounced affinity for the various dyes used; older cells and old fused sporidia did not.

**Corn seed treatment in Oklahoma**, J. H. McLAUGHLIN (*Oklahoma Sta. Bul.* 294 (1946), pp. 14).—This contribution advocates corn seed treatment as seedling-emergence insurance and backs up the recommendations with experimental data from tests over a 3-yr. (1943-45) period, showing the value and costs of the treatment and the larger numbers of fungus infections in the seedlings from untreated seed.

**Variation and variability of *Fusarium lini*, the fungus causing flax wilt: A review**, H. H. FLOR (*North Dakota Sta. Bimo. Bul.*, 8 (1946), No. 3, pp. 31-32).

**A seedling disease of flax caused by *Macrosporium* sp.**, J. B. LOUGHNANI: (*Nature [London]*, 157 (1946), No. 3983, p. 266).—A brief preliminary note on this apparently new disease.

**On the identity between yellow of kok-saghyz and yellow of aster and its possible relation to big bud in tomato**, K. S. SUKHOV and A. M. VOVK (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S.*, n. ser., 48 (1945), No. 5, pp. 365-368).—Yellows of kok-saghyz is virus-induced and transmissible from diseased to healthy plants by grafting; its vector is *Macrosteles quadripunctata* Klm. According to the literature (14 references) and studies by the authors, this virus in the U. S. S. R. attacks up to 45 plant species in 15 families. Comparisons of the vectors and hosts led the authors to believe the kok-saghyz virus identical with or a related strain of the aster yellows virus of America; similar comparisons also revealed its identity or close affinity to the causal agent of the big bud disease of tomato.

**Mosaic on Leguminosae**, A. M. VOVK (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S.*, n. ser., 48 (1945), No. 3, pp. 213-215).—The author briefly reviews the litera-

ture (22 references) on virus diseases of legumes, notes the various leguminous host plants which he has observed infected with mosaic, and briefly summarizes his cross-inoculation tests via the green peach aphid and sap from diseased plants. He believes that the mosaic on garden pea, sweet pea, and bean are all due to Pisum virus 2 of Doolittle and Jones; the mosaic virus of bean and pea induced no morbid symptoms on inoculation by these two methods to cucumber seedlings or to *Nicotiana tabacum* and *N. glutinosa*.

**Studier över de Svenska potatisfältens insektfauna och dess betydelse för spridning av virussjukdomar.**—I, Hemiptera, förekomst och utbredning [Studies of the insect fauna of Swedish potato fields and their role as vectors of virus diseases.—I, Hemiptera, incidence and geographical distribution], F. OSSIAN-NILSSON ([Sweden] *Statens Värtskyddsanst. Meddel.* 39 (1943), pp. 72, illus. 18; *Ger. abs.*, pp. 69-70).—A survey of the hemipterous fauna of the potato fields of Sweden, as well as the results of the author's study of their distribution in that country. There are 53 references.

**De herkenning van virus-ziekten der aardappelen langs serologische weg** [Determination of virus diseases of potatoes by serological methods], E. VAN SLOOTVELD ([Netherlands] *Lab. Bloembollen Onderzoek, Lisse*, No. 76 (1944), pp. 8, illus. 3).

**Spray and dust treatments of potato demonstration plots, 1945**, G. A. BRANDES and E. M. SWISHER (*North Dakota Sta. Bimo. Bul.*, 8 (1946), No. 3, pp. 33-39).—This paper is based on spray and dust treatments of demonstration plots of potatoes on farms of grower cooperators at 15 well-distributed points in the potato area of North Dakota in 1945. Of the four most important insect pests, the six-spotted leafhopper proved most difficult to control, with the potato leafhopper, potato flea beetle, and Colorado potato beetle more easily combated in the order named. Sprays and dusts containing DDT controlled these pests better than any of the other insecticides tried. The organic thiocarbamates Dithane and Fermate were more effective against alternaria early blight than the fixed coppers; the generally good control of flea beetles by DDT also resulted in a lower incidence of early blight. Late blight was not of general occurrence. Yield differences in most of the dust plots were only slightly significant, but the Cu-DDT plots outyielded the Cu-arsenical ones by 8.3 to 44.3 bu. per acre; DDT-Pyrocide-Cu and Dow F-508 dust slightly outyielded DDT-Cu. With DDT assumed at 100 percent, the average percentage ratings for the dust groups were DDT-Cu 100, DDT-Pyrocide-Cu 102.3, Dow F-508 102.2, arsenical-Lethane Cu 96.8, and arsenical-Cu 89.3. Yield variations were small and of little significance in the Dithane-DDT, Fermate-DDT, Copper A-DDT, Dithane-arsenicals, and Cuprocide DDT spray plots, but Dithane-DDT outyielded the general group of Cu arsenicals by 22.2 to 62.3 bu. per acre and the check receiving one application of arsenical dust and no fungicide by 73.8 bu. per acre. The average percentage yields for the spray material groups were Dithane-DDT 100, Fermate-DDT 99.1, Copper A-DDT 97.5, Dithane-arsenical 96.5, Copper A-arsenical-Lethane 96, Cuprocide-DDT 94.7, Cu-arsenical 88.6, and check 81.9. The combinations of all materials used are given.

**Evaluation of various spray and dust materials in the control of insects and of the fungus causing early blight of potatoes**, J. A. MUNRO and W. G. HOYMAN (*North Dakota Sta. Bimo. Bul.*, 8 (1946), No. 3, pp. 23-30).—In tests of the effectiveness of some of the newer insecticides and fungicides at Grand Forks and Park River, N. Dak., (1945), in which 17 dusts and 16 sprays were used, the six-spotted leafhopper showed the greatest resistance; the potato leafhopper, potato flea beetle, and Colorado potato beetle were lower in resistance in the order listed. Treatments containing DDT averaged the best in insect control, combinations of DDT (dichlorodiphenyldichloroethane) with arsenicals ranking lower. Aphids became

moderately abundant only on plots with arsenicals alone, indicating that the other insecticides used had a controlling effect on them. The prevalence of ladybird beetles and lace wing flies appeared to be correlated predominantly with the presence of the aphids on which they fed. Dust treatments containing DDT as the insecticide gave significantly better control of insects at Park River than corresponding spray treatments, while at Grand Forks the difference in control between the two methods was negligible. It is possible that the sulfur, Zerlate, or additional amount of Cu included in certain treatments added to the effectiveness of DDT in insect control.

Fungicides applied as sprays were more effective in preventing alternaria early blight than those applied as dusts. Except for the three materials containing an excessive amount of Dithane, the lowest infection at Grand Forks and Park River occurred on plots sprayed with Zerlate; Copper A and Copper A plus Zerlate were equally as effective at Park River as Zerlate. The best combination tested at Grand Forks for controlling both insects and early blight was Zerlate plus DDT spray; these were also included in the most effective dust. At Park River, the most effective combinations for the dual control were dusts containing Zerlate and DDT; Copper A and DDT; and Copper A, Zerlate, and DDT. The compositions and concentrations of the materials used are given.

**Two aids for the study of potato-late-blight epidemiology**, W. D. THOMAS, JR. (Minn. Expt. Sta.). (*Phytopathology*, 36 (1946), No. 4, pp. 322-324, illus. 1).—Potted potato plants grown in the greenhouse and protected from accidental infection were exposed in potato fields for periods of 4 hr. or overnight and subsequently incubated at about 21° C. and 100 percent relative humidity. Late blight lesions developing on the plants indicated the number of viable *Phytophthora infestans* spores falling on plants during the exposure period. The temperature among the leaves of potato plants in the field was in some cases as much as 10° lower than at 5 ft. above them; the relative humidity among the vines was also consistently higher than at 5 ft. above—sometimes as much as 20 percent.

**The potato-rot nematode *Ditylenchus destructor* Thorne, 1945, attacking potatoes in Prince Edward Island**, A. D. BAKER (*Sci. Agr.*, 26 (1946), No. 3, pp. 138-139).—The author presents "clear evidence that the potato rot nematode is present in a small portion of one field in Prince Edward Island."

**Verslag van het serologische onderzoek betreffende de vergelingsziekte der suikerbieten 1942-1943** [Contribution to the serological investigation of curly top of sugar beets, 1942-43], H. L. BOOIJ, M. P. DE BRUYN OUBOER, M. C. CREMER, and E. VAN SLOOTEN ([*Netherlands Lab. Bioenbollen Onderzoek, Lisse*, No. 73 (1941), pp. 28+, illus. 7).

**El efecto del "carbón" en las cañas de distintas variedades durante el año agrícola 1944-1945** [The effect of smut on different sugarcane varieties during the crop year 1944-45], W. E. CROSS (*Bol. Estac. Expt. Agr. Tucuman*, No. 55 (1945), pp. 31).—The author discusses the commonly planted varieties which are more or less seriously attacked by smut, resistance and immunity among varieties, the relation between genetic origin of a variety and its degree of resistance, varieties which in commercial plantings may be classed as practically immune and those which are attacked only slightly, and the progress of the disease in P. O. J. 36.

**Bud blight of soybean caused by the tobacco ring-spot virus**, W. B. ALLINGTON. (U. S. D. A. and 24 expt. stas.). (*Phytopathology*, 36 (1946), No. 4, pp. 319-322, illus. 2).—The author verifies earlier reports that tobacco ring spot virus infects and severely injures soybeans in areas of the midwestern United States, symptoms varying with stage of plant growth at infection time. Young plants show a characteristic curving of the terminal bud, bronzing of the leaves, browning of the pith, slight defoliation, poor seed set, and delayed maturity; heavier infection is more

evident at blossoming time and results in extensive losses. The pods present a dark irregular blotched appearance and usually fall off in great numbers. Unsound seed is produced. The symptoms on other hosts such as cucumber, bean, and tobacco are characteristic of those induced by this virus. Thermal inactivation and plant immunity tests gave further evidence of its identity. An insect vector is being sought.

**A "frenching" response of tobacco seedlings to isoleucine,** R. A. STEINBERG. (U. S. D. A.). (*Science*, 103 (1946), No. 2672, pp. 329-330).—A shortened stem and excessive development of axillary buds leading to a "witch's broom" type of growth followed use of isoleucine in the substrate—the symptoms varying with the concentration of this amino acid. The abnormalities described are characteristic of the tobacco disease called frenching, the cause of which is unknown.

**The effects of infection of tobacco plants (*Nicotiana tabacum*) with tobacco mosaic virus on some of the properties of the protein present in the leaves,** J. W. II. LUGG and R. J. BLIST (*Austral. Jour. Expt. Biol. and Med. Sci.*, 23 (1945), No. 3, pp. 235-239).—Infection of tobacco with mosaic virus led to a progressive change in the physical properties of the leaf proteins, these tending to precipitate much more readily from borate buffer at pH 9.2 when a mixture of 0.8 volume of alcohol and 0.2 volume of ether was added. The change appeared not to be reflected in any marked change in the amino acid composition of the proteins. Little change in composition merely in consequence of admixture of the normal leaf proteins with virus protein could be anticipated because—although these differ markedly in composition—the virus protein probably did not represent over about 5 percent of the total protein in the infected leaves. Of the N in the whole protein of healthy leaves, the percentage represented by amid was 5.48, by tyrosine 2.63, by tryptophan 1.82, by cyst(e)ine 1.35, and by methionine 1.45. These values are similar to those reported for the leaf portions of other flowering plants.

**On the rate of inactivation of tobacco mosaic virus by potassium salicylate,** R. J. BLIST (*Austral. Jour. Expt. Biol. and Med. Sci.*, 23 (1945), No. 3, pp. 221-226, illus. 2).—The inactivation rate for this virus by potassium salicylate at pH 7 and 30° C. followed a logarithmic course at salicylate concentrations of 0.51, 0.54, 0.61, 0.68, 0.8, and 1.0 M; below 0.3 M no inactivation could be detected within 48 hr. Loss of birefringence of flow, opalescence, and ability to form paracrystals paralleled the loss of infectivity. Between 0.3 and 1.0 M salicylate, inactivation was accompanied by precipitation of denatured protein, the amount increasing to a maximum at about 0.65 M and decreasing at higher concentrations until at 1.1 M the denatured protein was completely soluble. Dilution of such a solution resulted in the isolation of denatured protein equivalent to 69 percent by weight of the original virus. The denatured protein contained C, H, N, and S in amounts similar to the original virus but was devoid of P, the salicylate having split off the nucleic acid from the virus. The half-life periods of the virus were found to be 9, 18, 53, 97, 165, and 354 min. at 1.0, 0.8, 0.68, 0.61, 0.54, and 0.51 M salicylate, respectively. The necessary contact time for reducing 1 mg. of virus to one active particle was calculated from the half-life periods and found to be 6.5, 13, 38, 70, 119, and 255 hr. for the above concentrations of salicylate.

**The diagnosis of bacterial black chaff of wheat,** W. A. F. HAGBORG (*Sci. Agr.*, 26 (1946), No. 3, pp. 140-146, illus. 4).—A diagnostic procedure is presented which is reported to be effective and to obviate the difficulties experienced by many workers. All the essential parts of the method can be performed with equipment ordinarily available in the plant pathology laboratory. It consists essentially in the examination of macroscopic and microscopic portions of the diseased tissues, isolation of the causal organism, and its identification either by a study of its pathogenic or its serological reactions, coupled with a study of its morphology and physiological properties.

**The effect of chemical soil treatments on the development of wheat mosaic,** F. JOHNSON. (West. Wash. Expt. Sta.). (*Ohio Jour. Sci.*, 45 (1945), No. 4, pp. 125-128).—The author studied the action of certain chemicals commonly used as insecticides and nematocides on the development of winter wheat mosaic. Samples of a specified amount of virus-infested soil were subjected for 7 days to the gases of five volatile liquids and two solids; in addition, one contact insecticide was used. Calcium cyanide when applied in the largest amount and carbon disulfide, chloropicrin, and methyl bromide at each of the three concentrations employed gave complete control of mosaic. Ethylene dichloride reduced the incidence at the two larger dosages, but ethyl chloride gave no control at all. The naphthalene fumes and rotenone dust, when mixed with the soil, also completely eliminated the disease. The action of these chemicals was believed to be on the vector rather than on the virus.

**Influence of time, rate, and depth of seeding on the incidence of root rot in wheat,** F. J. GREANEY (*Phytopathology*, 36 (1946), No. 4, pp. 252-263).—Field tests in Manitoba (1936-44) on the relation between date, rate, and depth of seeding of spring wheat and the incidence of root rots by *Helminthosporium sativum* and *Fusarium* spp. indicated that early seeding reduces the incidence and increases the yields. Soil temperature as related to date of seeding was positively associated with root rot infection and negatively related to yields. Low soil temperature (early seeding) was thus associated with low disease incidence and high yields. The effect of high soil temperature on the incidence of root rot proved an important factor in reducing yields of late-sown crops of spring wheat. A close association was found between rate of seeding and development of root rot, its severity increasing with thickness of planting; deep planting also increased the incidence. As a factor in the control of root rot, depth of seeding was more important in some varieties than in others. These findings establish the practicability of reducing losses from these common root rots in Manitoba by seeding spring wheat at the earliest feasible date, and not too thickly or deeply.

**Growth and overwintering of *Xanthomonas vesicatoria* in association with wheat roots,** S. DIACHUN and W. D. VALLEAU. (Ky. Expt. Sta.). (*Phytopathology*, 36 (1946), No. 4, pp. 277-280).—*X. vesicatoria*, *X. phaseoli sojense*, and *Bacterium mediaginis phaseolicola* produced colonies on the surface of roots of seedlings of wheat, tomato, bean, and soybean grown aseptically in petri dishes within 2 days after the roots had been dipped into bacterial suspension. In each of five trials during December 11, 1943-March 14, 1944, *X. vesicatoria* was recovered from the roots of wheat growing out of floors in nonsterilized soil infested with the organism; it was not recovered on April 14. Attempts to isolate the other two species were unsuccessful.

**Vegetable seed treatment for Oklahoma,** J. H. McLAUGHLIN (*Oklahoma Sta. Bul.* 293 (1946), pp. 24).—This bulletin presents results of tests on the value of chemical treatment of vegetable seeds in Oklahoma; they were made on beet, cabbage, cantaloup, carrot, cucumber, eggplant, lettuce, lima bean, okra, pea, pepper, potato, radish, salsify, edible soybean, spinach, sweet corn, tomato, turnip, and watermelon seed. Recommendations based on these tests are as follows: Chemical seed treatment often results in marked increases in seedling stands; it is especially valuable on spinach, beet, pea, lettuce, carrot, salsify, sweet corn, cucumber, cantaloup, and watermelon seed when environal conditions after planting are unfavorable to seedling development. Although some kinds of seed do not respond as markedly as others to treatment, it should be a standard practice on all vegetable seed. The chemicals used are inexpensive and easy to apply. Most vegetable seed can be treated for approximately a cent per pound. Seeding rates with treated seed should be reduced to avoid stands that are too thick. Only a few chemicals are needed—

Arasan, Spergon, Semesan, Cuprocid, and Vasco 4 (zinc oxide) are those most widely used for vegetable seed treatment; Arasan and Spergon have shown the most outstanding and consistent increases in seedling stands and are also less poisonous and therefore less dangerous to use. Treated seed may be saved for later plantings or for use the following season. For specific recommendations on the control of diseases of most vegetables commonly grown in the State, the reader is referred to Circular 117 (U. S. R., 93, p. 46).

**Our experience with seed treatments in western Washington agriculture,** C. J. GOULD. (Wash. Expt. Sta.). (*West. Canner and Packer*, 37 (1945), No. 4, pp. 47, 49, 51, illus. 1).—The author presents the results of a seed treatment program carried out on some 19 garden crops, using many of the newer fungicides, such as Ceresan, red and yellow Cuprocid, Semesan, Spergon, AAZ Zinc Oxide, Barbak C, New Improved Ceresan, Arasan, Fermate, Dow 6-B, Dow 5, and USR No. 604, in comparison with calomel and  $\text{CuSO}_4$ . The results were especially promising for lima and snap beans, beets, chard, cucumbers, lettuce, peas, spinach, squash, tomatoes, and corn.

**Seedling blight of asparagus,** C. M. HAENSELER (*New Jersey Stat. Plant Disease Notes*, 23 (1946), No. 2, pp. 5-8).—For many years a blight of asparagus seedlings 2 to 4 in. high has been observed in southern New Jersey; no very characteristic symptoms occurred other than that when about 1 to 4 in. high the seedlings turned yellow, then brown, and died. Various suggestions as to the cause have been followed through but none has appeared to fit the situation. More recently studies of the insect populations of blighted fields have revealed the presence of springtails feeding near the soil surface. Preliminary tests with insecticides in 1945 gave some evidence that these insects may be implicated.

**Exploratory experiments with the big-vein disease of lettuce,** D. E. PRYOR. (U. S. D. A.). (*Phytopathology*, 36 (1946), No. 4, pp. 264-272).—Tests with leaf-feeding aphids, mechanical inoculation, and seed soaked in leaf juice or harvested from diseased plants resulted in no consistent transmission of big vein. The unfiltered leachate from infective soil added to disease-free soil produced big vein in 4 of 83 plants; filtered leachate (medium Mandler filter) caused no disease. Big vein was not eliminated from infective soil by leaching. Symptoms appeared in plants grown on big vein free soil to which chopped diseased leaves had been added. There was little difference in the amount of the disease developing in transplants to, vs. lettuce seeded directly in, infective soil. Trials in which one big vein plant was grown for 2 to 2.5 mo. adjacent to 3 healthy plants in a 6-in. pot filled with disease-free soil indicated that big vein spreads very slowly if at all through undisturbed soil during the experimental period used. There was a slight tendency for fewer diseased plants to appear in undrained pots filled with Imperial Valley soil than in drained pots, but in only one test was this difference statistically significant. Transplanting at intervals from infective to noninfective soils indicated that some infection occurs within 2 weeks from seeding, but at least 4 weeks were required for a large proportion of the plants to become infected. Diluting 1 part of big vein soil with 800 parts of autoclaved soil reduced the disease incidence only slightly. Stored air-dry soil remained infective for at least 8 yr. Under favorable air temperature, the optimum soil temperature for development of big vein appeared to be about 22° C., with some infection occurring at all soil temperatures from 14° to 30°. Air temperature also seemed to have some effect on symptom expression.

**Tipburn of lettuce—effect of maturity, air and soil temperature, and soil moisture tension,** E. M. ANDERSEN ([*New York*] *Cornell Sta. Bul.* 829 (1946), pp. 14, illus. 13).—Water deficiency, as indicated by high soil water tension, was shown to be the primary cause of the physiological break-down under study; the findings are in line with published work of certain other investigators (22 references). Low

soil temperatures increased the tipburn, probably by further decreasing the availability of soil moisture. In these experiments, there was a high correlation between severity and the difference between maxima of air and soil temperatures; tipburn was most severe when this difference was greatest. The largest difference between air and soil temperatures occurred when a cool moist period was followed by a sunny dry period. It is believed that under such conditions water intake is too low to replace water loss, and that the resulting water deficiency results in tipburn. It is also possible that tipburn may result from some physiological disorder which accompanies a reduced moisture supply to succulent tissues rather than directly from the reduced moisture supply itself. If such be the case, tipburn might be induced by other environmental conditions, thus accounting for the divergent views concerning its cause.

**Relation of color-inhibiting factor to smudge resistance in onion,** H. A. JONES, J. C. WALKER, T. M. LITTLE, and R. H. LARSON. (U. S. D. A. coop. Wis. Expt. Sta.). *Jour. Agr. Res. [U. S.]*, 72 (1946), No. 7, pp. 259-264.—Seed of onions segregating for white, cream, and red or yellow bulb color were sown in flats and the seedlings later planted in the field at Madison, Wis.; when the bulbs were about half-grown, cultures of *Colletotrichum circinans* were distributed over the lower portion of the plants which, when mature, were cured in shallow crates. Readings during mid-November indicated the white bulbs homozygous for the dominant color inhibitor (*I*) were also highly susceptible to smudge; colored bulbs (red or yellow) with the genetic constitution *ii* were highly resistant; the cream-colored bulbs (*Ii*) were about intermediate in resistance between the white and colored. The most important factor in resistance to this fungus disease is clearly the presence of pigment in the dry outer scales of the bulbs. There are 15 references.

**Influence of nitrogen nutrition on susceptibility of onions to yellow-dwarf virus,** P. BRIERLEY and N. W. STUART. (U. S. D. A.). (*Phytopathology*, 36 (1946), No. 4, pp. 297-301, illus. 1).—Four varieties of onions grown at 60 and 6 p. p. m. weekly initial N levels in Haydite were inoculated with the onion yellow dwarf virus; both infection and symptom expression were less at the lower N level. The immunity of the Utah Sweet Spanish variety was unaffected by repeated inoculation at a high-N level that enhanced infection in the susceptible Ebenezer and in the resistant varieties. Creole and Stockton Yellow Globe exhibited a resistance to infection distinct from the immunity of Utah Sweet Spanish.

**Reaction of onion varieties to yellow-dwarf virus and to three similar viruses isolated from shallot, garlic, and narcissus,** P. BRIERLEY and F. F. SMITH. (U. S. D. A.). (*Phytopathology*, 36 (1946), No. 4, pp. 292-296).—Of 27 onion varieties mechanically inoculated with onion yellow dwarf virus and related isolates from shallot, garlic, and narcissus, 10 samples proved immune to yellow dwarf and also to the isolates from garlic and narcissus; 17 varieties proved susceptible to these 3 viruses. All but Nebuka (*Allium fistulosum*) and an amphidiploid (Nebuka × White Portugal) were susceptible to the shallot virus; these 2 green-branching types were found immune to all 4 viruses tested. All 4 viruses were transmitted by *Myzus persicae*.

**Sweet corn seed treatments,** B. H. DAVIS and C. M. HAENSELER (*New Jersey Stas. Plant Disease Notes*, 23 (1946), No. 1, pp. 4).—The conditions favorable to seed and seedling decay—and therefore for pronounced results from seed treatment—are briefly discussed. In a 1945 test with Semesan, Arasan, and Spergon, not only was there an increase in the actual number of plants from treated seed but also a decrease in the number of weaklings and a significant increase in the height of the plants—with no marked differences among the fungicides used. "From the use of seed protectants on sweet corn we may expect not only increased stands in about 60 percent of the cases but also more uniform stands and greater plant vigor."

**Peach blotch**, R. S. WILLISON (*Phytopathology*, 36 (1946), No. 4, pp. 273-276, *illus.* 1).—A graft-transmissible leaf variegation of peach varieties is reported from Ontario. The symptoms comprise pale green to yellowish-green areas ranging from numerous small angular spots to large single blotches arranged either centrally and symmetrically along the midrib or as a band around the leaf margin; some leaves have yellow markings along the veins, and affected leaves occasionally show marginal scorch and emargination. Flowers, fruits, and twigs have no apparent symptoms. This disease—referred to as peach blotch—was transmitted to peach but not to the plum, cherry, or apricot varieties used as differential hosts. The peach varieties Marigold, Elberta, and Rochester exhibited the characteristic markings; Vedette and Golden Jubilee were little affected. Blotch—observed in nature on only two trees in widely separated localities—is similar to but not identical with the peach mottle and calico of the western United States.

**Mineral nutrient deficiencies in California citrus trees and their causes**, P. W. ROHRBAUGH (*Calif. Citrog.*, 31 (1946), No. 6, pp. 201, 225-228, *illus.* 2).—This paper represents "an effort to compile and interpret published work, most of which originated in the experiment stations of California and Florida."

**Some additional information on citrus psorosis**, H. E. STEPHENS [STEVENS]. (U. S. D. A.). (*Citrus. Indus.*, 27 (1946), No. 3, pp. 8-9, 15-17, 20-21, *illus.* 1).—The author's previous discussion of the history, characteristics, nature, and cause of the disease and certain suggestions as to control—especially in nurseries—have been noted previously (E. S. R., 89, p. 232). "Several new facts and angles have been uncovered in recent studies which may be used to advantage in preventing the future spread of this disease"; these are here considered under bark and leaf symptoms, bud transmission, tests for parent trees, stock infection, effect of psorosis on yield, and control. Infected budwood is the principal source of spread; production of nursery trees free from the disease is the most logical and practical method of control.

**Quick decline of orange trees**, D. C. MILBRATH (*Citrus Leaves*, 26 (1946), No. 3, p. 36).—A brief note based on recent general and detailed observations in California.

**A propos des pourritures des agrumes [Citrus fruit rots]**, G. VIENNOT-BOURGIN (*Fruits d'Outre Mer*, 1 (1946), No. 6, pp. 164-171, *illus.* 6).—On the penicillium rots of citrus and apple fruits—with special reference to those on the French markets—and their control. There are 41 literature references.

**Transmission of papaya bunchy top by a leaf hopper of the genus Empoasca**, J. ADSUAR. (P. R. Univ. Expt. Sta.). (*Science*, 103 (1946), No. 2671, p. 316).—The author found a species of *Empoasca* able to transmit the virus of papaya bunchy top; 71 out of 90 healthy trees exposed to these leafhoppers collected on diseased trees developed the symptoms, whereas the unexposed trees remained normal.

**Undersökningar över vissnesjuka hos sommaraster *Callistephus chinensis* (L.) Nees** (Investigations into the wilt of China aster (*C. chinensis* (L.) Nees)), I. BERGSTRÖM-KIELLANDER ([Sweden] *Statens Växtskyddsanst. Meddel.* 42 (1944), pp. 78, *illus.* 14; *Eng. abs.*, pp. 64-75).—In this review (52 references) and general investigation, the author takes up the symptoms, cause, effects, and control of the disease, culture studies of fungi isolated from asters, and taxonomic considerations. It was experimentally revealed that in Sweden (like most other countries) the true wilt disease is the most serious obstacle to the successful production of asters in the field. The pathogen isolated was in all cases *Fusarium conglutinans callistephi*. The control measures investigated were soil and seed disinfection, crop rotation, and use of resistant varieties; the last method is recommended as best.

**Undersökningar över "blad- och grentorka" hos importerade azaleor** (Investigations into "leaf and twig blight" in imported azaleas), D. LÖHNELL ([Sweden]

*Statens Värtskyddsanst. Meddel. 40 (1943), pp. 74, illus. 17; Eng. abs., pp. 63-73*) — The author reports a twig and leaf blight of azaleas imported chiefly from Belgium for forcing in Sweden during the winter months. The chief symptom consists of an abnormally copious dropping of the leaves beginning with the lowermost and progressing upward; the detachment of the leaves is the primary phenomenon, the "blight" being secondary. Various degrees of injury are encountered up to death of most of the branches and production of only a few flowers. Normally the transportation period covers 1 to 2 and latterly 3 to 5 weeks in more or less closed spaces without access to light and with very little air; the period during which they are packaged is probably much longer. As a general result of the experimental work it is considered that the trouble is nonparasitic in origin, the evidence at hand leading to the belief that the chief cause lies in CO<sub>2</sub> poisoning during the period of packaging. There are 28 references.

**Forcing lily bulbs after treatment for control of nematodes**, W. D. COURTNEY and E. P. BREakey. (U. S. D. A. and Wash. Expt. Sta.). (*Florists' Rev.*, 96 (1945), No. 2496, pp. 37-38) — Hot-water-formalin treatment of nematode-infested Croft lily bulbs resulted in earlier emergence of the plants, a larger total number of buds, and an increased number of early blooms; the treated plants were also significantly taller than the controls. There was no essential difference in the number of plants finally coming up, nor did dipping or curing for 2 to 16 days change the picture. The number of blind plants was greatly reduced in the treated plants, although its complete elimination was not effected. Dieback was completely done away with, except for one apparently recontaminated plant. The number of bunched plants was greatly reduced, though not fully controlled. Since the experimental lots were forced under typical commercial conditions, there appears to be little danger of serious nematode loss through contamination in the forcing period; this observation does not apply to propagation stocks. Blooms, buds, and foliage exhibited no injury from the treatment.

**Failure of bud and graft unions of rose induced by *Chalaropsis thielavioides***, K. F. BAKER and H. EARL THOMAS. (Univ. Calif.). (*Phytopathology*, 36 (1946), No. 4, pp. 281-291, illus. 2). — The black mold *C. thielavioides* caused bud unions in three central California rose fields (1940) and grafts in one greenhouse (1945) to fail; this trouble has not been found in southern California where roses are largely grown on immune ragged-robin rootstocks. Infected buds and cut surfaces of scion or stock become blackened and union is prevented. *Rosa odorata* and *R. chinensis manetti* understocks proved very susceptible, *R. multiflora* moderately so, and ragged-robin and *R. laza* immune. The immunity factor of ragged-robin is restricted to living cells and can be decreased by moderate heat treatments. The rose form of the fungus was found pathogenic to numerous other roses and woody plants, but the lupine, walnut, and Chinese elm forms proved nonpathogenic to roses. The fungus is disseminated by infected plant parts, irrigation water, splashing water drops, soil, and workmen; it survives nearly a year in soil or buried plant parts. A bait method for determining the presence of the fungus is described. Infection occurs only through wounds, and the fungus is aggressive only on dormant plant parts. Graft failures could best be avoided by use of budded roses, fungus-free rootstocks, sanitation, and chemical treatment of stems before grafting. Bud failures can be prevented by immediate planting of the cuttings or storing them at 0° C., rotation with immune crops, use of immune rootstocks, high budding into canes later made into cuttings, and by precaution against transfer of infection by workmen. Preventive chemical treatments of cut surfaces proved unsuccessful because of host injury.

**"Root nodules" on zinnia produced by nematodes**, K. L. JONES (*Mich. Acad. Sci., Arts, and Letters, Papers*, 30 (1944), pp. 67-70, illus. 2). — Healthy appearing zinnia plants from one garden were found to possess root galls apparently induced

by nematodes; their tunnels and the cells lining them were practically filled with one saprophytic bacterium—the slime-producing *Alcaligenes radiobacter*.

**Fusiform rust, a threat to slash pine plantations**, P. V. SIGGLER (*Miss. Farm Res. [Mississippi Sta.]*, 9 (1946), No. 1, pp. 1, 7, illus. 1).—Though slash pine is relatively free from needle disease and insect pests, *Cronartium fusiforme* infection is said to damage these and associated species seriously. Loblolly and slash pines are highly susceptible, whereas longleaf pine is more resistant; the rust has never been found on shortleaf pine in Mississippi. Species of oak likewise differ, water, willow, and laurel oaks being highly susceptible; others listed in the descending order of susceptibility are blackjack, bluejack, southern red, turkey, and live oaks. As a group, the white oaks may be disregarded as carriers, infection on them being very slight; the oaks usually suffer but little damage from this rust. Preventive measures are summarized. In general, the greater the number of cankered trees in natural stands, the higher will be the risk in establishing slash plantations. Practices hastening the growth of slash pine increase the susceptibility. Since direct measures of control are usually impractical, more reliance could well be placed on longleaf and shortleaf pines. Provided intensive measures are possible, early pruning of branch cankers will aid in reducing the spread.

## ECONOMIC ZOOLOGY—ENTOMOLOGY

**An ecological reconnaissance in the Medicine Bow Mountains**, I. H. BLAKE (*Univ. Nebr.*). (*Ecol. Monog.*, 15 (1945), No. 3, pp. 207–242, illus. 6).—This paper is offered as an introduction to some of the animal communities of these mountains of southern Wyoming; it is presented in the hope that it will prove a useful tool for those carrying on more detailed studies of the animal communities of the area, as well as of those found in ecologically similar localities of the Rock Mountain region in general. There are 33 references.

**The annual cycle of plants, mosquitoes, birds, and mammals in two Brazilian forests**, D. E. DAVIS (*Ecol. Monog.*, 15 (1945), No. 3, pp. 243–295, illus. 24).—In many parts of South America yellow fever is contracted in the forests of the jungles; the jungle form of the virus is presumably transmitted to the vertebrate hosts by forest-inhabiting arthropods, human infection appearing to be adventitious and seeming to play no essential role in the life history of the virus. The investigations here described in detail comprise part of a program undertaken to learn more about the lives of forest animals, with a view to finding out what species may fit the role of hosts and vectors of the jungle yellow fever virus.

**La protection des cultures sauve des millions [Crop protection saves millions]** (*Zurich: Off. Suisse Propagande pour les Produits de l'Agr. Suisse*, 1944, pp. 112, over 200 illus.).—A handbook of diseases and pests of cultivated plants and their control, including useful animals and insects. There are six colored plates.

**Mammals from Welaka, Putnam County, Florida**, J. C. MOORE (*Jour. Mammal.*, 27 (1946), No. 1, pp. 49–59, illus. 1).—The information presented was acquired as a result of field work on the University of Florida Conservation Reserve at Welaka. A description of the area (with map) precedes the accounts of the species. There are 18 references.

**An ecological study of the bighorn sheep in Rocky Mountain National Park, Colorado**, F. M. PACKARD (*Jour. Mammal.*, 27 (1946), No. 1, pp. 3–28, illus. 2).—The objectives of this study were to determine the approximate number of bighorn sheep in the park, with their distribution and ranges; to obtain information on the history of the species in this area as an aid in evaluating the seriousness of the evident decline and the factors back of it; to investigate possible methods of counteracting or removing the causes; and to reach some conclusions on the probable future of

the species in the park. The advent of white settlers caused the initial decline, due to hunting, restrictions of the lower winter range, and the introduction of scabies. Adequate protection after 1909 resulted in a recrudescence. A second decline became evident in 1921 and has continued to the present; this was traced tentatively to an apparent deficiency of mineral salts in the granitic soils of the current ranges which may be accompanied by protein deficiencies as well. The effect appears to be a reduction in stamina, with an increased susceptibility to various parasites. The lack of yearlings suggests that mortality of the lambs is high. Placing mineralized salt blocks on the range is recommended. It is believed doubtful whether predators or competition by elk have been of any real significance in the decline. Two years' observations indicated that about 300 individuals occupied the park area during 1939-40; the sex ratio was about 2 ewes to 1 ram.

**Rodent activity in a mixed prairie near Hays, Kansas, H. L. BROWN.** (U. S. D. A.). (*Kans. Acad. Sci. Trans.*, 48 (1946), No. 4, pp. 448-456).—The white-footed mouse was found to utilize 24 species of plants, but feeding tests indicated that—when available—88 percent of its diet consisted of insects, with grasshoppers preferred. The harvest mouse secured food from 11 plant species; in feeding tests, about 63 percent of its diet was insects when available. The wood rat and pocket mouse occurred on the rocky hills; the spermophile preferred the short grass—or other types where the vegetation was closely grazed. The meadow mouse was found occasionally on areas dominated by midgrasses, especially wheatgrass; it was more common before the 1933-39 drought. The present estimate is about 3,232 white-footed mice and 1,766 harvest mice per square mile; baited traps increased the catches of the latter but not of the former. Gravid ♀♀ of the white-footed mouse were caught each month of the study during September-March. Seeds of smooth sumac and ill-scented sumac were taken from fecal pellets of the wood rat; many were viable, and in some cases germination was increased by animal passage. The spermophile and white-footed mouse disseminated seeds of cactus and buffalo grass by storing them in caches. Burning the grass on the natural revegetation area increased the catches of the white-footed mouse, but no harvest mice were caught after burning; examination showed that the mice had not been burned, but had migrated in or out of the area. The findings revealed that the white-footed and harvest mice are beneficial to the farmer in this region, since much of their diet is of destructive insects that feed on native and cultivated plants. Animal populations vary from year to year, depending on the ecological factors which benefit or deplete the vegetation supporting them.

**Techniques for the study of the Norway rat (*Rattus norvegicus*), D. CHITTY and M. SILORTEN** (*Jour. Mammal.*, 27 (1946), No. 1, pp. 63-78, illus. 10).—Surplus baiting with wheat has been used to census wild rat populations, especially before and after tests with poisons; for a proper interpretation of the data and also of the factors involved in poisoning, the feeding behavior of the rats must be understood. Automatic half-hourly records of wheat consumption have shown the predominantly nocturnal habit of well-fed rats—even in a quiet environment. Where food is inadequate, rats can often be conditioned to feed rapidly on token baits at any time of day, though occasionally this response is shown only at night. It is possible to watch the feeding habits, the behavior toward changes in environment or food, and other actions. There is sometimes a lengthy adjustment to certain kinds of change, but baited rats get used to artificial light and can then be watched at night. For short-term studies, individual rats can be marked by making numbers with a depilatory in their fur; then both the total population and the average individual consumption of bait can be determined. Though most rats in a colony become well baited, others show peculiarities such as indifference to bait or long absence after a single mouthful; this accounts for the survival of certain rats after poisoning.

**Some helminth parasites of skunks in Texas**, J. D. TINER. (Mich. State Col.). (*Jour. Mammal.*, 27 (1946), No. 1, pp. 82-83).—Six kinds of parasites are said to have been recovered from stomachs and intestines of about 170 skunks of 3 genera collected in Texas. So far as known, *Molineus* sp. has not previously been reported from these hosts; *Lilaria martis* is reported for the first time from *Concypus mesoleucus* and *Melephitis mephitis*; *Physaloptera maxillaris* has not been reported previously in *Spilogale leucoparia*.

**The blackbird: A contribution to the study of a single avian species**, A. F. C. HILLSTAD (London: Faber & Faber, 1945, pp. 101, illus. 19).—This general contribution on the blackbird (*Turus merula merula*) considers such matters as its song, territory, behavior, nesting, food, migration, and plumage.

**Preliminary list of spiders of the Great Swamp**, J. L. C. and W. F. RAPP, JR. (*Bul. Brooklyn Ent. Soc.*, 41 (1946), No. 1, pp. 4-5).—An annotated list of spiders taken by sweeping in the terrestrial grasslands on the southern face of the Wisconsin Terminal Moraine forming the northern boundary of the Great Swamp, Morris County, N. J.

**Grasshoppers ovipositing in a pile of coal**, H. C. SEVERIN (*Bul. Brooklyn Ent. Soc.*, 40 (1945), No. 5, pp. 159-160).

**The Cercopidae or spittlebugs of Missouri**, R. C. PROECHNER (*Jour. Kans. Ent. Soc.*, 19 (1946), No. 1, pp. 30-35, illus. 4).—In addition to brief notes, the author presents keys to the Missouri subfamilies, genera, and species of the family Cercopidae.

**The Mexican species of Idiodonus (Homoptera: Cicadellidae)**, D. M. DELONG. (Ohio State Univ.). (*Ohio Jour. Sci.*, 46 (1946), No. 1, pp. 13-30, illus. 3).—Some 35 species of this leafhopper genus are considered in this taxonomic study; 30 are described as new. A key for separating species or groups by color patterns is provided.

**Erythroneura of the obliqua group from Ohio and Tennessee (Homoptera: Cicadellidae)**, D. J. KNULL. (Ohio State Univ. et al.). (*Ohio Jour. Sci.*, 46 (1946), No. 1, pp. 45-49, illus. 11).—Five new species of the leafhopper genus *Erythroneura* are described, with new records for Ohio, corrections, and synonymy included.

**The photography of types of Lepidoptera**, C. F. DOS PASSOS (*Bul. Brooklyn Ent. Soc.*, 40 (1945), No. 5, pp. 166-169, illus. 4).—The importance of photographing type specimens of Lepidoptera with the labels attached is considered by the author to be self-evident. The apparatus here described and illustrated is believed to obviate the difficulties of previous methods.

**Synopsis of the cerambycid beetles of the genus Stenosphenus Haldeman found in America, north of Mexico**, W. S. FISHER. (U. S. D. A.). (*Jour. Wash. Acad. Sci.*, 36 (1946), No. 3, pp. 86-94).—A key to the species is included.

**Competition between two entomogenous bacteria**, R. L. BEARD. (Conn. [New Haven] Expt. Sta.). (*Science*, 103 (1946), No. 2673, pp. 371-372).—A note on the possible antibiotic activity between *Bacillus popilliae* and *B. lentimorbus*, causes of two types of milky disease of Japanese beetles. Both types of parasitism do not occur in the same host individual. If a mixture of the two is used as inoculum only one form of the disease develops, the relative dosage largely determining which is successful.

**Myrmecological technique.—I, The use of ether in collecting ants**, C. H. KENNEDY. (Ohio State Univ.). (*Ohio Jour. Sci.*, 46 (1946), No. 1, pp. 10-12).

**Ant hosts of the fungus Laboulbenia formicarum Thaxter**, M. R. SMITH. (U. S. D. A.). (*Ent. Soc. Wash. Proc.*, 48 (1946), No. 2, pp. 29-31).—The parasitic ant fungus *L. formicarum* has been previously recorded in the United States from only a few forms of ants of the genera *Lasius* and *Formica*. Its discovery on eight new hosts—and especially on two more genera—seemed worthy of record; all the

ants known to be affected by this fungus are added to this list, along with pertinent comments. Contributions on the morphology, taxonomy, and biology of the fungus are given in the bibliography (10 references).

**Notes on the behavior of a few solitary wasps**, P. RAU (*Bul. Brooklyn Ent. Soc.*, 41 (1946), No. 1, pp. 10-11).—Miscellaneous field observations are presented.

**On the penetration of insecticides through the insect cuticle**, J. E. WEBB and R. A. GREEN (*Jour. Expt. Biol.*, 22 (1945), No. 1-2, pp. 8-20, illus. 2).—With the sheep tick as the test insect, the authors found that certain organic solvents (e. g., cresols, benzyl alcohol, 4-methyl-cyclohexanol) greatly increased the rate of action of diphenylamine; others (e. g., carbitol, methyl benzoate) gave little or no improvement in killing time. The degree to which a solvent induces rapid penetration of an insecticide is referred to as its "carrier efficiency." A high carrier efficiency was found to be correlated with a high rate of penetration through beeswax, a high partition coefficient of the solvent between beeswax and water, and a high solubility of insecticide in a water solution of the solvent; the volatility of the solvent and the solubility of the insecticide were also contributory factors. Mixtures of two solvents, each exhibiting no carrier efficiency but together possessing all the essential physical properties, revealed a carrier efficiency considerably higher than either alone; this is taken as supporting evidence that carrier efficiency depends on certain physical properties of the solvent. With a range of solvents having various degrees of carrier efficiency, comparable results were obtained in the use of dioxanthogen,  $\omega$ -nitrostyrene dibromide, and rotenone, showing that the synergy could be extended to other insecticides. It is suggested that certain solvents increase the rate of penetration of contact insecticides through the insect cuticle by (1) transporting the insecticide through the lipid elements of the epicuticle to the interface between it and the water permeating the exocuticle, (2) concentrating the insecticide at the interface between epicuticle and exocuticle and thus increasing the diffusion gradient of the insecticide across that interface, and (3) increasing the solubility of the insecticide in the water permeating exo- and endocuticles and thus further increasing its rate of diffusion, not only across this interface but also through exo- and endocuticles to the hypodermis.

**Review of United States patents relating to pest control [January-December 1945]**, R. C. ROARK (*U. S. Dept. Agr., Bur. Ent. and Plant Quar., Rev. U. S. Pat. Relat. Pest Control*, 18 (1945), Nos. 1, pp. 6; 2, pp. 6; 3, pp. 4; 4, pp. 1; 5, pp. 7; 6, pp. 3; 7, pp. 3; 8, pp. 6; 9, pp. 5; 10, pp. 4; 11, pp. 4; 12, pp. 5).—A continuation of this series (*E. S. R.*, 93, p. 600).

**Quarterly bibliography of insecticide materials of vegetable origin, No. 32 (July to September 1945)**, R. M. JOHNSON (*Bul. Imp. Inst. [London]*, 43 (1945), No. 4, pp. 287-292).—A continuation of this bibliography (*E. S. R.*, 94, p. 638).

**German insecticide evaluation**, L. B. KILGORE (*Soap and Sanit. Chem.*, 22 (1946), No. 3, pp. 122-125, 173, illus. 3).—The preceding papers (*E. S. R.*, 95, p. 80) on synthetic insecticides in Germany indicated the nature and scope of the activity of the German chemists in this field over the years immediately prior to and during World War II; the present paper is concerned primarily with the methods they employed to evaluate the toxicity of their various chemicals toward insects and warm-blooded animals. These methods involved the testing of contact and oral poisons and of repellents and the pharmacological testing of insecticides.

**Evaluating pyrethrum extract: A comparison of chemical and biological methods of evaluating concentrated extracts**, W. F. BARTHEL, W. A. GERSDORFF, F. B. LAForge, and J. J. T. GRAHAM. (*U. S. D. A.*). (*Soap and Sanit. Chem.*, 22 (1946), No. 3, pp. 129, 131).—Chemical analysis of a sample of purified pyrethrum extract prepared by the nitromethane-charcoal process showed that the Seil method gives consistently lower results than either the Association of Official Agricultural

Chemists or the hydrogenation methods. Biological comparisons against houseflies of sprays prepared according to the A. O. A. C. evaluation indicated that the pyrethrum preparation underwent the purification process without loss of insecticidal activity and retained its full activity for 10 mo. when kept at 2° C.

**Preliminary experiments with benzene hexachloride (666) as an insecticide,** G. G. DUSTAN, T. ARMSTRONG, and W. L. PUTMAN (*Sci. Agr.*, 26 (1946), No. 3, pp. 106-121).—This paper presents the results of exploratory tests with small samples of 666 received during 1944-45 on the codling moth, oriental fruit moth, diamond-back moth, greenhouse leaf tier, strawberry leaf roller, asparagus beetle, spotted asparagus beetle, striped cucumber beetle, rose chafer, pear psylla, green chrysanthemum aphid (*Rhopalosiphum rufomaculatum* (Wilson)), squash bug, large milkweed bug, chrysanthemum thrips, European red mite, and common red spider mite (*Tetranychus telarius* (Linn.)).

**D. D. T. as an agricultural insecticide,** C. F. H. JENKINS (*Jour. Dept. Agr. West. Austral.*, 2. ser., 22 (1945), No. 3, pp. 229-232).—In the experiments described and tabulated, DDT did not kill all important plant insects, and many mites proved particularly resistant. It was very effective against caterpillars. Cabbage and cauliflower treated periodically with 1 percent DDT dust were practically free of all signs of chewing injury; tomato plants treated from seedling to maturity showed a marked reduction in number of "wormy" fruits, and green tomato bug infestation was greatly reduced. Other pests against which DDT was very satisfactory were the potato tuber worm, *Agrotis radians*, *Otiorrhynchus cribricollis*, and *Empoasca terra-reginae*. The indications were that leaf-eating orchard pests can be controlled with 0.1 percent DDT sprays, but tests against scale insects and aphids were inconclusive, and *Bryobia* mite appeared to be unaffected. Though toxic to many useful insects such as ladybirds, wasps, and bees, its use with discretion should minimize its bad effects and exploit its beneficial properties.

**Compatibility of DDT with insecticides, fungicides, and fertilizers,** E. E. FLECK and H. L. HALLER. (U. S. D. A.). (*Indus. and Engin. Chem.*, 37 (1945), No. 4, pp. 403-405).—Some of the more common insecticides, fungicides, and fertilizers were tested for catalytic action in the dehydrochlorination of DDT. Materials used for diluents were shown to vary in their activity as catalysts for the decomposition of DDT. The anhydrous chlorides of iron, aluminum, and chromium were active dehydrochlorination catalysts for DDT. The catalytic action of anhydrous ferric chloride was found to be promoted by solution in naphthalene, chloronaphthalene, chlorobenzene, *o*- and *p*-dichlorobenzenes, and nitrobenzene, and inhibited by various hydrocarbon and fatty oils, alcohols, ketones, acids, and anhydrides.

**Influence of DDT on yeast fermentation,** M. I. TIMONIN (*Sci. Agr.*, 26 (1946), No. 3, pp. 122-129).—Media containing 5 to 20 mg. percent actual DDT gave a 1.96 percent reduction in total alcohol yield when that in control media was taken as 100; with less than 5 mg. percent DDT no reduction occurred. Alcohol production per gram of sugar consumed was not affected by adding to the medium up to 5 mg. percent of actual DDT; adding more than 5 and up to 21 mg. percent gave a 1.78 percent reduction when the yield in control media was expressed as 100. The intensity of fermentation in DDT-treated media was retarded during the first 5 days of incubation; this delay was largely compensated for later. Similar results, in general, have been obtained when grapes sprayed with DDT for control of insects were used in alcohol production. According to chemical analyses, no DDT was detected in the fermented grape juice obtained from DDT-sprayed grapes.

**The excretion of DDT (2,2-bis-(*p*-chlorophenyl)-1,1,1-trichloroethane) in man, together with clinical observations,** P. A. NEAL, T. R. SWEENEY, S. S. SPICER, and W. F. VON OETTINGEN (*Pub. Health Rpts.* [U. S.], 61 (1946), No. 12, pp. 403-409, illus. 4).—The experiment described reveals that ingestion of 11 mg. per 1 kg. of body

weight of DDT dissolved in olive oil—corresponding to a total dose of 770 mg.—failed to cause detectable toxic effects in one normal individual. It was further shown that—as in rabbits—part of the DDT ingested was metabolized to di-(p-chlorophenyl)-acetic acid (DDA) and excreted with the urine. Under the test conditions, the maximum excretion of this metabolite occurred on the second day, decreasing rapidly on the third and fourth days, and diminishing gradually over the following 10 days.

**The removal of DDT from water supplies**, J. A. CAROLLO (*Jour. Amer. Water Works Assoc.*, 37 (1945), No. 12, pp. 1310-1317).—DDT applied to any water gradually loses its ability to kill the yellow-fever mosquito; 0.0015 p. p. m. became ineffective in 48 hr. and 0.1 p. p. m. in 10 to 12 days. Turbidity in the water had little effect on the 48-hr. kill of mosquito larvae by DDT, but on settling out removed some of the DDT held in suspension. The normal concentrations of DDT used in mosquito larvicide work did not induce toxic effects in warm-blooded animals drinking water so treated. Any of the conventional water treatment processes involving coagulation, sedimentation, and filtration removed 80 to 98 percent of DDT in a water supply originally containing 0.1 to 10 p. p. m. Complete removal (to less than 0.001 p. p. m.) of DDT from a water supply is said to be possible if intimate contact with activated carbon is provided for 15 min. after coagulation and sedimentation, but before filtration.

**Alfalfa seed production in northern Saskatchewan as affected by lygus bugs, with a report on their control by burning**, J. L. BOLTON and O. PRICK (*Sci. Agr.*, 26 (1946), No. 3, pp. 130-137).—Populations of *Lygus* spp. have seriously affected the yields of alfalfa during certain years in this region. Fields producing the first seed crop tended to have lighter infestations than those grown later. A significant positive correlation was obtained between the number of these bugs in a field and the percentage of brown and shriveled seed taken before frost damage had occurred; this seed had a very low viability. The reduction in lygus populations found after burning of the stubble in early spring is believed to be due to the destruction of hibernated adults, of their food and shelter, and of their eggs on the new alfalfa growth; early spring burning is therefore offered as a practical control measure. Late spring burning is to be avoided, however, since it may seriously delay maturity of the crop.

**Relation of temperature to the expression of resistance in wheats to hessian fly**, W. B. CARRWRIGHT, R. M. CALDWELL, and L. E. COMPTON. (U. S. D. A. coop. Ind. Expt. Sta.). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 3, pp. 259-263).—The proportion of plants attacked and the intensity of infestation by the hessian fly were studied in seedlings of four resistant and two susceptible greenhouse grown wheat varieties at ranges of 60° to 65° and 75° to 80° F. At the higher temperatures the percentages and intensities of infestation were significantly greater on the resistant spring wheat W38 and its resistant winter-type progeny B36162A13-12. The temperature effects were similar with the susceptible varieties B42 (spring type) and Wabash (winter type), but in each case the relative magnitude of the effect was much smaller than for the resistant varieties. It was impossible to determine from this work whether the effects of temperature on infestation were due to the response of the host alone or to a combined response of both host and insect. The near immunity of the durum P. I. 94587 was not reduced at the higher temperature; on the other hand, the resistance of a common wheat (42-chromosome) derivative of this durum was greatly affected by temperature. The immutability of the resistance of the durum P. I. 94587 at different temperatures is believed to indicate a fundamentally different resistance in that strain, as contrasted with the resistance of the common wheat varieties studied.

**A new species of Keiferia on eggplant (Lepidoptera: Gelechiidae)**, C. HILLENRICH. (U. S. D. A.). (*Ent. Soc. Wash. Proc.*, 48 (1946), No. 2, pp. 35-36, illus. 4).—

*K. peniculo* n. sp. is described, since it may have some importance as an enemy of eggplant; it was collected and reared from larvae on this host near a port of entry.

**Soil nitrogen and thrips injury to spinach**, S. H. WITTWER and L. HASEMAN. (Univ. Mo.). (*Science*, 103 (1946), No. 2672, pp. 331-332).—A note on the striking relationship shown between the amount of soil N provided for spinach plants and their resistance to attack by greenhouse thrips; as long as the plants made a luxuriant growth as a result of adequate N, they were practically immune to insect attack. Several points of interest in the interpretation of the findings are offered.

**Apple blossom weevil and DDT**, G. L. HEY (*Agriculture, Jour. Min. Agr. [Gi. Brit.]*, 52 (1946), No. 12, pp. 554-557).—Promising results are reported (1945) for one treatment with a spray containing 0.5 lb. DDT per 100 gal. applied at the breaking to bursting stages of the buds. A side issue was the excellent control of the apple capsid *Plesiocoris rugicollis* in two cases where DDT was applied at the breaking stage and again later.

**Premiers essais de purification de la substance qui attire le doryphore vers les feuilles de pomme de terre** [First attempts to purify the substance which attracts the Colorado potato beetle to potato leaves], R. CHAUVIN (*Compt. Rend. Acad. Sci. [Paris]*, 221 (1945), No. 23, pp. 713-714).—The attractant substance isolated and briefly described in this preliminary report is said to act like a glucoside—perhaps related to the flavones.

**L'Attaque des tubercules de pommes de terre par les larves de doryphore** [Potato tubers attacked by larvae of the Colorado potato beetle], M. DURCHON (*Compt. Rend. Acad. Sci. [Paris]*, 222 (1946), No. 4, p. 240).—A brief note.

**Thigmotactisme et localisation sensorielle du contact dans l'enfouissement du doryphore adulte** (*Leptinotarsa decemlineata* Say) [Thigmotaxis and sensory localization of contact in the burrowing of the Colorado potato beetle], P. GRISON (*Compt. Rend. Acad. Sci. [Paris]*, 222 (1946), No. 5, pp. 306-308).

**Plum curculio control**, A. M. WOODSIDE. (Va. Expt. Sta.). (*Va. Fruit*, 34 (1946), No. 3, pp. 18-19).—Recommended control measures are outlined. The dates of capture of the first curculio adults by jarring trees—with stages of tree growth at Crozet, Va.—are tabulated for each of 11 yr.

**The use of DDT makes mite control necessary**, A. M. WOODSIDE. (Va. Expt. Sta.). (*Va. Fruit*, 34 (1946), No. 3, pp. 14, 16, 18).—The development of mite infestations in the three instances reported illustrates the fact that these pests may become serious on apple trees where DDT is used unless material for their control is added. It has been found that mites can be kept under control by use of DN-111 or xanthone in alternate sprays.

**DDT use in Tulare County**, A. M. BOYCE and W. H. EWART. (Calif. Citrus Expt. Sta. et al.). (*Citrus Leaves*, 26 (1946), No. 3, p. 7).—Extensive experimental treatments have shown DDT to be effective against citrus thrips and citricola scale in central California, but much more information is needed as to its safety, proper formulations, dosages, and timing as well as on possible injuries to beneficial insects. Use of DDT in citrus orchards should thus still be considered experimental; certain suggestions for such use on the basis of present knowledge are given.

**Biological control of prickly pear**, F. W. PETTEY (*Farming in So. Africa*, 21 (1946), No. 238, pp. 31-33).—A brief progress report on the mass production and liberation of *Cactoblastis cactorum*, of the cochineal insect *Dactylopius opuntiae*, and of the boring beetle *Lagocheirus funestus*, on what these insects have accomplished, and on investigations of the factors hampering their progress in the veld.

**Factors affecting recovery from diapause and hatching of eggs of the forest tent caterpillar**, *Malacosoma disstria* Hbn., A. C. HODSON and C. J. WEINMAN (*Minnesota Sta. Tech. Bul.* 170 (1945), pp. 31, illus. 6).—According to studies on the influence of temperature on the termination of an embryonic diapause of the forest

tent caterpillar, diapause lasted for about 3 mo. after embryonic development was completed. Hatching response after exposures to temperatures ranging from 25° to -5° C. indicated diapause could be broken only after conditioning at below 20° to 25° for a sufficient length of time, and that optimum conditions prevailed near freezing. Histological studies of embryos treated similarly showed the fore- and mid-gut were packed with yolk during diapause, and that nearly complete absorption of the yolk was necessary before hatching took place. Histological changes associated with yolk absorption were compared with hatching data and it became evident that temperature had little influence on diapause, but temperature influenced the course of development after the diapause was broken. Differential hatching after exposure to both high and low temperatures was thought to have been caused by some injury from high temperatures or desiccation, or by a beneficial effect of low temperature during a critical period. Through a range of favorable temperatures the optimum moisture conditions were between relative humidities of 70 and 100 percent. The secretion which covered the eggs' "spumaline" is hygroscopic, absorbs considerable moisture from atmospheres of high relative humidities, and prevents rapid desiccation of eggs in dry air. In soaking experiments temperatures at which eggs were soaked were more important than length of submergence. Parasites were less affected by soaking than embryos. Embryos and parasites were able to adjust themselves to a reduced oxygen supply or to an accumulation of CO<sub>2</sub>.

Eggs of the forest tent caterpillar are not very resistant to drying, and the hatching percentage was reduced considerably after 8 days drying over calcium chloride at 23° to 26° C. None hatched after 32 days of desiccation. On the other hand, egg parasites were quite resistant to desiccation.

**Budworm control in jack pine by forest management**, A. C. HODSON and P. J. ZEHNGRAFF. (Minn. Expt. Sta.). (*Jour. Forestry*, 44 (1946), No. 3, pp. 198-200).—Conclusive evidence is presented that outbreaks of the jack pine budworm (considered a distinct subspecies of *Archips fumiferana* (Clem.) if not a separate species) are closely correlated with an abundance of staminate flowers. New data are presented on the relation between classes of trees and staminate flower production in the light of which prompt removal of trees of poor or declining vigor is recommended. When it is considered that the suppressed and other trees of poor vigor bear the bulk of staminate flowers, that these are an essential part of the budworm diet, and that a small population of budworms is always present in trees producing staminate flowers, the benefit from removal of such trees seems obvious. The increase in yields attributed to thinnings is derived not only from accelerated increment on the residual stand, but also from the salvage of those trees which would not survive to the next cutting. Such trees should never be regarded as future crop trees in any commercial or noncommercial thinning.

**Erechthias fulguritella** Walk. (Lepidoptera) inhabiting pine cones, E. S. GOURLAY (*New Zeal. Jour. Sci. and Technol.*, 27 (1945), No. 3, Sect. B, pp. 248-250, illus. 2).—This native moth of New Zealand is recorded as associated with cones of *Pinus radiata*; its larvae invariably destroy the seed in infested cones but at present are said to have a negligible effect on seed production.

**The influence of temperature, humidity, and density on the oviposition of the small strain of *Calandra oryzae* L. and *Rhizopertha dominica* Fab. (Coleoptera)**, L. C. BIRCH (*Austral. Jour. Expt. Biol. and Med. Sci.*, 23 (1945), No. 3, pp. 197-203, illus. 2).—The oviposition rate and total number of eggs laid by the rice weevil (small strain) and lesser grain borer were determined at different temperatures and densities and in grain differing in moisture content. An interaction between temperature, density, and time was found in their effects on the oviposition rate of the rice weevil; the proportional effect of density differed with temperature and age of insect, and the effect of different temperatures also varied with age of insect. The maximum

oviposition rate of this weevil was attained at the age of 1 to 2 weeks, depending on temperature; the average length of life of the ♀ was 3 mo. and of the ♂ 2 mo. At a density of 1 insect per 10 grains, the oviposition rates of the rice weevil at 25.5° and 29.1° C. were significantly greater than that at 23°, but did not differ significantly from each other over most of the insect's life; a higher maximum rate and total was reached at 29.1°. At a density of 1 in 50, a higher rate was reached over most of the insect's life at 25.5° and the total was greatest at this temperature. The main effect of reduced density of insects per grain was to increase the oviposition rate after the first 8 weeks; the effect was greatest at 25.5°, when the largest number of eggs was also laid (384). The oviposition rate and total eggs laid were less at 32° than at 29.1°; at 35° only 5 eggs per ♀ were laid; at 15.2° only 1 egg per week was laid, and at 13°, none. The lowest moisture content of wheat at which eggs were laid by the rice weevil was 10 percent; none was laid at 9.5°. Fewer eggs were laid at 12 percent than at 14; the number differed but little between 11 and 12 percent moisture content. Eggs of the lesser grain borer were not laid at temperatures higher than 39°; the rate at 18.3° was slow—only 38 eggs in 4 mo. The maximum number of eggs (415) was laid at 34° in grain of 14 percent moisture content. The rate did not fall off markedly in dry wheat until the moisture content was below 9 percent; 8 percent was the driest wheat in which eggs were laid.

**The site of action of DDT in the cockroach,** K. D. ROEDER and E. A. WEIANT (*Science*, 103 (1946), No. 2671, pp. 304-306).—The authors conclude from experimental evidence that although DDT undoubtedly affects motor nerves and muscle fibers at concentrations greater than 1,000  $\mu$ . p. m., this action cannot be directly responsible for the clonic tremors in DDT-poisoned cockroaches which can be produced by internal concentrations of the order of 5 p. p. m.; DDT has no significant action on the cockroach central nervous system; its emulsion perfused through the leg of the cockroach in concentrations as low as 0.01 p. p. m. causes the appearance of a series of high frequency trains of axon spikes in the afferent fibers; and the tremors characteristic of DDT poisoning are due to an intense afferent bombardment of the motor neurons.

**Effect of temperature on knock-down and kill of mosquitoes and bedbugs exposed to DDT,** A. W. LINDQUIST, A. H. MADDEN, and H. O. SCHROEDER. (U. S. D. A.). (*Jour. Kans. Ent. Soc.*, 19 (1946), No. 1, pp. 13-15).—Following the experiments on houseflies (E. S. R., 93, p. 748), additional tests were carried out on the common malaria and southern house mosquitoes and on two species of bedbugs; the results are reported briefly.

**Two new species of *Aedes* (Finlaya) from New Guinea (Diptera: Culicidae),** W. V. KING and H. HOOGSTRAAL (*Ent. Soc. N'ash. Proc.*, 48 (1946), No. 2, pp. 37-38).

**Experiments upon the feeding of *Aedes aegypti* through animal membranes with a view to applying this method to the chemotherapy of malaria,** A. BISHOP and B. M. GILCHRIST (*Parasitology*, 37 (1946), No. 1-2, pp. 85-100, illus. 2).—In these experiments with the yellow-fever mosquito, *Plasmodium gallinaceum* was used as the malaria organism. Under suitable conditions the proportion of ♀♀ which gorge through membranes—though more variable than when a living chick was offered—proved great enough for experimental purposes. The gorging reaction was provoked by a heat gradient between environment and food-limiting membrane. Whole blood and red cells in saline, when ingested through membranes, went directly to the stomach which became fully distended; hemoglobin in plasma or distilled water was ingested to a lesser degree than whole blood or red cells in saline, and plasma alone was rarely ingested, but all these passed to the stomach; sweet solutions containing glucose or honey were seldom imbibed through membranes and passed to the stomach or diverticula, but only the latter were fully

distended. Offered as open drops, blood was seldom ingested but when taken in went to the stomach; hemoglobin in plasma or water, or plasma alone, were rarely ingested, but passed mainly to the stomach; sweet solutions (honey or glucose) or mixtures of blood and honey were readily ingested and passed mainly to the diverticula, which became fully distended, though traces might be found in the stomach. The yellow-fever mosquito may be infected satisfactorily with *P. galinaceum* by allowing engorgement on drawn infected chicken blood through a membrane. When infected mosquitoes were allowed to gorge on uninfected blood through membranes they ejected viable sporozoites into the blood. When young chicks were intravenously infected with this blood, infections were produced which in incubation period and intensity were comparable to those resulting from the direct bites of infected mosquitoes. The ejection of sporozoites through membranes in this manner provides a ready means of obtaining sporozoites free from glandular tissue. Those collected by this method should prove suitable for in vitro experiments on the action of drugs and also as a source of material for tissue-culture studies of the developmental stages of the malaria parasite arising directly from the sporozoite. There are 25 references.

**Studies on imported malarias.—II, Ability of California anophelines to transmit malarias of foreign origin and other considerations,** J. A. MOORE, M. D. YOUNG, N. H. HARDMAN, and T. H. STUBBS (*Jour. Natl. Malaria Soc.*, 4 (1945), No. 4, pp. 307–329).—It is believed justifiable to conclude from the detailed continuation of experimental results here reported (E. S. R., 93, p. 749) that control measures are necessary for the foreign malarias brought to the American west coast by relapsing carriers. In a comparison of the infectivity of foreign malarias to the California mosquitoes (*Anopheles maculipennis freborni* Ait., *A. maculipennis occidentalis* D. & K., *A. punctipennis* (Say), and *A. pseudopunctipennis franciscanus* (McCrack.)), all appeared to have about the same susceptibility and all developed sporozoites. Transmission was tried and successful with the first three.

**Note on Bironella (Brugella) hollandi Taylor,** L. J. DUMBLETON (*New Zeal. Jour. Sci. and Technol.*, 27 (1945), No. 3, Sect. B, pp. 250–253, illus. 1).—The known distribution of this anopheline mosquito in the Solomon Islands is given, along with some information on its biology and a description of the egg.

**Description of Chagasia rozeboomi, an anopheline from Ceará, Brazil,** O. R. CAUSEY and L. M. and M. P. DEANE (*Jour. Natl. Malaria Soc.*, 4 (1945), No. 4, pp. 341–350, illus. 24).—This new anopheline mosquito from Brazil was first recorded from the eggs. The description and illustration of all stages of its life cycle and a table of differential characters for identification of the four known species of the genus are here presented.

**Studies on mosquitoes of the genus Haemagogus in Colombia (Diptera: Culicidae),** H. W. KUMM, E. OSORNO-MESA, and J. BOSHELL-MANRIQUE (*Amer. Jour. Hyg.*, 43 (1946), No. 1, pp. 13–28, illus. 7).—Eight species of *Haemagogus* were found in Colombia—seven in the lowlands and one in the highlands. The commonest and most widely distributed species is *H. spegazzinii falco* (illustrated in color), which has been incriminated as a vector of jungle yellow fever. Keys and diagrams are given for separating the larvae, adults, and ♂ terminalia of the genus as it occurs in Colombia.

**Phoniomyia hirsuta, a new sabethine from Jamaica (Diptera: Culicidae),** R. B. and C. M. HILL (*Ent. Soc. Wash. Proc.*, 48 (1946), No. 2, pp. 39–41, illus. 5).—The ♀, ♂, pupa, and larva of this new mosquito are described.

**An investigation on new repellents for the protection of man against mosquito attacks,** D. BLAGOVESCHENSKY, N. BREGETOVA and A. MONCHADSKY (*Roy. Soc. Trop. Med. and Hyg., Trans.*, 39 (1945), No. 2, pp. 147–150).—According to the authors, it has “been demonstrated that the d- $\alpha$ -pinene fraction of juniper oil is a

very effective repellent substance. It can be employed both in its pure form or as a substitute for turpentine."

**DDT against house flies:** The comparative toxicity to houseflies of *p,p'* DDT, *o,p'* DDT, and pyrethrum extract, W. A. GERSDORFF. (U. S. D. A.). (*Soap and Sanit. Chem.*, 22 (1946), No. 3, pp. 126-127, illus. 1).—The experimental data given show that, when estimated by comparison of the concentrations causing a 50-percent kill, *p,p'*-DDT was 53 times as toxic as *o,p'*-DDT. This ratio did not differ greatly throughout the course of toxic action, being 44 at the 10-percent mortality level and 60 at the 90-percent level. When these two compounds were compared with the pyrethrum extract, the variation of the ratio with change of mortality level was relatively greater, the ratio ranging from 1.7 to 4.4 for *p,p'*-DDT and from 0.038 to 0.073 for *o,p'*-DDT. The knock-down effect of *o,p'*-DDT in 25 min. was very similar to that of the *p,p'*-DDT, both of which were much less effective than the pyrethrum extract.

**The fleas of Puerto Rico (Las pulgas en Puerto Rico)**, J. MALDONADO CAPRILES (*Puerto Rico Jour. Pub. Health and Trop. Med.*, 21 (1945), No. 2, pp. 173-183, illus. 8; *Span. pp.* 184-192).—The main purpose of this paper is to aid workers in prompt and correct identification of the seven flea species thus far recorded in Puerto Rico; included also is the widely distributed rat flea, though it has not yet been reported on the island. A simple key with drawings showing the important taxonomic characters of the eight species is provided, and the relations of these fleas to disease and to the rat fauna of the island are briefly discussed.

**Notes on *Trombicula deliensis* Walch, 1923 (Acarina: Trombididae), with description of the adult**, C. D. RADFORD (*Parasitology*, 37 (1946), No. 1-2, pp. 42-45, illus. 9).—Notes on the life history and description of this mite, larvae of which were obtained from a number of small mammals and birds.

**The water balance in *Ixodes ricinus* L. and certain other species of ticks**, A. D. LEES (*Parasitology*, 37 (1946), No. 1-2, pp. 1-20, illus. 8).—Unfed ticks gain water from humid air or water in contact with the cuticle and lose water by evaporation. While attached to the host they gain water from ingested blood and lose it in their excrement; the engorged tick usually lacks the ability to take up water from humid air. Water exchange occurs mainly through the cuticle; regulation of the water balance is thus brought about by the activity of the epidermal cells. The cuticle comprises two principal layers—the endocuticle and the epicuticle; the latter is overlaid by a lipoid possessing important waterproofing properties. The pore canals—which traverse the endocuticle—are occupied by cytoplasm and may be important in the active transfer of water through the cuticle; they do not penetrate the epicuticle. Water loss from the unfed tick is not closely related to saturation deficiency, particularly at high humidity; this departure is due to the ability to secrete water. Such a state of equilibrium is attained at about 92 percent relative humidity; at lower humidities the tick loses water by evaporation, whereas at higher humidities it takes up water. Water retention at humidities below the point of equilibrium is due to both physical and secretory properties of the epicuticle; near this point, the loss or gain over a wide temperature range is determined by the relative humidity. Water uptake from humid air occurs when the tick is desiccated but ceases as the normal water content is restored. After previous exposure to saturated air the adapted tick at first loses water at relative humidities above the point of equilibrium, but later comes to retain water completely. Both unfed and engorged ticks can prevent or limit temporarily the entry of water in contact with the cuticle. The nine species examined differed considerably in their powers of limiting evaporation; this may reflect differences in the nature of the epicuticular lipoid. The order of their resistance was as follows: *Ornithodoros moubata*, *Dermacentor andersoni*, *D. reticulatus*, *Rhipicephalus sanguineus*, *Amblyomma cajennense*, *A. maculatum*,

*I. canisuga*, *I. hexagonus*, and *I. ricinus*. The more resistant species also take up water through the cuticle after desiccation; indeed, the rate over a unit area of cuticle was approximately the same in all species of Ixodidae. Uptake of water thus appears to be limited by the ability of the epidermal cells to secrete water. There are 29 references.

**The ecology of the sheep tick, *Ixodes ricinus* L.: Distribution of the tick on hill pasture.** A. MILNE (*Parasitology*, 37 (1946), No. 1-2, pp. 75-81, *illus.* 2).—Further details (E. S. R., 91, p. 574) are given of the distribution of the castor-bean tick on the pastures of a typical hill farm in England. Sheep paths and their borders had tick populations similar in density to those of the general pasture; the night resting places, significantly lower nymphal densities than the general pasture. With ♂♂ and ♀♀ the difference was in the same direction, but it was less marked. On the typical hill, the vegetation layer becomes thinner and the nymphal density decreases with altitude; the case was not quite so clear with adult ♂♂ and ♀♀. Provided the vegetation was suitable—i. e., sufficiently thick—altitude had no limiting effect on nymphal distribution density within the levels observed. Tick density distribution is thus a function of vegetation conditions, the latter being influenced by altitude. The distribution of ticks on apparently uniform areas of vegetation was studied, and the sampling methods are discussed. Probably no more than an average of 12 nymphs per square yard are present in heavily infested pasture. The numbers per 100 sq. yd. differed significantly; the approximate numbers per acre also differed significantly in rather more than half of the observed cases. Larger area units within uniform stretches of pasture probably carry similar numbers of ticks. The practical applications of the findings to tick control are indicated.

**The biology of *Ornithodoros delanoei acinus* Whittick, 1938.** G. G. ROBINSON (*Parasitology*, 37 (1946), No. 1-2, pp. 82-84).—The life history of this tick was studied under laboratory conditions at 30° C.; it is here presented and summarized in tabular form.

**Nairobi sheep disease: The survival of the virus in the tick *Rhipicephalus appendiculatus*.** E. A. LEWIS (*Parasitology*, 37 (1946), No. 1-2, pp. 55-59, *illus.* 6).—It is clear from the experiments described that the virus will survive in this tick up to at least 871 days. The period for which infested land may remain dangerous for susceptible sheep is therefore longer than the 18 months' freedom from sheep and goats formerly recommended by another worker. "Indeed, it appears that the virus of Nairobi sheep disease, once it is introduced into an area where *R. appendiculatus* exists, will persist so long as unfed infected ticks remain on the land."

***Rhipicephalus neavei* Warburton, 1912, as a vector of East Coast fever.** E. A. LEWIS, S. E. PIERCY and A. J. WILEY (*Parasitology*, 37 (1946), No. 1-2, pp. 60-64, *illus.* 4).—From the preliminary experimental studies reported, it is concluded that *R. neavei* probably can—under favorable conditions in the field—maintain and spread East Coast fever in cattle, either in the presence or absence of the usual vector, *R. appendiculatus*.

**Lipids in the central nervous system of the honey bee.** E. K. PATTERSON, M. E. DUMM, and A. G. RICHARDS, JR. (*Arch. Biochem.*, 7 (1945), No. 1, pp. 201-210).—“Lipids were extracted and analyzed from the head portion of the central nervous system of approximately 1,300 honeybees. Standard micromethods were used to determine sterols, glycerol, fatty acids, phosphorus, choline, sphingomyelina, and sugars. Nitrogen determinations were carried out on the residue. Values for neutral fat, total phospholipids, and proteins were calculated. No evidence was found for the presence of cerebrosides. The data are compared with data from various vertebrates. It is concluded that the lipids of the insect nervous system are, in general, roughly comparable to those from the brains of young vertebrates prior to the appearance of visible medullation.”

## ANIMAL PRODUCTION

**Digestibility of Kobe lespedeza hay** (*Dairy Res. Digest* [Louisiana Sta.], 4 (1946), No. 1, pp. 1, 4).—Studies of the comparative digestibility of Kobe lespedeza hay cut at different stages of maturity showed that it is more economical to cut hay early to insure higher percentages of protein and total digestible nutrients.

**High protein content makes winter fat valuable forage for Colorado ranges**, C. H. WASSER (*Colo. Farm Bul.* [Colorado Sta.], 7 (1945), No. 5, pp. 6-7, 13, illus. 1).—Winter fat, a white sage, was shown on monthly analyses to have a high protein content which ranged from 8.12 percent in November to 18.59 percent in May. This was compared with buffalo grass, which had 4.36 percent in November to 9.45 percent in June, and western wheatgrass, which had 2.47 percent in February and 11.60 percent in May.

**Nutritive value of distillers' dried solubles as a source of protein**, C. W. HUGHES and S. M. HAUGE. (*Ind. Expt. Sta.*). (*Jour. Nutr.*, 30 (1945), No. 4, pp. 245-258).—Study was made of the nutritive value of dried brewers' yeast and various combinations of yeast and solubles for determining the value of yeast in the fortification of solubles. Yeast was of greater nutritive value than dried solubles as the sole source of protein and effectively supplemented solubles, corn, and combinations of these products. Biological tests with rats showed that distillers' dried solubles were inadequate as the sole source of protein and as a protein supplement because of deficiencies in lysine and tryptophan. Chemical studies revealed that solubles contain considerably less lysine and tryptophan than yeast. In vitro digestion experiments with proteolytic enzymes indicated that these amino acids are less available in solubles than in yeast. A small amount of yeast definitely increased the nutritive value of dried solubles, and the production of dried solubles with a higher yeast content would seem desirable.

**Carotene loss in stored leaf meals and extracts**, M. E. WALL and E. G. KELLEY. (U. S. D. A.). (*Indus. and Engin. Chem.*, 38 (1946), No. 2, pp. 215-218, illus. 5).—Carotene retention in vegetable leaf meals was found to depend primarily on the storage temperature. Of the three temperatures used in these tests (5°, 24°, and 37.5° C.), the greatest carotene stability was at 5° and the least at 37.5°. Retention varied with the species of leaf, and a high oxalic acid content of the leaf seemed to be favorable. Carotene concentrates from leaf meals dissolved in oils were more stable than crystalline carotene in the same oils, possibly owing to the tocopherol in the concentrate. Levels of carotene up to 1,000 µg. per gram were more stable than the 5,000- and 15,000-µg. levels. Oil solutions of carotene, of whatever source and at any concentration, were in most cases more stable at 5° than at higher temperatures. Addition of *d*-isoascorbyl palmitate and soybean lecithin to the carotene solution was ineffective in reducing loss of carotene.

**The utilization of simple compounds of nitrogen by ruminants**, W. D. GALLUP. (Okla. Expt. Sta.). (*Okla. Acad. Sci. Proc.*, 25 (1945), pp. 54-55).—In recent steer-feeding experiments, "urea has been fed by itself and in combination with hominy and molasses as a supplement to prairie hay. The apparent digestibility of the ration nutrients and the amount of nitrogen (protein) stored by the animals were determined during 10-day periods. The average value for nitrogen storage was negative, -14.4 gm. per day, when hay was fed alone and -0.8 gm. when urea was fed as a supplement at the rate of 89.4 gm. per day. In some instances nitrogen balances were positive during urea feeding. There was practically no change in the digestibility of hay constituents when urea was fed, consequently it appears that this improvement in nitrogen balance resulted from utilization of urea nitrogen, either directly or through the interaction of rumen organisms. There is the possibility, however, that the nitrogen of the hay was utilized in metabolism more efficiently

when urea formed a part of the ration. When approximately 89.4 gm. of urea were fed daily in combination with carbohydrates (hominy feed and molasses) nitrogen storage was further increased to about +3.4 gm. per day. However, the addition of this combination of urea and carbohydrates increased the digestibility of dry matter and crude fiber of the hay. It is possible, therefore, that when this supplement was fed a part of the observed increase in nitrogen storage resulted from increased digestion of nitrogen from the hay."

**Studies on the carotenoid and vitamin A levels in cattle, I, II, W. BRAUN.** (Univ. Calif. and U. S. D. A.). (*Jour. Nutr.*, 29 (1945), No. 1, pp. 61-79, illus. 4).—Two papers are presented:

I. *Seasonal changes of the carotenoid and vitamin A levels and the normal carotenoid-vitamin A ratio of the blood* (pp. 61-71).—The carotenoid and vitamin A levels of the blood of 49 cows maintained in 4 groups with carotenoid and vitamin A intake were determined periodically for 1 yr. Seasonal changes in the carotenoid level were mainly dependent on the carotenoid intake but varied with the age and breed of the animal. There were individual variations which were not statistically significant between the means of animals. Seasonal changes were dependent on carotenoid and vitamin A intake. Vitamin A levels showed temporary decreases during parturition, abortion, and acute infections, but rose immediately after feeding either shark-liver oil or yeast. A linear increase of vitamin A with increasing carotenoid levels was found. The ratio of vitamin A to carotenoid levels was established, decreasing with increasing carotenoid levels and reaching a constant value at high carotenoid levels. There were deviations in the ratio, however, and it was below normal in physiological disturbances and slightly above normal if the animals were subject to decreasing carotenoid intake and well above normal if a vitamin supplement was fed. Breed differences in the ratio are briefly discussed.

II. *Carotenoids and vitamin A in the liver, their ratio and their relationship to blood levels* (pp. 73-79).—The carotenoid and vitamin A values were obtained from liver samples of cows in four dietary groups with different carotenoid and vitamin A intakes. The vitamin A levels were significantly different among three of the four dietary groups, but similar for the shark-liver-oil-supplemented group regardless of their basic ration. An optimum level for vitamin A storage was thus indicated. The livers of animals which had been maintained on a vitamin A-enriched ration for 6 to 8 mo. indicated a rather lasting effect on the vitamin A storage of a relatively short period of vitamin A feeding. Observations on livers from vitamin A-starved animals and partially hepatectomized animals indicated that utilization of stored vitamin A first forces available carotenoid stores to be converted into vitamin A, thus decreasing carotenoid level without decreasing the vitamin A level. A typical relationship between carotenoid levels and corresponding vitamin A levels appears to exist in the liver similarly to the A-carotenoid ratios observed in the blood. Changes in the ratio with differences in carotenoid levels are probably caused by the tendency to maintain a constant vitamin A store. The ratio was modified if the animal was fed vitamin A and in certain pathological conditions. A tendency toward a direct relationship between vitamin A stores and the vitamin A level of the blood was found to exist only when the former fall below normal levels.

**Vitamin A, ascorbic acid, and spinal fluid pressure relationships in the young bovine, L. A. MOORE.** (Md. Expt. Sta.). (*Jour. Nutr.*, 31 (1946), No. 2, pp. 229-236).—The increased spinal fluid pressure previously noted in the bovine to be associated with vitamin A deficiency (E. S. R., 86, p. 679) was further studied in three groups of calves. One group received various quantities of carotene in the form of dehydrated alfalfa leaf meal. There was an increased spinal fluid pressure accompanied by depressed ascorbic acid values in blood and spinal fluid. Even though normal ascorbic values in blood and spinal fluid were maintained by the

feeding of chlorobutanol or by the subcutaneous injections of ascorbic acid, there was still an increase in the spinal fluid pressure in vitamin A-deficient calves.

**July-planted Hodo sorghum unsatisfactory for grazing by beef cattle after frosts.** R. H. MEANS (*Miss. Farm Res. [Mississippi Sta.]*, 9 (1946), No. 1, p. 7).—There seems need for a suitable follow-up crop for beef cattle that may be harvested after oats, as on dallis grass pasture cattle begin to lose weight in December. A big problem for cattle production is to provide a satisfactory and economical supplemental feed from December 15 to March 20. In search of such a crop, a 15-acre field was planted with Hodo sorghum in July after harvesting an oat crop and pastured with 33 grade Angus cows. Soon after the first freeze the sorghum lodged and the heads were all on the ground within 2 weeks. The cattle lost an average of 51 lb. during the 35-day cattling-down period. After 1 week the frosted sorghum was not palatable, and after 2 weeks some of the cows were losing weight. The weather conditions were unfavorable, but not unusual.

**Selecting, fitting, and showing the beef steer.** R. S. GLASSCOCK (*Florida Sta. Bul.* 421 (1946), pp. 37, illus. 11).—General directions for selecting, feeding, grooming, and showing the steer, with instructions on making rope halters.

**The vitamin D requirement of the sheep.** E. D. ANDREWS and I. J. CUNNINGHAM (*New Zeal. Jour. Sci. and Technol.*, 27 (1945), No. 3, Sect. A, pp. 223-230).—The daily requirement for vitamin D of lambs from 6 to 12 mo. of age was approximately 180 International Units for each 100 lb. body weight. Sunlight was a natural source and calciferol was an available supplemental source of vitamin D. The composition of the blood of rachitic lambs was altered from the normal. Whole blood inorganic phosphate and serum calcium were reduced and plasma phosphatase increased. The ash content of rachitic bones was slightly less than normal.

**Cooked potato silage gives good results in pig-feeding experiment.** W. E. CONNELL and A. L. ESPLIN (*Colo. Farm Bul. [Colorado Sta.]*, 7 (1945), No. 6, pp. 14-15).—Continuing the study of the feeding of potatoes, made with lambs and steers (E. S. R., 94, pp. 247, 248), comparison of the use of silages for pigs showed that neither dehydrated potato pulp nor cooked potato silages produced as good gains as did corn. When fed free-choice with corn, the daily gain was increased from 0.55 to 1.36 lb. with the dehydrated potato pulp and from 0.95 to 1.48 lb. with the cooked potato silage. Raw potatoes proved unpalatable. The test was conducted with six lots of eight or nine pigs, the dehydrated potato pulp and cooked potato silage being fed with and without corn. Other lots received corn or raw potatoes alone. All were hand-fed soybean meal, alfalfa meal, and minerals.

**Forage crops for pigs save harvested grain.** P. G. BEDENBAUGH (*Miss. Farm Res. [Mississippi Sta.]*, 9 (1946), No. 1, p. 6).—In one trial, 3 groups of 10 pigs each were fed on ground corn with cottonseed meal or cottonseed meal and shrimp meal with soybean pasture. The average daily gains with the different protein supplements were 0.99 and 0.90 lb., respectively, as compared with 1.67 lb. gain produced in dry lot, in an 85-day experiment. In another experiment two varieties of soybeans were used for hogging down corn and soybeans in a 14-day trial. The average daily gains in this trial were 2.47 and 2.33 lb.

**Effect of feeding green food to the pregnant sow on the incidence of piglet anaemia.** R. BRAUDE and A. S. FOOT (*Vet. Jour.*, 102 (1946), No. 3, pp. 71-73, illus. 1).—The hemoglobin curves of the individual size of litters of sows receiving a concentrate mixture and minerals with and without 7 lb. of marrow-stem kale per day were compared. There was no reason to believe that lactational failure was due to the absence of kale in the rations of the three sows without it as contrasted with the pigs of four sows receiving kale. The hemoglobin levels of the sows dropped to a dangerously low level, but the feeding of kale had no effect. Direct dosing of the pigs with iron pyrophosphate caused a rapid recovery in hemoglobin level in some cases before the growth curve had been significantly affected.

**Effect of thiouracil on growing swine**, M. E. MUHRER and A. G. HOGAN. (Mo. Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc.*, 60 (1945), No. 2, pp. 211-212).—Four groups of Chester White and Poland China crossbred hogs were pair-fed for 28 days on rations made up of corn 60 parts, wheat 13, tankage and soybean oil meal 10 each, alfalfa meal 5, and mineral 2 parts by weight, plus 0.2 percent of thiouracil in the test ration. The average daily gains per head were 1.4 and 2.1 lb. for the check and thiouracil lots. The test animals were less active, and at the end of the period they were shorter and fatter than the controls. Although they gained weight more rapidly and more economically, it is believed that their increased gain was not true growth but “apparently an example of retarded growth with rapid gains in weight due to deposition of an excessive amount of fat.”

**A study of canine hysteria produced by feeding certain baked dog foods and wheat gluten flour**, J. R. WAGNER and C. A. ELVEHJEM. (Wis. Expt. Sta.). (*Jour. Nutr.*, 28 (1944), No. 6, pp. 431-441, illus. 4).—Baked dog food containing wheat flour produced a type of nutritional canine hysteria which did not result when the wheat products were absent from the ration. The disease appeared to be caused by some toxic factor present in these products. Although the proteins of wheat products were deficient in lysine, protein and lysine supplements did not prevent the disease. Hysteria may be caused in dogs on nutritionally adequate rations by the addition of wheat gluten flour. A total of 12 dogs were included in the 6 experiments.

**Poultry production**, W. A. LIPPINCOTT, rev. by L. E. CARD (*Philadelphia: Lea & Febiger*, 1946, 7. ed., rev., pp. 440, illus. 238).—In this seventh edition (E. S. R., 82, p. 376), several chapters have been completely rewritten and a new chapter has been added on diseases and parasites.

**Activity of synthetic estrogens on oral administration in the domestic fowl and turkey**, R. G. JAAP. (Okla. Expt. Sta.). (*Endocrinology*, 37 (1945), No. 5, pp. 369-376).—“Seventeen synthetic estrogens have been tested for oral activity in the domestic fowl and turkey. All but two of these may be considered as derivatives of stilbene. Dianisylhexane was most active at the level of 10 mg. per pound of feed in the chick but practically inactive in the turkey poult. At levels of 20 or more milligrams per pound of feed, the dimethyl ether of diethylstilbestrol was the most potent estrogen for oral administration in both species. Compounds estrogenically inactive at the levels fed were dihydroxystilbene, its diacetate and its dimethyl ether; the dimethyl ether of benezestrol; and triphenylethylene. In contrast triphenylchloroethylene was relatively active on oral administration in both species. Further data were obtained showing that estrogenic activity of these chemicals is greatly increased by solution in soybean oil before dispersion in the feed.”

**The effect of feeding thiouracil to hens upon the thyroid gland of chicks**, F. N. ANDREWS and E. E. SCHNETZLER. (Ind. Expt. Sta.). (*Endocrinology*, 37 (1945), No. 5, pp. 382-384).—The thyroid glands of chicks from hens receiving thiouracil were definitely enlarged. Thiouracil was present in the eggs of hens treated with it. Egg white contained 0.07 to 0.15 mg. per gram and egg yolk 0.08 to 0.12 mg. per gram. There was no observable gross evidence of functional differences at the time of hatching or during the first week of life. At the level fed, the thiouracil apparently did not affect egg production, egg size, fertility, or hatchability in adult ♀ fowls. The study was based on eggs produced by two groups of 12 White Leghorn hens, one group of which received thiouracil at a level of 0.2 percent of the ration.

**Crystalline vitamin B<sub>6</sub> in relation to the cellular elements of chick blood**, C. J. CAMPBELL, M. M. MCCABE, R. A. BROWN, and A. D. EMMETT (*Amer. Jour. Physiol.*, 144 (1945), No. 3, pp. 348-354).—Data are presented on the cellular blood elements of normal vitamin B<sub>6</sub>-deficient, and vitamin B<sub>6</sub>-treated chicks. Crystalline

vitamin B<sub>6</sub> prevented macrocytic anemia, leukopenia, and thrombopenia in chicks during the first 4 weeks of life. Since perosis occurred in chicks raised on a purified ration containing all of the known B vitamins in crystalline form supplemented with manganese, it is suggested that another perotic factor exists. Earlier work has been noted (E. S. R., 93, p. 485).

**Rumen contents a promising source of B complex vitamins for poultry rations,** P. R. FREY and F. H. KRATZER (*Colo. Farm Bul. [Colorado Sta.], 7 (1945), No. 6, pp. 7-9, illus. 1*).—The dry rumen contents of 140 steers contained averages per 100 gm. of 1,000 µg. of thiamin, 1,200 µg. of riboflavin, 4,300 µg. of niacin, and 4,900 µg. of pantothenic acid. The average dried rumen contents furnished about four times the requirement of riboflavin for the growing chick and breeder and eight times the requirement for the layer. In terms of pantothenic acid, the dried rumen contents furnished about four times the requirement for the growing chick and breeder and six times the requirement for the layer. Dried rumen contents of sheep as well as cattle contained large amounts of the vitamin B complex.

**Soybean oil meal in poultry rations,** T. B. CLARK and C. J. CUNNINGHAM (*West Virginia Sta. Bul. 325 (1945), pp. 15*).—A control ration containing 2.5 percent each of fish meal and meat scrap and 12.5 percent of soybean meal was compared for growth of chicks with a ration containing 2.5 percent of meat scrap and 17.5 percent of soybean meal as principal proteins in the first series and one containing 20 percent soybean meal in the second series. The control ration produced a significantly greater growth in both sexes with less feed per unit of gain up to 12 weeks of age. At 20 weeks of age the differences between the lots of pullets in the first series were negligible, while in the second series the chicks on the control ration were slightly larger than those on the soybean ration. The feed efficiency between 12 and 20 weeks was not consistent in the two experiments. Pullets taken from the growth trials were used in laying trials with determination of feed consumption during November and March. It was shown that for egg production a mash in which soybean meal is the sole source of supplementary protein will give satisfactory results when balanced with necessary vitamins and minerals. Some animal protein should be included in starting and hatching rations, and, although the studies do not show how much is necessary, a minimum of 2.5 percent seems needed. For rapid growth the animal protein should be supplied in part by fish meal.

**Value of sunflower seed protein,** C. R. GRAU and H. J. ALMQUIST. (Univ. Calif.). (*Soc. Expt. Biol. and Med. Proc., 60 (1945), No. 3, pp. 373-374*).—Tests with 2-week-old White Leghorn chicks on diets in which the entire 20-percent protein of the diet was supplied by a South American sample of sunflower seed meal with 46.7 percent protein or a laboratory-prepared meal with 39.9 percent protein indicated that the value of this product for chick growth and efficiency of feed utilization is very high. According to the authors, "it compares favorably with other recognized complete sources of amino acids for the chick. In fact, the protein of sunflower seed meal is the most complete vegetable protein for chick growth that we have studied." Even lysine was present in adequate amount.

**Mung beans as a source of protein for turkey poults,** T. T. MILBY. (Okla. Expt. Sta.). (*Okla. Acad. Sci. Proc., 25 (1945), pp. 50-53, illus. 2*).—Cracked mung beans may be used to replace at least two-thirds of the vegetable proteins of turkey starting rations. Mung bean protein differs from the protein of cottonseed meal and soybean meal in that it does not need cooking. The tests in 1943-44 were conducted with 5 lots of about 140 Bronze and White Holland day-old poults each.

**Dietary anemia in the pigeon,** H. R. STREET. (*Jour. Nutr., 28 (1944), No. 6, pp. 395-406, illus. 4*).—A severe anemia developed in pigeons on a ration containing thiamine, riboflavin, pyridoxine, nicotinic acid, and calcium pantothenate, but lacking other members of the vitamin B complex. Extracts of yeast, liver, or rice bran

restored hemoglobin levels to normal. The antianemic agent in extracts of liver remains in the filtrate upon treatment with fuller's earth at pH 4. A second or weight restoration factor seemed to be required by the pigeon. In all the 36 pigeons placed on the experiment, there was an initial hemoglobin level of 15 gm. per 100 cc. of blood, or higher. This was rapidly reduced during the first week when the birds received none of the B factors other than thiamine. After 7 weeks the hemoglobin had fallen to levels of 12 gm. per 100 cc. or lower, with a range of 8.5 to 12 gm. in 23 of 34 surviving birds.

A short period for obtaining R. O. P. egg weights, E. E. SCHNETZLER. (Ind. Expt. Sta.). (*Poultry Sci.*, 25 (1946), No. 1, pp. 28-32).—Egg weights of 1,802 R. O. P. candidates of 3 Indiana breeders for the 4 spring months only were practically the same as for the entire year. Correlations between the weights determined by the two methods in three flocks were 0.96, 0.98, and 0.99. For 90 percent of the birds the differences between the averages for the two methods were less than 0.7 oz. per dozen. There was a considerable reduction in the labor-saving of the two methods, since only approximately 50 percent as many weights had to be taken.

### DAIRY FARMING—DAIRYING

Comparison of molasses-grass silage and ground barley-grass silage as feeds for the milking cow, W. A. KING (*New Jersey Stat. Bul.* 722 (1945), pp. 18).—Continuing this series of studies (E. S. R., 92, p. 693), 3 groups of 5 cows each were fed for 18 weeks on grass silage or corn silage. The first-cutting grass was preserved with either molasses or ground barley and compared with the corn silage for maintenance of condition and total milk production. Both the molasses and ground barley made palatable silages, but the ground barley-grass silage was the less palatable of the two although its feeding value was significantly the greater. Additions of ground barley to grass resulted in a well-preserved silage, and both were more palatable than corn silage, and an abnormal condition developed with the latter in one cow. The total digestible nutrients and metabolizable energy of the ground barley-grass silage were higher than those of the molasses-grass silage, but lower than expected, as was shown in the studies of the chemical composition of the silage and digestibility of the dry matter and nitrogen-free extract of the barley silage in total digestible nutrients and metabolizable energy. The loss amounted to about 30 percent of the nutrients of the ground barley or 10 percent of the nutrients of the entire silage. When fed alone ground barley-grass silage was more digestible than when fed with hay and grain. The digestibility of the crude fiber of the ground barley-grass silage was significantly lower than that of the molasses-grass silage. Losses of nitrogen on drying silage and feces caused significant error in the coefficient of digestibility of crude protein and especially in protein metabolism results. Mixed grass silage preserved with either molasses or ground barley was conducive to the retention of nitrogen, calcium, and phosphorus.

Comparison of molasses-timothy silage and ground barley-timothy silage as feeds for the milking cow, W. A. KING (*New Jersey Stat. Bul.* 723 (1945), pp. 17).—In this, the fifth study of grass silages for milk cows (see above), experiments were made on (1) the feeding value of timothy silage preserved with molasses or ground barley, (2) the apparent digestibility and metabolizable energy of these silages, and (3) the protein and mineral metabolism of cows fed on them. Fifteen cows were divided into 3 groups of 5 each, all of which received hay and grain; this being supplemented with corn silage, molasses-timothy silage, or ground barley-timothy silage for two 6-week and one 3-week periods. The timothy silage preserved with 200 lb. ground barley to a ton of green material resulted in a palatable and well-preserved silage. A greater quantity of nutrients was present than in

timothy silage preserved with molasses, but less than in good corn silage on the dry-matter basis. Molasses-timothy silage was more palatable than ground barley silage. In terms of 4 percent fat-corrected milk per pound of total digestible nutrients, corn silage and molasses-timothy silage were about equal, whereas ground barley-timothy silage was significantly lower. Cows fed corn silage made better gains in live weight and better milk production than cows fed the timothy silages. All nutrients of the ground barley-timothy silage fed as a part of a complete ration were more digestible than those of molasses-timothy silage, and the metabolizable energy was higher. When fed alone the digestibility of ground barley-timothy silage seemed to be depressed. Additions of ground barley as a silage preservative failed to increase the total nutrients of the timothy silage as much as would be anticipated. This is explained as due to a loss of nutrients of the ground barley calculated to be 25 percent. The importance of fresh samples of silage and feces for nitrogen analysis is stressed, as in the above bulletin. Also losses of volatile acids should be considered. Calcium was well utilized, whereas nitrogen and phosphorus were retained in two-thirds of the individual cases when the timothy silages were fed as a part of a complete ration with hay and grain.

**Distillers' by-products and soybean meal in dry calf starters for calves on limited quantities of milk.** H. P. DAVIS and G. W. TRIMBERGER (*Nebraska Sta. Res. Bul. 142 (1946), pp. 29*).—A total of 55 grade Holstein heifer calves received whole milk for 3 weeks, after which they were fed to 6 mo. of age in 6 groups. Each calf was allowed 50 lb. of skim milk, after which they were expected to obtain their nutrients from the protein supplement in liquid form until the calf reached 52 days of age, when a calf starter and later a grain mixture and alfalfa hay were provided. The basal grain mixture used throughout, but modified during the dry calf starter period, was 150 lb. of ground yellow corn, 150 lb. of ground oats, 100 lb. of wheat bran, 100 lb. of soybean meal, 12 lb. of steamed bone meal, and 6 lb. of iodized salt.

Various protein supplements were added to this basal mixture during the first 15 weeks, to make up 6 calf starters, with 15 to 18 percent protein. These included 50 lb. of soybean meal for group 1, 37.5 lb. of soybean meal plus 13.8 lb. of nonfat dry milk solids for group 2, 200 lb. of distillers' grain solubles for group 3, 25 lb. of soybean meal plus 26.6 lb. of nonfat dry milk solids for group 4, 50 lb. of nonfat dry milk solids for group 5, and 200 lb. of distillers' grain insolubles for group 6. Group 2 had approximately one-fourth and group 4 approximately one-half the nonfat dry milk solids of group 5 (control). Vitamins A and D were supplied first as a liquid and later as a part of the dry calf starter.

The calves of group 1 did not make consistent gains in weight until after the fifth week, and 3 of the 8 calves had to have additional whole and skim milk. In group 2 the calves made small gains in the early part of the experiment, and it was necessary to feed additional whole and skim milk to 2 of the 9 calves. During the first 5 weeks the calves in group 3 did not make consistent gains and it was necessary to feed 2 of the calves additional whole and skim milk. Additional skim milk seemed needed by only 1 of the 10 calves of group 4. The 10 calves of group 5 made gains every week and the largest total gain, but the gains were not always uniform. No additional milk beyond the 50-lb. skim milk was given to this group. Group 6 received the same liquid feed as group 5 for the first 30 days, and made consistent but somewhat irregular gains throughout the experiment.

Measurements of the calves and height at withers showed no significant differences by the several groups at the various stages of the experiment. The heart girth may possibly have shown significant differences at 2 mo. of age. The greatest inequalities during the early stages of the experiment occurred in weight, but there were no significant differences revealed by skeletal measurements. Differences in weight

were largely due to differences in degree of fatness, which was mainly eliminated by the time 6 mo. of age was reached. Nonfat dry milk solids had an ameliorating effect even in small amounts when substituted for small quantities of soybean meal. A dry calf starter consisting of 10 percent of nonfat dry milk solids produced normal gains with young calves. Satisfactory growth was produced with a grain mixture containing soybean meal as the principal protein supplement as the calves reached 18 weeks. Distillers' dried grains, both solubles and insolubles, used as the principal high protein supplement in a dry calf starter gave good results after 2 mo. of age. Nonfat dry milk solids were particularly useful in getting calves started growing until the time they eat grain and hay for feed. Data are given on the feed allowed each calf, with the initial and final weights and gains and measurements.

**Modern method of raising calves**, H. C. DICKEY. (Vt. Expt. Sta.). (*Holstein-Friesian World*, 43 (1946), No. 5, pp. 17-18, 127).—Modern methods of feeding and management are discussed. Daily feeding schedules for calves of various dairy breeds are included.

**Milk cows in miniature**, W. W. SWETT. (U. S. D. A.). (*Guernsey Breeders' Jour.*, 69 (1946), No. 5, pp. 480-482, 489-490, illus. 2).—A recent survey of mammary development of 52 Holstein and 45 Jersey cows at different ages in the U. S. D. A. Beltsville herd showed that those which had been graded as calves for mammary development were most accurate as an indication of milk production in the first lactation when the production was estimated on calves 3 to 5 mo. of age, but the grades assigned for 6 mo. of age showed little if any positive production relationship. For the Holsteins, the unweighted milk production average for the empirical grades (as calves) 1, 2, and 3, was 16,243 lb. of milk in the first lactation, grades 4, 5, and 6, 18,369 lb.; grades 7, 8, and 9, 19,639 lb. of milk, and for Jerseys, grades 1, 2, and 3, 10,243 lb. of milk, grades 4, 5, and 6, 12,707 lb. of milk, and grades 7, 8, and 9, 14,634 lb. of milk in the first lactation.

**High average production by Calhoun dairy herd** (*Dairy Res. Digest* [Louisiana Sta.], 4 (1946), No. 1, p. 2).—Shortage of labor made it necessary to do away with silage for the dairy herd and feed alfalfa hay and pasture this crop. The use of improved permanent pasture plus oats for fall, winter, and spring and sudan grass for late summer greatly assisted in maintaining the high production level obtained.

**Six thousand pounds milk per acre** (*Dairy Res. Digest* [Louisiana Sta.], 4 (1946), No. 1, p. 2).—Higher milk yield was produced from renovated pasture.

**The estimation of the weight of bulls from heart girth measurements**, C. BRANTON and G. W. SALISBURY. (Cornell Univ.). (*Jour. Dairy Sci.*, 29 (1946), No. 3, pp. 141-143, illus. 1).—The coefficient of correlation between heart girth and weights of 25 Holstein and 25 Guernsey bulls ranging in weight from 852 to 2,351 lb. was 0.976. The regression of actual live weight on heart girth was indicated by  $X = 53.42 Y - 2,827.40$ , wherein  $X$  = the calculated estimate of weight and  $Y$  = the measured heart girth. The correlation coefficient between body weight and semen volume was 0.2079, which was not significant.

**Some observations on the total ketone bodies of the blood of apparently healthy dairy cattle**, J. SAMPSON and L. E. BOLEY. (Univ. Ill.). (*Cornell Vet.*, 35 (1945), No. 4, pp. 314-320).—The ketone bodies of the blood of cows in lactation, of dry cows, and of heifers were found to be significantly greater during the months of June and July than during November and January. There was some evidence of an inverse relationship between the length of lactation and total ketone content of the blood of dairy cows, particularly with reference to the first 4 weeks as contrasted with the subsequent period of milk production. Differences of breed seemed to bear no significant relation to the variation in the ketone content of the blood of normal healthy cows. The mean or average value for 49 lactating cows in June

and July was 4.25 mg. and for 51 lactating cows in November and January 0.74 mg. per 100 cc. of blood.

**Studies on ketosis in dairy cattle, VII, VIII, J. C. SHAW.** ([Conn.] Storrs Expt. Sta.). (*Jour. Dairy Sci.*, 29 (1946), No. 3, pp. 131-139, illus. 1; pp. 151-155).—Continuing this series (E. S. R., 93, p. 488), two papers are presented:

VII. *The efficacy of B vitamins and methionine in the treatment of ketosis.*—Neither methionine nor thiamine hydrochloride administered orally or intravenously, alone or in combination with nicotinic acid, calcium pantothenate, riboflavin, pyridoxine, *p*-aminobenzoic acid, inositol, choline, and biotin, were effective in the treatment of seven cows with ketosis. Data were recorded for the cattle on the daily blood analysis up to 8 to 60 days for different cows on the blood glucose, blood acetone bodies, milk production, and treatment with one or more of the B vitamins.

VIII. *Spontaneous recovery.*—Data are presented on the milk production, blood glucose, or blood acetone bodies of five cows which spontaneously recovered from ketosis in about 27 to 50 days without treatment, thus emphasizing need for care in interpretation of results on effects of treatment.

**Ketosis in the Hawaiian Islands, J. M. HENDERSHOT** (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 827, pp. 74-75).—This condition is reported as occurring in the Hawaiian Islands not only in dairy cows but in range cattle kept in certain areas of Molokai where at times the only available forage is the Kiawe bean (*Prosopis juliflora*). Tests with steers indicated that the vitamin A deficiency hypothesis as to the causative factor may be subject to question and that the functional capacity of the liver may be a promising subject for investigation.

**Pasteurization of milk, cream, and dairy by-products** (*Canada Dept. Agr., Farmers' Bul.* 33, rev. (1945), pp. 28, illus. 20).—The primary purpose of this bulletin is to effect a greater efficiency in the pasteurization of milk, cream, and dairy byproducts in Canada, and to present in a concise form information with respect to pasteurization methods and equipment.

**Cleansing of square and round milk bottles, T. V. ARMSTRONG and L. H. BURGWALD.** (Ohio State Univ.). (*Milk Dealer*, 35 (1946), No. 6, pp. 52, 124-129, illus. 1).—This study is concerned with the comparative cleansability of the square bottle and its degree of sterility as compared with the round bottle when washed under identical conditions. Several hundred washed bottles were obtained from nine plants using seven types of washers. Examination of quarts and half pints as received and comparisons of the effect of a chlorine rinse indicated that "there is no difference in the commercial practicability of cleansing and sterilizing the returnable square milk bottle and the conventional round bottle in typical dairy soaker equipment."

**A light-sensitive enzyme in cow's milk, H. D. KAY** (*Nature [London]*, 157 (1946), No. 3990, p. 511).—Observations by Mattick and Kay (E. S. R., 79, p. 384) of losses in the lipase content of milk kept in glass bottles on the laboratory bench for a few hours have been resumed, and it is concluded that the lipase (tributyrylase) of cow's milk is quite sensitive to sunlight. Exposure to bright sunshine of fresh milk in glass vessels to a depth of about 1 cm. and at a temperature under 5° C. was found to destroy 40 percent of the enzyme in 10 min. and about 80 percent in 30 min. Exposure out of direct sunlight on a laboratory window sill may cause a 30-percent destruction in 30 min., and a 30-min. exposure to an 800-w. (220-v.) quartz mercury lamp at a distance of 15 cm. may destroy 75 percent of the lipolytic power. Sunlight falling directly on the milk was rather more effective than sunlight through glass, but the destructive effect of sunlight was greatly minimized by removal of oxygen and less markedly by the addition of sodium cyanide. On the other hand, the rate of photo-destruction could be considerably increased by the addition of riboflavin. In milk exposed for a few minutes to sunlight and then kept in the dark, the destruction of lipase continued rapidly at first but ceased in about 3 hr., and

fresh milk added to milk in which the lipase was completely inactivated by light lost none of its activity even upon standing for several hours.

**The vitamin content of mare's milk.** A. D. HOLMES, B. V. MCKEY, A. W. WERTZ, H. G. LINDQUIST, and L. R. PARKINSON. (Mass. Expt. Sta.). (*Jour. Dairy Sci.*, 29 (1946), No. 3, pp. 163-171).—The average values for the milk of three Percheron mares during normal lactation were as follows: "Ascorbic acid 12.9 mg., nicotinic acid 0.72 mg., pantothenic acid (three samples) 2.77 mg., riboflavin 0.11 mg., thiamine 0.39 mg. per liter, fat 1.2 percent, fat globule size 3.4 $\mu$ , total solids 10.20 percent. Of these values ascorbic and nicotinic acid, riboflavin, fat, and total solids were lower than the corresponding values for cow's milk, but the thiamine values were higher."

**Bacteriology of butter.**—VIII [a], Salt distribution in butter and its effect on bacterial growth, W. H. HOECKER and B. W. HAMMER (*Iowa Sta. Res. Bul.* 339 (1945), pp. 709-762, illus. 2).—In continuation of this series (E. S. R., 82, p. 814), the micromethod of Guthrie and Ross (E. S. R., 30, p. 877) was used for ascertaining the distribution of salt and moisture in normal and abnormal commercial butter. The salt in some samples was uniformly distributed, but in others it was not. There was no significant difference in the salt distribution before and after printing, but the moisture was more thoroughly incorporated in the butter before printing than after. The salt was more uniformly distributed as working was continued. Salt was unevenly distributed in some samples with abnormal flavors but not in others before and after printing. In mottled butter usually less salt was found in the light-colored than in the dark-colored portions, but in butter having a conspicuous color defect the light-colored portions generally contained more salt than the dark-colored portions. With normal butter there was less variation in salt than in moisture. The percentages of salt in the serum calculated from analysis of microportions frequently varied less than the percentages of moisture. In most samples there was a correlation between the distribution of moisture in the butter, as shown by the distribution of the number and size of moisture droplets when butter was freshly cut. In butter with abnormal flavor, moisture was often not as uniformly distributed as in thoroughly worked normal butter. Salt was uniformly distributed in the serum of some samples but not in others, and the salt content of large moisture droplets varied considerably in some samples but not in others. Bacterial action was greatly inhibited in butter held at 15.5° C. by the addition of 1.5 percent salt. The distribution of salt influenced the growth of various organisms in butter churned from inoculated pasteurized cream. The lowest bacterial counts were obtained in butter having the salt well distributed. Growth was most rapid in unsalted butter. The numbers of organisms were less and they were more uniformly distributed in experimental butter containing organisms capable of producing a defect when the salt was well dispersed than when it was poorly dispersed. Cultures from drops of moisture appearing on the freshly cut surface of the butter were variable, some showing excessive growth and others no growth. The pH of the serum of experimental butter churned from cream inoculated with lactic-acid-producing streptococci and held at 15.5° decreased more with salt poorly distributed than when well distributed, but in other comparisons there were no significant differences. Increases in the acid numbers of the fat of experimental salted butter churned from pasteurized cream inoculated with lipolytic organisms and held at 15.5° were influenced by the distribution of salt, the largest increases occurring when the salt was poorly distributed. When butter from cream inoculated with organisms capable of producing a defect was held at 15.5° with salt well distributed, it was usually free from the defect, but when the salt was poorly distributed the defect developed. Poorly worked unsalted butter was more likely to show defects. Frequently defects did not develop from *Pseudomonas putrefaciens* added either to the

cream or to the wash water when the butter had salt well distributed, whereas butter having the salt poorly distributed sometimes showed the defects. Unsalted butter usually became putrid regardless of whether the organism was added to the cream or the wash water. Greater inhibition of organisms producing defects occurred when the salt was well distributed than when poorly distributed, and they developed more uniformly in unsalted butter. There was considerable lack of uniformity in the effects of various conditions on the development of flavor defects.

**Relation of corn and alfalfa silage to the quality of cheese and its carotene and vitamin A content,** K. HIGUCHI, W. V. PRICE, and W. H. PETERSON. (Wis. Expt. Sta.). (*Jour. Dairy Sci.*, 29 (1946), No. 3, pp. 157-162).—Cheese from the milk of groups of five cows each on corn silage, corn and alfalfa silage, and alfalfa silage only was studied with respect to its quality and carotene and vitamin A contents. Cheese made from milk produced on an alfalfa silage ration equaled or excelled that in quality and vitamin A potency of cheese made from milk produced on a corn silage ration. The distribution of vitamin A potency in cheese making was shown to be such that 85 percent was retained in the cheese, 7 percent found in the whey, and 8 percent unaccounted for. A pound of milk, which contained on the average 83 µg. of carotene and 109 µg. of vitamin A, gave cheese containing 69 µg. of carotene and 93 µg. of vitamin A. The whey accounted for 6.5 µg. of carotene and 7.5 µg. of vitamin A, thus leaving about 7.5 µg. of carotene and 8.5 µg. of vitamin A unaccounted for. The vitamin A potency of the cheese remained unchanged during storage for 1 yr. The carotene or vitamin A were ascertained for brick, Cheddar, and Swiss cheese by methods of Berl and Peterson (*E. S. R.*, 92, p. 304).

## VETERINARY MEDICINE

**Crotalaria spectabilis poisoning in Louisiana livestock,** P. L. PIERCY and L. L. RUSOFF. (La. Expt. Sta.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 827, pp. 69-73, illus. 4).—This is a more technical account than previously noted (*E. S. R.*, 94, p. 518). Experimental feeding of cattle and chickens and field studies with cattle demonstrated toxicity of a chronic nature with fatal effects after the slow, cumulative assimilation of the toxic principle weeks or even months after grazing or feeding. The poisonous alkaloid, monocrotaline, was isolated from all portions of immature plants in flowering and early pod stages. When injected into chickens, this material acted identically with the poisonous principle which had been isolated in Florida from mature plants. Monocrotaline was most highly concentrated in the seed portions of the plant.

Notwithstanding the outstanding value of *C. spectabilis* as a leguminous cover crop and its low palatability, its restriction to areas not grazed by livestock is deemed necessary.

**Sex hormones in veterinary practice,** D. K. DETWEILER (*Pa. Univ., Vet. Ext. Quart.* No. 98 (1945), p. 26, illus. 3; abs. in *Vet. Jour.*, 102 (1946), No. 2, pp. 45-52).—It is the purpose of this paper to discuss the physiology of the sex hormones and to correlate this with the products now available to the veterinarian.

**Studies on antimalarial drugs: The metabolism of quinine and quinidine in birds and mammals,** F. E. KELSEY, F. K. OLDHAM, and E. M. K. GEILING (*Jour. Pharmacol. and Expt. Ther.*, 85 (1945), No. 2, pp. 170-175, illus. 1).—In vitro studies indicated that quinine is more readily metabolized than quinidine in the rabbit and rat, but that the reverse is the case with the chicken, turkey, pigeon, duck, and goose. In vivo, the rabbit metabolizes quinine much more rapidly than quinidine, but in the duck and chicken the two drugs are metabolized at approximately the same rate. The duck metabolizes both alkaloids more slowly than does the chicken, and the two species differ in the distribution of the drugs between red cells and plasma.

**The degradation of quinine in the duck, chicken, and dog,** E. H. DEARBORN and E. K. MARSHALL, JR. (*Jour. Pharmacol. and Expt. Ther.*, 85 (1945), No. 2, pp. 202-205).—The authors report that there are probably at least two degradation products of quinine to be found in the duck after administration of quinine. The degradation of quinine appears to be qualitatively similar in ducks, chicks, and dogs.

**The biological activity of phenolic compounds: The effect of surface active substances upon the penetration of hexyl resorcinol into *Ascaris lumbricoides* var. suis,** A. E. ALEXANDER and A. R. TRIM (*Roy. Soc. [London] Proc., Ser. B*, 133 (1946), No. 871, pp. 220-234, illus. 7).—The effect of sodium cholate, sodium oleate, and cetyl trimethyl ammonium bromide (C.T.A.B.) upon the penetration of hexyl resorcinol into the pig roundworm has been measured quantitatively, and parallel measurements carried out upon the interfacial activity of these solutions against an inert mineral oil. In all three cases a marked similarity of action, differing only in degree, was observed. Using a fixed hexyl resorcinol concentration (0.025 percent) the soap in dilute solution accelerated the penetration of this drug, the maximum accelerations being in the order sodium cholate > sodium oleate > C.T.A.B., but when present in high concentration the penetration was completely inhibited. The soaps alone were found to penetrate *Ascaris* very slowly, if at all, the amounts taken up being reasonably explained on the basis of surface adsorption only.

The possible bearings of the findings upon in vivo activity of hexyl resorcinol as an anthelmintic, and upon drug action in general, are briefly mentioned.

**Anthrax treated with sulfadiazine,** L. C. ABELSON ([U. S.] *Off. Surg. Gen., U. S. Army Med. Dept. Bul.*, 5 (1946), No. 3, pp. 363-364).—A case is reported of an Army sergeant in China with a lesion from which an organism presenting the appearance of *Bacillus anthracis* was observed. He was brought to an ambulatory condition in the absence of anti-anthrax serum and penicillin by oral and intravenous injections of sulfadiazine.

**The Physaloptera (Nematoda) of carnivores,** B. B. MORGAN. (Univ. Wis.). (*Wis. Acad. Sci., Arts, and Letters, Trans.*, 36 (1944), pp. 375-388, illus. 14).—The purpose of this paper is to present briefly what is known of the various species of *Physaloptera*, a redescription of one species, a key to the species found in carnivores, and a world host list. About 60 citations to the literature are appended.

**Ps. pyocyanea: Study in vitro and in vivo of the bactericidal and therapeutic properties of  $\alpha$ -oxyphenazine and a lipoidal product,** J. ZWEIF (*Vet. Jour.*, 102 (1946), No. 3, pp. 55-70, illus. 5).—This investigation was undertaken to study methods of preparation and the chemical and antibiotic properties in vitro and in vivo of various metabolites obtained from *Pseudomonas pyocyanea* cultures, with special attention to  $\alpha$ -oxyphenazine and the lipoidal products against organisms of veterinary importance. The  $\alpha$ -oxyphenazine was obtained in a crystalline state in a high degree of purity and was shown to be active in vitro against the following organisms: *Corynebacterium pyogenes*, *Vibrio foetus*, *Pasteurella bovis*, *Bacillus anthracis*, *Streptococcus agalactiae*, *S. dysgalactiae*, *Staphylococcus aureus*, *Brucella abortus*, *Bacillus coli*, *Salmonella choleraesuis*, *Clostridium welchii*, *C. septique*, *C. chauvoei*, and *C. tetani*. Its use in *Brucella abortus* infections in guinea pigs and cows and in bovine mastitis is discussed.

In general, the lipoidal products were obtained in a crude form by chloroform extraction of dried bacterial bodies or of whole lipid culture, and proved to be active against *Bacillus anthracis*, *Brucella abortus*, *Streptococcus agalactiae*, *S. dysgalactiae*, *Staphylococcus aureus*, human and bovine, and *Mycobacterium tuberculosis*. The therapeutic effects were compared to those of  $\alpha$ -oxyphenazine in tests with *B. abortus* in guinea pigs and cows and bovine mastitis, and tests were also made with tuberculosis in guinea pigs.

**A case of canine *S. typhimurium* infection with notes on other *Salmonella* infections in animals,** J. F. SHIRLAW, S. McDONALD, and W. HAYES (*Indian Jour.*

*Med. Res.*, 33 (1945), No. 1, pp. 1-3).—This is a case report of the isolation in the dog of a strain identical, biochemically and serologically, with *S. typhimurium*.

**Salmonella epidemic from commercially prepared sandwiches.** A. P. GREENBLATT, P. D. DELAY, L. BRESLOW, and I. J. GREENBLATT ([U. S.] *Off. Surg. Gen.*, U. S. *Army Med. Dept. Bul.*, 5 (1946), No. 3, pp. 345-348).—In an outbreak of *Salmonella* food poisoning, 97 cases were hospitalized during a 4-day period. The infected food was a mayonnaise spread used in commercially prepared sandwiches. Convalescent patients excreted the organism for as long as 38 days, and it is pointed out that while rodents, poultry, and eggs have received attention as carriers of *Salmonella*, "perhaps the human carrier makes a greater contribution to the *Salmonella* problem than current emphasis indicates."

**Phase variation of *Andrewes* in a coliform bacterium.** P. R. EDWARDS and M. G. WEST. (Ky. Expt. Sta.). (*Jour. Infect. Diseases*, 77 (1945), No. 3, pp. 185-186).—A coliform culture which fermented lactose, coagulated milk, and liquefied gelatin is described. It possessed *Salmonella* H and O antigens and was diphasic. It is represented by the antigenic formula XVI:  $z_{10}-c, n \dots$

**A simple technique for the fixation and staining of *Trichomonas* in cultures and vaginal mucus.** V. D. VAN SOMEREN (*Vet. Jour.*, 102 (1946), No. 3, pp. 73-78, illus. 4).—This iodine fixation technic is described as employed with *T. foetus* of bovines. Notes on the morphology of this species are included.

**Studies of vesicular stomatitis, with special reference to a virus of swine origin.** M. S. SHAHAN, A. H. FRANK, and L. O. MOTT. (U. S. D. A.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 826, pp. 5-19, illus. 10).—A strain isolated from a natural outbreak in swine and designated as N.J.-M was studied in comparison with three previously typed strains from cattle and horses (N.J., Ind., and Ind.-C). The N.J.-M strain was pathogenic for locally exposed horses, cattle, swine, and guinea pigs. Hog cholera-immune swine inoculated intravenously with vesicular stomatitis virus readily contracted the latter disease. When the virus was inoculated at the same time with large doses of hog cholera virus, there was a tendency toward delay or absence of formation of vesicular lesions.

"Swine readily contract vesicular stomatitis through contact with affected animals under certain conditions. Contact with convalescent swine or pens from which convalescent swine had been recently removed failed to convey the infection. Occult, or inapparent, infection, resulting in immunity, may result from contact with swine in the acute stages of the disease. Pigs appear to be less susceptible to infection by contact than older swine. Virus was demonstrated in the blood of clinically affected swine which became infected through contact."

Secondary lesions occurred in 13 of 26 swine primarily infected by contact or through inoculation on the snout with New Jersey type virus. Of 18 swine similarly infected with Indiana type virus, none developed "secondaries."

Sheep failed to develop vesicular stomatitis when inoculated with either Indiana or New Jersey type virus. Cattle failed to develop vesicular lesions when inoculated intramuscularly with either type of vesicular stomatitis virus. Some but not all of such cattle became immune. It is suggested that the contrasting results from lingual inoculations of sheep and intramuscular inoculations of cattle with the viruses of foot-and-mouth disease and vesicular stomatitis may be properly applied as an integral part of differential diagnosis of the two diseases. "Either inapparent or clinically evident vesicular stomatitis infections generally produce substantial immunity to the same immunologic type of virus. In some cases, however, measurable resistance is of short duration. In consequence, it becomes necessary to check the immunity of animals that have recovered from type specific infection before proceeding with tests to determine the immunologic character of a virus of unclassified type."

**Studies on the immunization of guinea pigs against *Brucella* infection, I. LIVE, F. G. SPERLING, and E. L. STUBBS. (Coop. U. S. D. A. et al.).** (*Jour. Infect. Diseases*, 77 (1945), No. 1, pp. 16-24).—An active immunity against moderate doses of virulent *B. abortus* was obtained in guinea pigs both with sonic extract of *B. abortus* containing a total of 5 mg. of protein injected either subcutaneously or intracutaneously and with subcutaneous injections of a total of 75 billion to 300 billion ether-killed whole *B. abortus* organisms. Even more effective in protecting guinea pigs against *Brucella* infection, however, were intracutaneous injection of one-tenth the number of ether-killed *B. abortus*.

Injections of sonic extract or ether-killed whole cells of *B. abortus* produced either low agglutinative titers or no demonstrable agglutinins in the blood serums of the guinea pigs. Furthermore, animals which had acquired an immunity did not develop agglutinins as a result of the injection of the infecting dose. Therefore, it would appear that the immunity produced did not depend upon the presence of serum agglutinins.

**The culturing of blood clots for *Brucella* organisms, D. E. WEST and E. K. BORMAN** (*Jour. Infect. Diseases*, 77 (1945), No. 3, pp. 187-192).—The development of a method for routine culturing of *Brucella* from clots of blood specimens received for agglutination tests is described. By its use 40 *B. abortus* and 2 *B. suis* cultures were isolated from the clots of 4,051 routine blood specimens received for agglutination test. The method is deemed a valuable supplement to the agglutination test as a diagnostic aid in suspected brucellosis.

**Progress in the control of contagious abortion in New Zealand by vaccination, M. B. BUDDLE** (*Austral. Vet. Jour.*, 21 (1945), No. 5-6, pp. 122-129).—In studies with strain 19 of *Brucella abortus*, supplied in 1941 by the U. S. D. A. Bureau of Animal Industry, it was found that of 15 heifers vaccinated as calves with strain 19 and artificially exposed to virulent infection during pregnancy, 2 aborted from brucellosis, 1 aborted from a nonspecific cause, 1 calved prematurely, and 11 calved normally. Three of these heifers became permanently infected with brucellosis. Of 15 unvaccinated heifers similarly exposed to infection during pregnancy, 9 aborted, 1 calved prematurely, and 5 calved normally. Eleven of these heifers became permanently infected with brucellosis. In a field trial of calfhod vaccination commenced in New Zealand in 1942, there were 22 abortions from all causes out of 465 first pregnancies of vaccinated heifers, or less than 5 percent in 1943. Thirty-two percent of unvaccinated heifers aborted in these herds in 1942. Of 293 second pregnancies of these vaccinated animals in 1944, 4, or 1.4 percent, terminated in abortion. In 1944, of 10,725 first pregnancies of heifers vaccinated as calves only 3 percent terminated in abortion. Twenty-two percent of unvaccinated heifers aborted in these herds in 1943.

It is stated that 43,000 heifer calves were vaccinated in New Zealand in 1944 and 107,000 in 1945.

**Studies on the detection of mastitis in New Zealand dairy herds.—V, Composition of milk from quarters reacting to the bromthymol blue test for mastitis, F. H. McDOWELL** (*New Zeal. Jour. Sci. and Technol.*, 27 (1945), No. 3, Sect. A, pp. 258-269).—Individual quarters of cows' udders were classified as negative and positive on the basis of the reaction of the foremilk to the bromthymol test. The results showed, in the great majority of cases, the abnormalities in composition associated with mastitis milk. The reacting quarters yielded a smaller volume of milk than the corresponding sound quarters.

**Studies in infectious mastitis.—I, Penicillin as a therapeutic agent, J. L. BYRNE, J. W. PULLIN, and H. KONSKE** (*Canad. Jour. Compar. Med. and Vet. Sci.*, 10 (1946), No. 1, pp. 16-23).—This preliminary report deals with work in which a total of 266 quarters—179 infected with *Streptococcus agalactiae*, 6 with *S. dysgalactiae*, 5 with

*S. uberis*, 21 with unidentified streptococci, 49 with pathogenic staphylococci, and the remainder showing only clinical and chemical manifestations of infection—were treated with penicillin. From one to six treatments were given at 4-day intervals. The number of Oxford units ranged from 10,000 to 100,000, and the volumes of diluent (sterile physiological saline) varied from 25 cc. to 250 cc. Best results, particularly in streptococcic mastitis, were obtained when 40,000 Oxford units dissolved in 100 cc. of diluent were employed. Under these conditions, 204 of 266 treated quarters recovered in from one to three treatments and 38 failed to show improvement after six treatments.

**Penicillin and mastitis control**, C. S. BRYAN. (Mich. State Col.). (*Milk Plant Mo.*, 35 (1946), No. 2, pp. 27-28, 65).—This is a practical discussion of the penicillin treatment. In conclusion it is pointed out that "in mastitis of cattle prevention is the most important item in dealing with the disease. Chemotherapeutic agents may be successful in curing many of the udder infections, but they do not protect the recovered cow from reinfection. Penicillin can cure many cases of infectious mastitis, but responsibility for the conduct of preventive—milking and herd management—procedures will always remain on the shoulders of the dairyman."

**Bovine trichomoniasis**, B. B. MORGAN. (Wis. Expt. Sta.). (*Minneapolis 15: Burgess Pub. Co.*, 1946, rev., pp. 165+, illus. 7).—A revision of this monograph (E. S. R., 92, p. 564). The bibliography now includes 447 citations and the parasite-host list 93 *Trichomonas*.

**Some observations on the incidence of bovine helminths in Plateau Province, Northern Nigeria**, J. F. A. SPRENT (*Vet. Jour.*, 102 (1946), No. 2, pp. 36-40).—A survey of helminths of Zebu cattle examined in Northern Nigeria is described. A list is given of the species found, and the incidence of certain of the intestinal nematodes is recorded. Autopsy examination of 250 cattle failed to show any important lesions caused by helminths, but examination of the hemoglobin values of the blood of these cattle showed that the values are lower in the rainy season (May to September) than during the dry season. The anemia was shown to bear no relationship to worm infestation.

**Lead poisoning of cattle**, R. FENSTERMACHER, B. S. POMEROV, M. H. ROEPKE, and W. L. BOYD. (Minn. Expt. Sta.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 826, pp. 1-4).—This discussion, based in part on the diagnosis of 11 cases, indicated that lead poisoning of cattle and especially of calves occurs more frequently than reports would indicate. The painting of calf pens with paint containing white lead and access to discarded paint residues are frequently responsible. Analyses of bovine livers are included as made by a modification of the dithiazone method of Bambach and Burkey,<sup>2</sup> which is described as neither a difficult nor lengthy procedure.

**Scrapie: A disease of sheep.—A review of the literature**, P. J. G. PLUMMER (*Canad. Jour. Compar. Med. and Vet. Sci.*, 10 (1946), No. 2, pp. 49-54, illus. 2).

**Survival of nematode parasites of sheep on pasture during summer**, E. R. DOLL and F. E. HULL (*Kentucky Sta. Bul.* 482 (1946), pp. 4).—These studies were planned to determine the longevity of parasitic larvae on permanent pasture when rested from grazing. The tests were made on two plots of permanent pasture measuring 10 by 20 ft., all of the surface being exposed to the sun except for shade of board fences around the plots. The herbage was Kentucky bluegrass, white clover, and wild grasses, kept clipped to a height of 2½ to 3 in. throughout the exposure period. Contamination was accomplished by scattering fresh sheep manure in pellet form over the plots. Egg counts on the feces ranged from 100 to 500 eggs per gram. About 2 gal. of pellets were scattered daily on each plot for 15 days, plot 1 being contaminated from June 1 to 15, inclusive, and plot 2 from June 16 to 30, inclusive. Animals were kept off the plots until October 1, when a test for infectivity was begun

<sup>2</sup>Indus. and Engin. Chem., Analyt. Ed., 14 (1942), No. 11, pp. 904-907.

by grazing the plots with two parasite-free lambs each. The lambs were permitted to graze for 2 weeks, removed to a bedded pen for 3 weeks, and then killed and the nematodes removed, identified, and counted.

In the viscera of the two lambs grazing on plot 1, which had an exposure period of  $3\frac{1}{2}$  mo., were found 2 tapeworms (*Moniezia expansa*) and 2 *Nematodirus filicollis*. No other nematodes were present in the gastrointestinal tract. From the second pair of lambs, grazing on plot 2 with an exposure period of 3 mo., 6 *N. filicollis*, 17 *Ostertagia circumcincta*, 4 *Haemonchus contortus*, and 2 *M. expansa* were recovered. Other nematodes were absent from the stomach and intestines. No lesions caused by nodular worms were found in any of the lambs, but ova of *H. contortus* and *O. circumcincta* were present in the feces of the lambs grazed on plot 2 when they were slaughtered.

"From these findings it was evident that keeping sheep off a pasture for 3 to  $3\frac{1}{2}$  mo. during midsummer and early fall should reduce nematode larvae on the pasture sufficiently for practical control. Combined with correct use of phenothiazine, pasture rotation should materially increase the efficiency of the parasite control program."

**Efficacy of phenothiazine in the treatment of sheep for control of internal parasites.** C. ELDER, O. S. CRISLER, and R. F. GENTRY (*Missouri Sta. Res. Bul.* 396 (1946), pp. 12, illus. 1).—Treating ewes once in December and once the following March with a full dose of liquid phenothiazine and every 28 days thereafter with 1.5 percent copper sulfate until the following December did not control nodular worm infestation even though at the beginning of the experiment the sheep were placed upon clean pasture. Neither did treating sheep with liquid phenothiazine every 4 weeks from December to March (giving a total of four treatments) and then giving them 1.5 percent copper sulfate every 28 days, although 1.5 percent copper sulfate solution was found very satisfactory in keeping the lambs free from *Haemonchus contortus*. However, treating sheep with liquid phenothiazine every 4 weeks from December to early April and then allowing them access to phenothiazine-salt mixture (1 part phenothiazine to 10 parts salt) was very satisfactory in controlling nodular worm infestation, and held the *H. contortus* infestation down to an average of about 19 per lamb. This method of handling did not satisfactorily control *Ostertagia*, *Nematodirus*, *Cooperia*, or tapeworms, and whipworm counts were not materially different in any of the three experiments. Average weight of the lambs was very much higher in this experiment. Phenothiazine was not found toxic to sheep either in a 1:10 phenothiazine-salt mixture or when the medicine was given as a drench every 28 days throughout the entire year, and its use has not interfered with breeding efficiency. Worm egg counts by the flotation method did not contribute any aid in this study, but are deemed useful in sheep infested with only one species of parasite or with species that can be definitely identified by microscopic examination alone.

**Abortion in sheep following the administration of phenothiazine.** B. L. WARWICK, R. D. TURK, and R. O. BERRY. (Tex. Expt. Sta.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 826, pp. 41-42).—Experiences are reported which indicated that phenothiazine may be toxic to ewes during the later stages of pregnancy. The period of danger is approximately 2 to 3 weeks prior to parturition.

**Studies on enzootic staphylococcal infection in lambs associated with tick-bite.**—I, The nature of the disease, clinical findings, and differential diagnosis, A. McDIARMID (*Vet. Rec.*, 58 (1946), No. 10, pp. 103-104).—A specific enzootic staphylococcal infection in lambs of various breeds is described as occurring on tick-infested farms throughout Great Britain. This infection is characterized by the development of suppurative foci in different parts of the body, including the skin, musculature, tendon sheaths, joints, viscera, and meninges. In addition to the pyemic form of disease, an acute infection also occurs, the diagnosis of which can only be

made by bacteriological methods. The disease frequently coexists with other infections such as louping-ill, lamb dysentery, pulpy kidney disease, and tick-borne fever.

**Infectious rhinitis in swine (bull nose),** C. E. PHILLIPS (*Canad. Jour. Compar. Med. and Vet. Sci.*, 10 (1946), No. 2, pp. 33-41, illus. 6; *Fr. abs.*, p. 41).—This is a preliminary report on an outbreak of an extremely infectious atrophic rhinitis in pigs which has been spreading very rapidly in Ontario, apparently through the introduction of infected breeding stock.

The infection becomes established shortly after birth, although visible signs are not observed until 2 to 4 weeks of age. The first indication is that of sneezing, this symptom becoming more exaggerated as the pig grows older. At from 3 to 6 weeks of age the skin on the snout begins to wrinkle and the snout usually appears to bulge or thicken, the observable distortion varying according to the head type. There is a constant progressive dissolution of the softer bony structures of the nose and a variable exudate apparently not that of necrosis. The tissue changes present a convenient channel for bacterial invasion with resultant encephalitis, although this takes a rather minor toll in the early stages. The majority of the affected pigs are rough and chronically poor doers, requiring up to 12 mo. to market.

Initial experiments indicate that a filtrable factor is the primary etiological agent, but that secondary organisms play a large part in the destructiveness of the disease. The organism most consistently isolated from the nose and secondary lesions was *Corynebacterium pyogenes*.

**A note on the tuberculin test applied to pigs,** A. L. CLAY (*Austral. Vet. Jour.*, 21 (1945), No. 5-6, pp. 149-150).—Tests with 64 brood sows are reported.

**Complement-fixing and neutralizing antibodies against Japanese B virus in the sera of Okinawan horses,** H. L. HODES, L. THOMAS, and J. L. PECK (*Science*, 103 (1946), No. 2673, pp. 357-359).—An outbreak of encephalitis among the natives of Okinawa was studied with relation to the possible role of horses. Tests of sera from nine Okinawan horses showed in all cases that the sera fixed complement in the presence of Japanese B virus in a final dilution of 1:16 or greater, but all failed to fix complement to a significant degree when tested against Western equine encephalitis virus and in three cases when tested against Eastern equine encephalitis virus. Other evidence was obtained by neutralization tests that these horses had been in contact with Japanese B virus. "The nature of this contact is not known, but the results described support the idea that horses may have been of epidemiologic importance in the outbreak."

**Penicillin treatment of acute equine infectious anemia,** L. O. MOTT, C. D. STEIN, and J. O. HEISHMAN. (U. S. D. A.). (*Vet. Med.*, 41 (1946), No. 4, pp. 131-136, illus. 4).—An experimental acute case of infectious anemia was produced, for penicillin treatment, with a particularly virulent strain of virus which had produced acute cases in 22 exposed horses, 20 of which had died. The usual clinical symptoms of acute swamp fever were noted. Penicillin treatment was started 23 days after the horse showed evidence of infection during the third temperature reaction. Six million units were administered intramuscularly over a period of 40 hr. at an average rate of 375 units per kilogram of body weight per hour. An initial dose of 1,000,000 units was followed by injections at the rate of 500,000 units every 4 hr. There was little response to treatment, and death ensued 14 days following the last treatment.

**An outbreak of salmonellosis in horses and mules,** D. R. CORDY and R. W. DAVIS (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 826, pp. 20-24, illus. 3).—An outbreak of eight cases which occurred in India among 300 horses and mules after sea and rail shipment from the United States is reported. Weakness, posterior incoordination, and fever were the most consistent symptoms. Severe gastroenteritis with hemorrhage and superficial necrosis of the gut mucosa was the most marked lesion. The cecum and colon were chiefly affected; the liver showed extreme fatty changes,

and the spleen was engorged with blood. *Salmonella morbificans* was isolated from the intestinal contents and urine.

**Preliminary studies on the absorption and excretion of streptomycin in dogs,** B. E. GRAHAM, M. J. VANDER BROOK, and M. H. KUIZENGA (*Science*, 103 (1946), No. 2673, pp. 364-365).—Streptomycin varying in potency from 100 to 500 units per milligram was administered to 14 dogs intravenously, intramuscularly, and orally in amounts of 100,000 to 420,000 units. High blood levels of streptomycin were observed after parenteral administration, and 23 to 65 percent was excreted in the urine of normal dogs. After 4 or 5 hr. only small amounts were detected in the blood. The maintenance of blood levels was no better with intramuscular than with intravenous administration. Following the oral administration of as much as 420,000 units of streptomycin, it could not be detected in the plasma, but up to 3.9 percent was recovered from the urine.

**Sulfathalidine in the treatment of enteric infections of small animals,** L. P. HEDEMAN. (Mich. State Col.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 827, pp. 89-91).—Response to sulfathalidine therapy is reported in 10 cases of canine enteritis and 4 cases of feline enteritis. In 1 case each of canine coccidiosis and feline panleukopenia, the results were less promising.

**The normal blood count of the domestic cat,** W. H. RISER (*North Amer. Vet.*, 27 (1946), No. 2, pp. 93-98, illus. 7).—Blood counts for 20 cats and 5 kittens are tabulated and discussed.

**Ablation of the scent glands of skunks,** R. K. ENDERS and E. M. PAXSON (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 827, pp. 84-86, illus. 7).—A method is described as having been used with considerable success on old and young animals which is not only relatively simple but if used with care avoids noticeable odor.

**Poultry diseases common to farm flocks,** R. CONNELL (*Canad. Jour. Compar. Med. and Vet. Sci.*, 10 (1946), No. 2, pp. 42-48).—This account deals especially with pullorum disease, tuberculosis, nutritional diseases, and respiratory diseases.

**Studies on nutrition and avian malaria, III, IV,** A. O. SEELE and W. H. OTT (*Jour. Infect. Diseases*, 77 (1945), Nos. 1, pp. 82-84; 3, pp. 181-184, illus. 1).—In part 3, Deficiency of "Folic Acid" and Other Unidentified Factors, *Plasmodium lophurae* infections were more severe, as judged by the parasite counts, in chicks deficient in folic acid and other unidentified factors than in chicks on an adequate diet. Continued passage of *P. lophurae* through chicks deficient in folic acid and other unidentified factors did not increase the severity of the infection beyond that reached in the initial transfer to the deficient host. Transfer of a *P. lophurae* strain to adequately nourished chicks after 13 passages through birds deficient in folic acid and other unidentified factors did not produce a disease that was more severe than that observed in infected chicks on an adequate diet.

In part 4, Protein Deficiency, *Plasmodium lophurae* infections were found to be more severe in protein-deficient chicks than in chicks on a diet containing an adequate amount of protein. Not only did the parasite counts reach much higher levels in the deficient birds than in controls on a high protein diet, but the mortality due to the disease was greater in the deficient birds. The protein deficient chicks were unable to clear the parasites from their blood streams as readily as were chicks fed a diet containing ample protein.

**The absorption of cinchona alkaloids in the chick and its relationship to antimalarial activity,** P. B. MARSHALL (*Jour. Pharmacol. and Expt. Ther.*, 85 (1945), No. 4, pp. 299-309, illus. 2).—The work described was designed to investigate how far the absorption, red blood cell, and plasma concentrations and rates of destruction of a group of cinchona alkaloids and derivatives could be correlated with their antimalarial activity in chicks infected with *Plasmodium gallinaceum*.

Determinations of the rate of absorption from the gut, red cell concentrations, and

antimalarial activity in chicks of the four natural alkaloids of cinchona and four derivatives showed that antimalarial activity was, in most cases, correlated with rate of absorption and red cell concentrations. In three optically active pairs of alkaloids, the *d*-isomers showed a greater rate of absorption, higher red cell concentrations, and higher antimalarial activity than the *l*-isomers. The rate of "destruction" of the alkaloids by chick liver suspensions was not related to optical configuration. Cinchonine and cinchonidine, unlike the other alkaloids, were not metabolized at all. Saturation of the double bond in quinine doubled the antimalarial activity. Dihydroquinidine, however, showed no greater activity than niquidine.

**Growth of protozoa in tissue culture.**—I, *Plasmodium gallinaceum*, exoerythrocytic forms, F. HAWKING (Roy. Soc. Trop. Med. and Hyg., Trans., 39 (1945), No. 3, pp. 245-263, illus. 29).—A technic is described for the cultivation of the exoerythrocytic forms of *P. gallinaceum* in tissue cultures of chicken cells of the macrophagoreticulo-endothelial type. It was found that cultures may be made from the spleen, buffy coat, marrow, and many other organs. Active multiplication of the parasites occurs, and living parasites have been recovered from these cultures after 89 days. Growth occurs in the presence of penicillin, 10 units per cubic centimeter.

Chickens can be inoculated from the cultures; exoerythrocytic forms appear at an early stage of the resulting infection, which thus resembles the infection produced by sporozoites rather than that produced by trophozoites. The infection can also be passed to cultures of clean chicken tissue, but passage is difficult and uncertain. It has not been possible to infect erythrocytes from these cultures.

Cultures have been made from the spleen of a chicken inoculated intravenously with sporozoites 1 hr. previously. It has not been possible to infect cultures of chicken cells by means of sporozoites.

Attempts were made to cultivate the endoerythrocytic forms of *P. gallinaceum*. Some parasites survived for 5 days, but no satisfactory multiplication could be obtained. Survival of the parasites was greatly improved by the presence of erythrocyte extract and of glutathione.

**Increased parasitemia in chicken malaria (*Plasmodium gallinaceum* and *Plasmodium lophurae*) following X-irradiation**, W. H. and L. G. TALIAFERRO and E. L. SIMMONS (Jour. Infect. Diseases, 77 (1945), No. 2, pp. 158-176, illus. 6).—Chickens with sporozoite- or blood-induced infections of *P. gallinaceum* or with blood-induced infections of *P. lophurae* were irradiated with 500 or 600 r. (roentgens) of X-rays at intervals beginning on the day of infection and with smaller doses (100-400 r.) of X-rays about 40 days after their initial infection. Irradiation induced increased parasitemia in both avian malaras but affected different periods of the two infections. Thus, in blood- or sporozoite-induced *P. gallinaceum* infections, irradiation on the day of infection produced a higher parasitemia and a statistically significant decrease in survival time of the host; during the acute rise and crisis of infections treated with quinine to reduce their severity, it was followed by acute fatal infections; and thereafter led to malarial relapses of varying degrees. On the other hand, in blood-induced *P. lophurae* infections, irradiation on the day of infection produced severe, often fatal, infections and only slight relapses thereafter. The effectiveness of a given dose of X-rays varied with the age and susceptibility of the chicken, the species of parasite, the period of the malarial infection, and the intensity of the infection prior to and at the time of irradiation. Also, as far as tested during the developed infection of *P. gallinaceum*, single doses from 300 to 600 r. were increasingly effective, with those of 100 or 200 r. being practically ineffective. In general, two doses totaling 500 r. or more within about a week of each other had a cumulative effect, but, in general, were not equal to single doses of the same magnitude.

**In vitro opsonic tests with *Plasmodium gallinaceum* and *Plasmodium lophurae*,** A. ZUCKERMAN (*Jour. Infect. Diseases*, 77 (1945), No. 1, pp. 28-59, illus. 5).—An opsonic test has been developed with macrophages grown in vitro from blood agranulocytes of chickens. Red blood cells from chickens having acute initial infections with *P. gallinaceum* and *P. lophurae* served as antigens, and serums from normal, homologous immune (initial latent infection) and homologous hyperimmune (after repeated superinfection) chickens served as test serums. Complement was not essential. Circulating antibody against normal and parasitized red cells from homologous infections was demonstrated in undiluted hyperimmune serums from chickens superinfected with *P. gallinaceum* and *P. lophurae*, but was not found in immune serums from birds recovering from acute initial infections. Phagocytic indices of undiluted hyperimmune serums were two to nine times as high as the normal controls for anti-*lophurae* serums and two to four times as high as the normal controls for anti-*gallinaceum* serums. These opsonic titers were of a lower order than those attained with antipneumococcus serum. The antibody in anti-*gallinaceum* hyperimmune serum was more efficiently absorbed by normal red cells than by an equivalent quantity of homologous parasitized red cells. *P. gallinaceum*-infected red cells were opsonized not only in vitro but in vivo under certain conditions. The phagocytic index of parasitized blood in normal serum was higher when the antigen was collected around the time of the crisis than when it was collected during the early acute rise or just after the crisis. The amount of phagocytosis in the presence of normal serum varied inversely with the amount of antigen when the latter was collected at the peak of the infection and during the immediately ensuing crisis.

**Infection of chick embryos with non-pigmented forms of *Plasmodium gallinaceum*,** V. H. HAAS, A. WILCOX, and F. M. EWING (*Jour. Natl. Malaria Soc.*, 4 (1945), No. 4, pp. 279-284).—Serial transmission in chick embryos of a form of *P. gallinaceum* infection characterized by predominance of exoerythrocytic forms has been carried through seven passages by inoculation of brain emulsion into yolk sacs. In addition to the predominance of exoerythrocytic forms and the low density of erythrocytic parasites, this infection has been noteworthy for the appearance of nonpigmented parasites in the red blood cells. Observations of these nonpigmented erythrocytic forms indicate that they have developed from merozoites released by exoerythrocytic schizonts, and that they are probably unable to produce pigment during their initial intraerythrocytic developmental cycle, but that they acquire this ability later. The results of this study indicate the ability of *P. gallinaceum* to survive indefinite serial transmission in chick embryos with negligible invasion of the erythrocytes and without manifesting that type of metabolization of hemoglobin which results in the production of malaria pigment.

**Immunological relationships of *Plasmodium gallinaceum* and *Plasmodium lophurae*,** W. H. and L. G. TALIAFERRO (*Jour. Infect. Diseases*, 77 (1945), No. 3, pp. 224-248, illus. 12).—Chickens immune (3-5 or 7-8 weeks after initial infection) or hyperimmune (following repeated superinfections) to *P. gallinaceum* and to *P. lophurae*, respectively, were tested for their homologous and heterologous immunity to these two species by reinjecting them intravenously with large numbers of plasmodia and ascertaining the time of the disappearance of the plasmodia from the blood. *P. gallinaceum* gave a marked homologous and heterologous immunity, whereas *P. lophurae* gave a marked homologous but only a slight, if any, heterologous immunity. These immunities were stronger after 8 weeks in chickens infected with *P. gallinaceum* and after 4 to 5 weeks in chickens infected with *P. lophurae*. Hyperimmunization by repeated superinfections fortified the immunity against *P. lophurae* but not against *P. gallinaceum*. These differences seemed to be correlated, in part, with the amount and specing of the hyperimmunizing doses and,

in part, with the fact that immunity to *P. gallinaceum* increases over a considerable period whereas immunity to *P. lophurae* diminishes more or less rapidly. Erythrocytic stages and sporozoites of both parasites were used for immunization, and erythrocytic stages and sporozoites of *P. gallinaceum* and erythrocytic stages (no sporozoites) of *P. lophurae* were used for the test injections. These stages reacted essentially similarly as measured by the parasitemia, and any differences seemed to be due to differences in the quantity of antigen absorbed by the chicken.

**Continuous intravenous chemotherapy of Plasmodium lophurae infection in ducks.** A. C. BRATTON, JR. (*Jour. Pharmacol. and Expt. Ther.*, 85 (1945), No. 2, pp. 103-110, illus. 1).—A method incorporating a simple rotary injection pump is described for continuous intravenous administration of drugs to ducks infected with *P. lophurae*. On the basis of dosage, quinine was more effective at the level of minimum therapeutic response when given intravenously in single daily doses than when given by continuous infusion; at a high level of response, the converse was true. At the level of minimum response, cinchonine was equally effective when given in single daily intravenous doses or continuously. Tartar emetic, sodium antimony thioglycollate, and mapharsen were effective in doses at or near the toxic level. Penicillin, streptomycin, and quinine were inactive in the doses employed.

The results suggest that quinine, quinacrine, and pamaquine each possess a different principal mechanism of drug action against *P. lophurae* in the duck.

**Cannibalism in chickens** (*Wash. State Col. Ext. Bul.* 334 (1946), pp. 4).—The causes of this condition and its prevention and control are discussed.

**On the chemotherapy of caecal coccidiosis (*Eimeria tenella*) of chickens.**—II, Further studies on the use of drugs in established infections, W. E. SWALES (*Canad. Jour. Compar. Med. and Vet. Sci.*, 10 (1946), No. 1, pp. 3-13, illus. 1).—Experiments on the chemotherapy of caecal coccidiosis of chicks have supported previous findings<sup>3</sup> that sulfamerazine (2-sulfanilamido-4-methylpyrimidine) and its sodium salt are strongly coccidiostatic and will check the disease when administered soon after bleeding from the intestine has commenced. The dimethyl and the unmethylated counterparts, sulfamezathine and sulfadiazine, are likewise coccidiostatic, but limited experiments have indicated that the fully methylated drug 2-sulfanilamido-4,5,6-trimethylpyrimidine and the 2-sulfanilamido-4,5-dimethylpyrimidine are inactive. Other chemicals, related only through the pyrimidine structure, did not show any indication of a coccidiostatic effect or of relationship to the activity of the parasite. Studies on dosage and period of treatment showed that 2 gm. of 2-sulfanilamido-4-methylpyrimidine per pound of feed or 2 gm. of its sodium salt per liter of drinking water should be used for 3 days, commencing as soon as bloody droppings appear, if optimum results are to be obtained from the use of this drug. A commercial preparation was found to have equal efficiency as long as dosage was increased to counteract dilution of the 2-sulfanilamido-4-methylpyrimidine by other ingredients. Measurements of the blood hemoglobin levels of infected chicks served as a valuable indicator of the extent of the disease and of the action of drugs. No toxic effects from the use of the active drugs in the dosages indicated were apparent.

**Sodium sulfamerazine in the treatment of cecal coccidiosis.** P. A. HAWKINS and R. RAUSCH. (*Mich. Expt. Sta.*). (*Poultry Sci.*, 25 (1946), No. 2, pp. 184-185).—Tests with 6-week-old White Leghorn chicks indicated that the soluble sodium salt of sulfamerazine in the drinking water is very effective in both the control and the treatment of *Eimeria tenella* infections. All birds consuming enough of the drug to reach the 5 to 6 mg. percent level previously found necessary with sulfamezathine (E. S. R., 93, p. 625) survived. No untoward results as manifested by weight changes were noted, and no gross pathological change other than a slight distension of the uriniferous tubules with a whitish substance, possibly urates.

<sup>3</sup> *Canad. Jour. Res.*, 22 (1944), No. 6, Sect. D, pp. 131-140.

**Prophylactic vaccination against infectious laryngo-tracheitis**, T. L. FURNISS (*Austral. Vet. Jour.*, 21 (1945), No. 5-6, pp. 142-146).—Experiences in New South Wales are reported showing that from 1940 to 1944, 950,000 cockerels and pullets between the ages of 8 and 20 weeks were vaccinated, with results in the main entirely satisfactory. In none of these did laryngo-tracheitis occur as a direct result of vaccination. In some cases, however, a temporary bilateral paralysis was noted.

**The occurrence and distribution of *Salmonella* types in fowl.—I, Isolation from hens' eggs**, F. E. CHASE and M. L. WRIGHT (*Canad. Jour. Res.*, 24 (1946), No. 1, Sect. F, pp. 77-80).—Using selective media, an examination of 2,400 hen's eggs was made to determine the incidence of *Salmonella* types in the egg or on the shell. The contents of 1,000 eggs laid by a flock of presumably normal hens did not yield any representative of the *Salmonella* group. Of a similar number of eggs produced by a flock of 55 known pullorum reactors, 61 were found to contain *S. pullorum*; no other *Salmonella* organisms were isolated. The exteriors of an additional 400 eggs obtained from the latter source failed to produce any *Salmonella* types.

**A note on artificially infected fowl as carriers of *Salmonella***, N. E. GIBBONS and R. L. MOORE (*Poultry Sci.*, 25 (1946), No. 2, pp. 115-118).—Following the authors' finding of *Salmonella* types in Canadian dried egg powder (F. S. R., 92, p. 730), the present study was undertaken to elicit some information on how long infected chickens carry the organisms and whether the organisms could be isolated from many of the eggs of infected birds.

Six Barred Rocks, approximately 18 mo. old, five of them pullorum positive, were observed over a period of 37 days before making any tests. Aqueous suspensions of *S. bareilly* were then fed, and the organisms were eliminated from the intestinal tract in 2 to 4 days. When broth cultures were fed, the organisms were excreted over periods of 18 to 38 days. Autopsies of a few birds which were excreting *S. bareilly* indicated that "in adult fowl the organisms apparently localize in the intestinal tract. It is therefore quite possible that eggs may be contaminated through fecal matter. In these experiments *S. bareilly* was isolated from the shells of 3 of 37 eggs laid while this organism was being excreted."

**Outbreak of gastroenteritis—*Salmonella pullorum***, R. B. MITCHELL, F. C. GARLOCK, and R. H. BROH-KAHN ([U. S.] *Off. Surg. Gen., U. S. Army Med. Dept. Bul.*, 5 (1946), No. 3, pp. 248-250).—An extensive outbreak of gastroenteritis at an Army air base in Texas is ascribed to *S. pullorum* from eggs combined with other ingredients in a rice pudding. Cultures of *S. pullorum* were isolated from 11.7 percent of the hospitalized patients and *S. derby* from 0.6 percent.

**Bacteriological examination of shells and contents of eggs laid by turkeys naturally or artificially infected with *Salmonella typhimurium***, H. C. GAUGER and R. E. GREAVES. (N. C. Expt. Sta.). (*Poultry Sci.*, 25 (1946), No. 2, pp. 119-123).—*S. typhimurium* was not recovered from the contents of 164 eggs laid by 6 turkey hens with natural *S. typhimurium* infection. Thirty-four of the 164 eggs were laid by 1 bird, proved infected at autopsy by recovery of *S. typhimurium* from blighted ova.

A total of 184 eggs laid by 12 turkey hens artificially infected with *S. typhimurium* were cultured. Of 117 eggs in which both the shell and contents were cultured, 27 had infected shells and 6 had infected shells as well as infected contents. In 15 eggs in which only the contents were cultured, none had infected contents. In 52 eggs in which only the shells were cultured, 5 had infected shells. At autopsy *S. typhimurium* was recovered from one or more sites in 8 of the 12 hens.

**Experimental edema and ascites in poults**, L. H. SCRIVNER (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 826, pp. 27-32).—Experiments to determine the cause of this disease are reported in which the effect of sodium bicarbonate, carbonate,

citrate, iodide, hydroxide, and sulfate and of carbonated water was studied. It was found that sodium chloride and bicarbonate, when administered to poult in proper proportions in feed or water, will produce the disease, and that other sodium compounds may also do so provided the effective level is not so unpalatable as to prevent consumption. All the sodium compounds tested appeared to be lethal at comparatively low intake levels, and it also appeared to be possible that formaldehyde fumigation, which was also tested, could be a cause. It is suggested that investigations should be made of the sodium intake of poult flocks from which losses are reported from edema and ascites.

**Nicotinic acid deficiency in turkey poults and the occurrence of perosis**, G. M. BRIGGS. (Md. Expt. Sta.). (*Jour. Nutr.*, 31 (1946), No. 1, pp. 79-84, illus. 1).—Turkey poults fed a highly purified diet containing all necessary nutrients except nicotinic acid grew poorly and developed certain deficiency symptoms such as inflammation of the mouth, diarrhea, low feed consumption, poor efficiency of feed utilization, poor feathering, and perosis. The perosis in the deficient birds occurred in spite of ample manganese, choline, and biotin in the diet. All symptoms were prevented by the addition of 3 to 5 mg. of nicotinic acid per 100 gm. of ration, but it is thought that higher levels may be needed for optimum growth.

**Duck disease at Tulare Lake**, D. D. McLEAN (*Calif. Fish and Game*, 32 (1946), No. 2, pp. 71-80, illus. 2).—An outbreak caused by the toxin of *Clostridium botulinum* type C is described. This outbreak started in the Tulare Lake area in 1938 after the heavy runoff floods of that spring and summer. It continued each late summer and fall through the years following until 1945, when little or no disease was in evidence. The outbreak was associated with irrigation procedures whereby post-harvest flooding and slow withdrawals of water resulted in extensive decomposition of vegetable and animal matter. Changes in the methods in 1942 whereby standing water was avoided are credited with the subsequent reduction of the disease.

## AGRICULTURAL ENGINEERING

**Training agricultural engineers to meet today's challenge**, G. B. NUTT. (Clemson Agr. Col.). (*Agr. Engin.*, 27 (1946), No. 3, pp. 112, 130, 133).—This is a general discussion of the largely increasing demand for graduates in agricultural engineering, the need for improved teaching facilities in this department at many institutions, the desirability of more practical training in the teaching of this subject, the need for more opportunities for graduate work in agricultural engineering, "a critical need" for textbooks of a more technical character, etc.

**[Agricultural engineering studies in Colorado]** (*Colo. Farm Bul. [Colorado Sta.]*, 7 (1945), No. 6, pp. 2-4, 6, illus. 2).—Brief reports are made entitled Sugar Beet Growers Look to Mechanical Harvesters to Solve Labor Problems, by E. M. Mervine and R. T. Burdick (pp. 2-4); and Mechanical Post-Hole Digger Digs Hole 30 Inches Deep in 40 Seconds (p. 6).

**A practical and inexpensive irrigation headgate frame that is easy to make**, W. P. KINTZLEY (*Colo. Farm Bul. [Colorado Sta.]*, 7 (1945), No. 5, pp. 8-9, illus. 2).—The sides of the frame consist of two lengths of 2 in. by  $\frac{3}{8}$  in. angle iron welded at top and bottom to two pieces of  $2\frac{1}{2}$  in. strap iron. Four burs are welded to the inside of the outward-turned fin of each of the side pieces and far enough out to permit free vertical movement of the gate. Eight bolts are welded to the back of the frame to project into the concrete into which the frame is to be set. A catch to hold the gate at any desired degree of opening consists of a short piece of strap iron pivoted upon a single bolt attaching it to the outer face of the gate near one edge, over which it projects just enough so that it will press against the side

angle iron and will not pass over center. As illustrated, the frame is for a bell tile 15 to 18 in. in diameter, but it may be made in any size. The frame should be made to the measure of the tile bell, and may then be placed against a tile 3 in. larger without retarding water flow.

**Slash disposal on the Colville Indian Reservation, H. WEAVER** (*Jour. Forestry*, 44 (1946), No. 2, pp. 81-88, *illus.* 5).—Because of risk of damage to remaining trees "there has had to be a constant compromise between cost and proper insurance against fire." Mechanical piling with equipment somewhat similar to that described in the succeeding article, together with spot burning controlled by methods here carefully detailed, was found to give much better fire protection and to permit better forestry than did hand piling.

**Development and use of Forest Service slashbuncher teeth, L. L. COLVILL.** (U. S. D. A.). (*Jour. Forestry*, 44 (1946), No. 2, pp. 89-91, *illus.* 1).—Slash bunching by means of a commercial rock blade attached to a caterpillar tractor was not generally found preferable to hand bunching when first tried but came into use when hand labor ceased to be available. It required various additions to the tractor for the protection of machine and operator. An attachment of the buckrake type to be used on a bulldozer could not be made universal because of wide variations in the frames of these machines. Removable teeth fitted to the conventional bulldozer blade (a device attributed to W. L. McDonald, equipment engineer, U. S. D. A. Forest Service) furnished the practical solution. In the design adopted, the teeth for a 30-40 size tractor are of mild steel, 1.5 in. thick, 4 in. wide at the bottom tapering to 2 in. at the top, and 5 ft. long. They extend 20.75 in. above the top of the bulldozer blade to provide protection for the radiator, and approximately 6 in. below the cutting edge of the blade to allow room for dirt to sift through. Each tooth is shaped to fit the curve of the blade. A shoe 4 in. wide and 9 in. long, rounded in front and tapered behind, is welded to the bottom of the tooth to keep it from digging into the ground. The cutting edge of the blade rests in a clip welded to the tooth at the desired distance above the ground. A set screw slightly above the top of the blade serves to draw the tooth tightly against the blade vertically. An anchor block is welded to the top and back side of the blade to hold a "U" bolt which serves to pull the tooth snugly against the blade. Two small blocks are welded near the bottom of the blade on each side. A web is welded in the bend of the tooth to add strength. Four teeth make a set. The two end teeth are fastened to the blade a few inches from the ends, and the other two are located to equalize the remaining distance.

In practical use it was found that "an inexperienced operator can do irreparable damage to the residual stand and run up the cost in excess of piling by hand, whereas an experienced tractor operator can, in most cases, lower the cost and do far better work than can be done with hand labor. The job will be better because with machinery it is possible to include the large fuels such as pitch tops, down snags, cull logs, and large limbs not possible to pile by hand." Cost of the operation varied from \$8 to \$14 per acre. Some tractor bunching was contracted at from \$10 to \$10.50, as compared with hand work under like conditions contracted at from \$14 to \$15 per acre and limited to material less than about 4 in. in diameter.

**Farm power, J. B. DAVENSON.** (Iowa State Col.). (*Agr. Engin.*, 27 (1946), No. 3, pp. 131-133, *illus.* 3).—The author outlines the development of the use of power for farm work from the stage of almost purely hand labor, still existent in 1776, to the present average use of about 10 hp. of motor capacity "for each person gainfully employed in agriculture." Comparing this available power with the average output of 0.1 hp. by a man in good physical condition during an 8-hr. day and with the farm labor power available in the slave labor era, he notes that "each worker has the equivalent of 100 slaves to aid him. This is about the number wealthy slave holders had in the time of the Revolution."

With reference to probable future developments, the author notes general agreement among engineers that much of the advantage of the light weight of the internal combustion engine in proportion to available power is lost in the practice of weighting the tractor to give traction. Self-propelled machines avoid this waste. There is need also of a variable-weight tractor, provided with "a ready and conventional means of changing weight as needed." The need for variability of power output by variation of motor speed is also pointed out. "At the present time farm engines must be operated at the most desirable speed for the heavy power tasks, and are thus operated very inefficiently at light loads. A variable-speed motor operating, say, at a speed of 1,600 r. p. m. when 40 hp. is required, and at only 400 r. p. m. when 10 hp. is needed, would not only make for economy of fuel consumption but would extend the life of the engine." It is concluded that "the changes in the application of power to farm operations in the years ahead may be the most significant of those of all time."

**Preliminary report on ear corn drying**, F. D. YUNG (*Nebraska Sta., Agr. Engin. Prog. Rpt. 14* (1946), pp. 4, illus. 2).—Experiments on corn drying by forced draught ventilation and on drying at temperatures of from 200° to 300° F. are described. In a round wire crib with raised floor, shelling trench, and slatted vertical central ventilator, about 1,000 bu. of ear corn of 26 percent average moisture content when cribbed were dried in about 2 weeks by the use of a 24-in. double-inlet centrifugal fan to an average moisture content of 16.37 percent, the air having been driven into one end of the shelling trench, of which the other end was blocked. Heat from a weed burner was used during 12.5 hr. to raise the temperature of the air input to about 25° above that of the outdoor air. Detailed operational data from this experiment are given.

In the heated air drying experiments, drying temperatures from 190° to 200° cause no damage visible in the ear corn, but shelling showed the germ ends of the kernels shriveled, somewhat brittle, and discolored. Similarly, rapid drying at air temperatures of about 300° caused discoloration visible in the ear corn, numerous heat-damaged kernels being found in the shelled corn. The hot-air dried corn was not significantly different from that dried at room temperature with regard to carotene and amide nitrogen content. Comparative feeding experiments (white rats) gave somewhat inconclusive results as to any effects upon nutritional value.

**A forced ventilation hay drier**, A. T. HENDRIX. (U. S. D. A. coop. Va. Expt. Sta.). (*Agr. Engin.*, 27 (1946), No. 3, pp. 113-116, 120, illus. 7).—The author reports upon the design principles, construction, and performance of a drier of the central duct and slatted floor type having some features not hitherto in general use. The system is of relatively simple construction, does not require high quality or dressed lumber, and was found to provide good air distribution with low pressure loss in the system. Performance and results have been very satisfactory in the experimental trial under an initial 14-ft. depth of hay, about 5/6 alfalfa, the remainder being soybean hay added on top. The quality of the hay produced, though not graded officially, was considered excellent.

**Factors controlling the rate of moisture removal in barn hay-curing systems**, C. E. FRUDDEN (*Agr. Engin.*, 27 (1946), No. 3, pp. 109-111, illus. 7).—Observations and deductions here discussed led to the following conclusions:

To ensure production of hay free from mold, the drying rate must be such that the moisture content of all damp hay will be reduced to 10 percent within 7 days after it is placed in the mow. The rate of moisture removal is governed by the temperature and humidity ("condition") and by the quantity of the air passing through the drying zone. The air delivered by the fan is not all effective for drying, since there is a leakage loss through paths offering an air-flow resistance less than that of the drying zone. This leakage loss was found to be least when the

mow walls are smooth and airtight and the hay next to the walls carefully tramped, chopped hay offering a drying zone air-flow resistance greater than that of long hay. An increasing proportion of leakage loss with increasing depth of the hay was found to limit the successful application of floor duct systems, the air pressure required being increased or the volume delivered decreased with increasing depths of hay. These factors may reduce the drying rate at a 20-ft. level to not more than one-third of that attained in hay 5 ft. deep. An illustration shows a portable engine blower described as delivering 20,000 c. f. m. against 1.5 in. static pressure and arranged to utilize waste heat from the engine to warm the air input.

**Calculating fan, motor, and duct requirements, G. R. SHIER** (*Agr. Engin.*, 27 (1946), No. 3, pp. 121-122).—Although he finds each installation an individual problem, the author feels that some parts of the mow hay-curing system may be standardized. Particular stress is laid upon the bearings, which must ensure that the fan will operate at full load continuously and without failure for two or more weeks after lying idle during winter and spring. Bearings “of the highest quality.” sealed against loss of lubricant or entrance of air, are held to be required. As a good “rule of thumb” for fan selection, the author proposes that the readily measured fan outlet should provide at least 1 sq. ft. for each 2,500 c. f. m. at  $\frac{1}{2}$ -in. static pressure and at least 1 sq. ft. for each 2,000 c. f. m. at 1-in. static pressure. More air can be forced through fans than this would indicate, but it usually requires excessive power. Somewhat slower outlet velocities are usually more efficient in the use of power. To avoid the cost of special V-belt pulleys, motors having shafts larger than  $1\frac{1}{2}$  in. should not be selected. Because of limited power capacity often encountered in rural service lines, motors capable of being brought up to speed at low voltages are to be desired.

Air duct design is dealt with in somewhat less detail, emphasis being given especially to designing in accordance with detailed knowledge of the given mow and with the method to be used in placing and removing the hay. In connection with design of the lateral system, either inverted trough or slatted floor, compensating for unequal air resistance in the hay load is given first consideration. Subfloor distribution is held to be of little present importance.

**Factors affecting the nutritional value of forage plants, H. A. MACDONALD.** (Cornell Univ.). (*Agr. Engin.*, 27 (1946), No. 3, pp. 117-120, illus. 1).—The factors referred to are those involved in the cutting, curing, handling, and storage of grass, leguminous, and mixed hays. The points considered in the quality grading of hay, though related to its nutritional value, are held to serve only as a general guide, nutritional value being more accurately measurable by digestibility and by protein, carbohydrate, mineral, and vitamin content. Although legumes are usually of a nutritive value higher than that of grasses, the yield of most perennial herbage plants increases rapidly during the early stages of growth, is fairly constant during the flowering period, and declines thereafter. In the case of annual and biennial plants the decline following flowering is much less marked. Nutritional values discussed in relation to mechanical and timing factors in haymaking include carotene content, leaf loss, difficulties in either field or barn curing introduced by the matting of succulent forage upon wilting, dry matter losses due to heating in storage, which are shown to affect first and most largely the components of the most nutritional value (proteins, carbohydrates, and vitamins) even when the heating falls considerably short of spontaneous combustion temperatures, leaching losses occurring upon exposure of partially or fully cured hay to wetting, losses caused by cell respiration after cutting, etc. Numerous data, tabulated or cited in the text, are brought together to show the importance of the factors considered.

“The difficulty of curing hay plants at their most nutritious stage of growth, without excessive loss, and the problem of maintaining their high nutritional value during

handling and storage is one of the greatest problems facing us today in the field of forage production. It would seem therefore that, at the present time, greater advances can be made in this field through the development of improved ways and methods of handling forage efficiently than by any other means."

**Water for the modern farmstead** (*U. S. Dept. Agr., 1946, AIS-44, pp. 4, several illus.*).—A layout design taking water to every point in the house and farmstead where it is needed is shown in a diagrammatic drawing, overhead irrigation being included both in the lay-out drawing and in the statement of data upon which to base total requirements of a water system "easily adaptable to most modern farmsteads." The type of pump needed and its protection from freezing are briefly dealt with, a capacity of 350 gal. per hour and a 42-gal. storage tank being mentioned as generally minimal for average farm use. Pipe sizes are indicated only in the general caution to "be sure that all pipes are large enough" to avoid inconvenience or such injuries as scalding of a bather by the turning on of the cold water at another point in the circuit.

**Electrical heating of water for livestock**, J. B. DOBIE (*Washington Sta. Bul. 182 (1945), pp. 11, illus. 4*).—Various methods of using electric light globes as a source of heat warmed the water satisfactorily but proved impracticable in other ways.

Hotbed-warming cable covered with deproteinized rubber was successful and practical in a number of experiments here reported, both those carried out in a refrigerator room kept at a temperature of from 6° to 8° F. and those made in actual working conditions under which temperatures near 0° were satisfactorily met. In the refrigerator experiments, water in a shiplap box 30 in. square and 24 in. deep immersed in a metal stock watering tank was maintained at 60° by the continuous operation of two 200-w. hotbed cable units. With the use of a thermostat set at 50°, current consumption was 276 watts; at 40°, 208 w. In outdoor trials at two locations in successive winters, a thermostat setting of 36° was used, and was sufficient to prevent formation of more than a surface film of ice at any time. The first of these outdoor tests required a total of 406 kw.-hr. from December 20 to March 15; the second, 435 kw.-hr. from Dec. 26 to March 25.

Under the head of recommendations, precautions necessary to avoid risk of shorts, shocks, and fire hazards are emphasized. A bill of materials with approximate costs is appended.

**Planning your farmstead wiring and lighting** (*U. S. Dept. Agr., Misc. Pub. 597 (1946), pp. 31, several illus.*).—This publication is intended as a guide to the correct placement of an adequate number and type of lighting fixtures, other outlets, and switches in typical farmhouse rooms, closets, halls and stairways, and porches; yard light systems; and such work buildings as the pump house, barn, milk house, hen house and brooder, hog house, and farm shops. Many of the conventional symbols used in wiring plans are explained and are used in the drawings indicating probable needs in rooms and work spaces. The wiring itself is regarded as a technical job, to be left to the wiring contractor. Only such technicalities as need to be understood for planning an efficient system are here discussed.

**The needs of a farm structures program**, D. G. CARTER. (*Univ. Ill.*). (*Agr. Engin., 27 (1946), No. 3, pp. 123-124*).—Points especially considered in this general discussion are: (1) A more adequate concept of the need for and functions of farm structures; (2) offsetting existing deficiencies; (3) farm dwelling improvement; (4) farmstead organization for efficiency, health, and enjoyment; (5) definition of functional requirements; (6) farm structures research; (7) extension education; (8) training of personnel; (9) planning services; and (10) coordinating and integrating industry and public service activity.

**A small rigid summer shelter**, L. M. BLACK (*New Jersey Stas. Hints to Poultrymen, 32 (1945), No. 4, pp. 4, illus. 1*).—Detailed plans with a bill of materials for the

construction of a rigid type of summer shelter to house 90 growing pullets to maturity are presented. The author states that among the principal advantages for the small type unit are that it is more practical than the collapsible type of shelter, can be economically constructed, will promote health in the birds assigned to it, and will tend to prolong the life of crops on the range area. With a little planning an attendant can take care of a great many birds distributed in these smaller type structures, and the percentage of good pullets that will be harvested from them will undoubtedly exceed the percentage that will result if larger, more cumbersome shelters are provided.

**Electric ventilation of poultry houses, G. W. KABLE** (*Agr. Engin.*, 27 (1946), No. 2, pp. 61-66, illus. 8).—The author reviews the present engineering design recommendations and developments in electric ventilation for poultry housing. He points out the need for more basic and fundamental functional data to aid in overall designs and lists the following items as suggested investigational challenges to research: (1) At just what threshold temperature or difference in inside and outside temperatures is the health and production of a hen hazarded; (2) what is the actual heat and moisture production of hens of different breeds, ages, and weights under different environmental conditions; (3) what is the critical relative humidity to preserve health and production under flock conditions; (4) how much water must be evaporated from droppings and removed by ventilation to keep litter in usable condition; (5) why does litter keep drier the second year than the first year of use; (6) can a figure be determined for the cubic feet per minute per bird which must be removed by ventilation in the different housing zones and for different size hens; (7) we need more data on the heat retained in buildings and in the ground that is available as a supplement to the heat produced by the hens; (8) additional studies are needed on number, types, and spacing of intakes, bearing in mind that the cost should be kept low and windows used, if possible; (9) the effect of recirculation in providing higher temperatures at floor or roost level and other desirable conditions merits further study; (10) studies should be made of actual suction pressures developed within typical insulated and uninsulated houses when exhausting 1 to 4 c. f. m. of air per hen to learn the actual pressures against which fans must operate; (11) special poultry house ventilation fans need to be made available with nonoverloading and noncorroding blades that are easy to keep clean, reasonably low in cost, and driven by fire-safe motors capable of operating continuously for 5-mo. periods with little attention; and (12) should air volumes be controlled at low temperature peaks by manual control of intakes or outtake dampers, or by automatic thermostats or solenoids.

In summing up the over-all ventilation problem the author states that sufficient information is available to warrant the installation of electric ventilation systems in poultry houses. They should be watched, however, and studied for possible improvements in design and operation. Suitable fans are needed at prices which will permit rugged construction and carefree operation without making the ventilation cost prohibitive. It must be decided whether the most important consideration in ventilation is dry litter, dry walls, unfrozen water, the poultryman's comfort, etc., and design for that purpose. Research work on the effect of ventilation on hens should be extended.

Electric ventilation is justified only if it does a better job or does it cheaper or more reliably than other systems of ventilation. Ventilation is only one factor in poultry management. It must be considered in connection with building insulation, feeding, labor requirements, and other management problems, and not as an end in itself.

**The application of mechanical refrigeration to ranch egg cooling, F. W. LORENZ.** (Calif. Expt. Sta.). (*Agr. Engin.*, 27 (1946), No. 2, pp. 69-73, illus.

5).—Studies made on the rate of temperature loss from eggs enabled the development of a general expression relating cooling rate to air velocity under various conditions. It was found that rapid cooling minimized moisture loss from eggs and albumen quality was not affected by the cooling rate within wide limits. Tests of a specially designed experimental refrigerated egg-cooling cabinet, suitable for use on a poultry ranch of moderate size and operated at a temperature of 55° F., gave appreciable improvements in egg quality over the quality of eggs cooled and held in an evaporative cooler egg room. Of those eggs tested, the difference reported in grade represented an extra 2.8 doz. of grade AA eggs per case of eggs cooled in the refrigerated cooler. Had the comparison been made with eggs held in the feed house (as they are on many ranches), the differences would have been more striking. During one 3-week period in August and September, 555 doz. eggs were cooled in the experimental cooler and 1,173 doz. were held in the egg room. At the prevailing prices an additional income of \$7.61 was obtained from the eggs cooled in the experimental unit, with a total power cost of operation during the test period of only \$1.81.

**A water cooled egg storage cabinet, F. D. YUNG** (*Nebraska Sta., Agr. Engin. Prog. Rpt. 13* (1946), pp. 3, illus. 3).—This cooler consists of an insulated cabinet provided with a fin and tube cooling coil through which air is drawn by an electric fan and circulated through the cabinet. In baskets, the eggs nearest the fan were cooled quickly, the remainder not sufficiently rapidly. In mesh-bottomed pails set over holes slightly smaller than the bottoms of the pails and cut through the floor of the cooling compartment, the eggs were cooled with uniform rapidity, well water at about 57° F. in the cooling coil maintaining an egg temperature of from 60° to 65° in an ambient air temperature as high as 110° and preserving the eggs in good marketable condition for a week. The cabinet as shown contains a storage compartment in addition to the initial-cooling section with two floor holes for mesh-bottomed pails. The high humidity needed for satisfactory storage of eggs was maintained by means of wet sand placed in the bottom of the cabinet.

## AGRICULTURAL ECONOMICS

**Farm production in war and peace, G. T. BARTON and M. R. COOPER** (*U. S. Dept. Agr., Bur. Agr. Econ., 1945, F. M. 53, pp. 85+, illus. 19*).—Wartime and prewar changes in farm production and production per worker are measured and analyzed through the use of two recently developed indexes—gross farm production and farm output. The methods used in constructing the new indexes are described. They “supplement in two important respects the Bureau of Agricultural Economics index of volume of agricultural production for sale and home consumption which has been published since 1928. The gross-farm-production index includes farm-produced power of horses and mules as an item of farm production, whereas the production-for-sale-and-consumption index does not. The production-for-sale-and-consumption index is available for the United States only, but the farm-output and gross-farm-production indexes have been constructed for each of the nine census geographic divisions as well as for the United States, thus making possible an analysis of important geographical changes in farm production. All three of these index series are needed in order to analyze farm-production changes adequately.” Other sections of the report describe, analyze, and discuss war and prewar gross farm production and output, the changes in composition and wartime increases in gross farm production, the factors responsible for wartime increases in farm output, wartime and peacetime farm employment and gross production and output, size and nature of the wartime farm labor job, how farm workers did the wartime production job, and after the war. The two new indexes, the production-for-sale-

and-consumption index, and the Works Projects Administration indexes of agricultural production and output per worker are compared. The index of crop production per acre used in the present report and the crop-yield index of 28 crops, published by the Bureau of Agricultural Economics, are also compared.

**Feed grains and meat animals in war and peace**, C. W. CRICKMAN (*U. S. Dept. Agr., Bur. Agr. Econ., 1945, F. M. 51, pp. 55+, illus. 23*).—"The purpose of this report is to trace the developments in production and consumption of feed grains, meat animals, and meat during the two World Wars and intervening years, and to explore the circumstances which may influence the course of changes during the early postwar period." Tables and charts are included and discussed, showing the changes since 1910 in the acreage and production of corn, oats, barley, and sorghums; total feed consumption; hog production; numbers of beef cattle, sheep, and lambs; and prices of meat animals and feeds. Wartime changes in feed grains and meat production and consumption are discussed. Other sections deal with the situation in the near future and longer-time postwar prospects.

**Agricultural land ownership and operation in the southern San Joaquin Valley**, E. E. WILSON and M. CLAWSON (*U. S. Dept. Agr., Bur. Agr. Econ., 1945, pp. 100+, illus. 16*).—"Presented here is a brief historical statement of the major events in the disposal of public land in the San Joaquin Valley and the subsequent settlement, ownership, and operation of land up to 1940. The major part of the report is devoted to presenting factual information on landownership and land operation in the agricultural portions of Madera, Tulare, and Kern Counties. Some consideration is given to the effect of the present Reclamation law and of possible modification in this law upon the pattern of landownership and land operation which might be expected to develop after the Central Valley Project is completed."

**Economic land classification of Fluvanna County**, G. W. PATTESON and F. V. SHELTON (*Virginia Sta. Bul. 371 (1945), pp. 9, illus. 1*).—"The primary object involved in the preparation of the economic land-classification maps and reports of Virginia counties is to designate those areas of land which are not adapted to farming from those which are suitable for agricultural production. This delineation of the submarginal land from the marginal or better agricultural land is necessary to the development of a land utilization program in the State." General descriptions are included of the county and of the purpose of economic land classification. The agricultural trends, economic soil groups, and the agricultural and land potentialities of the county are discussed. The land classes are defined. A map of the county, accompanying the bulletin, shows the areas in different land classes and the types of roads and buildings. Tables show the percentages of lands in different land classes; by census periods, 1879-1940, the land in farms, acreages in important crops, and numbers of different kinds of livestock; the value of farm products sold, traded, or used by farm households in 1939, and the variation in total value; and the classification of farms by major source of income.

[**Economic land classification in Virginia counties**] (*Virginia Sta. Buls. 372 (1945), pp. 10, illus. 1; 376, pp. 7, illus. 1; 379, pp. 7, illus. 1; 385, pp. 9, illus. 1*).—These bulletins continue the series noted above. The counties included are: Bulletin 372, Greene County, by G. W. Patteson and F. V. Shelton; Bulletin 376, Shenandoah County, by G. W. Patteson and S. C. Shull; Bulletin 379, Culpeper County, by G. W. Patteson and A. J. Harris; and Bulletin 385, Botetourt County, by G. W. Patteson and J. A. McCartney.

—**Michigan farm organization and practices: Type-of-farming area 9**, L. H. BROWN (*Michigan Sta. Spec. Bul. 336 (1946), pp. 32, illus. 3*).—"This study was made to learn which enterprises and practices are becoming established and the relative profitableness of the various types of farming." It is based chiefly on information from account records kept by farmers during the period 1936-43, and more

detailed information obtained in 1942 and 1943 by visits to 33 of the farmers. The history of the area (Arenac, Clare, Gladwin, Iosco, and Ogemaw Counties) and the lands are described briefly. The cropping program, the livestock program, the combination of enterprises, and organization on farms typical of the area are discussed. A chart shows the land utilization and land classes by counties. Tables show, among other things, the cropping pattern and crop yields on the farms studied; the livestock programs—numbers of animals, income, etc., from cattle, poultry, hogs, and sheep; the relation of dairy product sales and cattle income to farm earnings; and by counties, the utilization of land in 1940, and the proportion of land in various soil classes. Another table compares the size of business, crop programs, livestock programs, number of men, and other items on farms with typical organizations. The productive days' work per man per year and the labor income for these organizations were: Small dairy, 234 days and \$1,213; medium-size dairy, 341 and \$1,788; dual-purpose cattle and sheep, 242 and \$1,288; dairy, beef, and sheep, 331 and \$3,178; and beef breeding herd, 204 and \$309.

**Facts about cotton and southern farming** (*U. S. Dept. Agr., Misc. Pub. 594 (1946), pp. 64, numerous illus.*).—This publication, prepared in cooperation with the State Agricultural Extension Services, presents pictorially background information for farm leaders in the cotton section.

**A farm management analysis of dairy farming in Putnam County, Georgia, 1944**, J. C. ELROD and W. E. HENDRIX (*Georgia Sta. Bul. 244 (1945), pp. 55, illus. 24*).—"The primary objectives of the study have been: (1) To provide an analytical description of farms engaged in dairying, including their utilization of land, capital, and labor, their production rates, and their efficiency and success of operations; (2) to describe the dairy enterprise, including its use of land, buildings, and equipment, its labor requirements, production practices, and costs and returns; and (3) to ascertain factors generally associated with successful operations." It is based mainly on the 1944 operations of 54 farms from which milk was delivered to the Eatonton Cooperative Creamery. Data as to milk sales, feeds, supplies, etc., were obtained from the creamery. Data on 1944 operations were obtained in a field survey. Census reports, soil surveys, and other sources of data were also used. The county and the development of dairying in it are described. Analyses are made of the amount and distribution of capital, land use, crop acreages and yields, the livestock enterprise, labor organization, expenses, receipts, income, etc., for the farms studied, and also of the size of dairy herds, production rates, feeding practices, distribution of labor, buildings and equipment, costs, receipts, etc., for the dairy enterprise. More detailed analysis is made of the effects on returns of size of business, labor efficiency, production rates, cost of producing milk, milk prices, and balance of the farm business.

Some of the findings were: Milk sales accounted for 72.8 percent of the farm receipts, milk subsidy for 11.4, and crops for 7.2. Average milk production per cow on a 4 percent butterfat equivalent was 4,888 lb. Net cost of milk production averaged \$3.65 per 100 lb. Income to operator for labor and management averaged \$1,652 per farm. "As the number of factors in which the farm operator was average or above increased, the labor income increased. Farms that were below average in all of five factors (productive man-work units, production index, work units per man, proportion of man labor applied to cows, and number of cows) had an average labor income of only \$282. Farmers above average in only one factor had an average labor income of \$637, in two factors \$1,839, in three factors \$2,038, in four factors \$2,775, and in five factors \$4,571. A comparison of the 10 best farms with the 10 poorest farms indicates that the former were twice as large as measured by productive man-work units, had 26 percent higher production rates, made 28 percent more efficient use of labor, made 14 percent more efficient use of capital, had 149

percent more improved pasture per cow, purchased 28 percent less of the feed used, and had net cost per 100 lb. of milk produced 27 percent less than did the 10 poorest farms. Family-operated dairy farms in 1944 had a family labor income averaging \$1,904 compared with \$439 for family-operated cotton farms. Labor income on the two types of farms would have been about the same had milk sold for around \$2.45 per 100 lb. instead of for around \$4. Without the milk subsidy, income from the two types of farms would have been about equal had milk sold for around \$3.10 per 100 lb."

**Economic studies of vegetable farming in New York.**—III, **Truck crop production and prices**, E. G. MISNER ([*New York*] *Cornell Sta., A. E. 546* (1946), pp. 46+, *illus. 5*; *A. E. 551*, pp. 33+, *illus. 5*).—These are the second and third supplements to Bulletin 679 (E. S. R., 78, p. 711). No. 546 includes data on acreages, yields, production, prices, and farm values, 1936–45, and supplements A. E. 480 (E. S. R., 92, p. 718) by the addition of data for 1944 and 1945. No. 551 covers the years 1928–45, and is "based on revised estimates of acreage, yields, production, prices, and values by the Bureau of Agricultural Economics, U. S. Department of Agriculture."

**Practices used in the production, canning, and marketing of northwestern Arkansas tomatoes in 1940–41**, O. T. OSGOOD and T. R. HEDGES. (Coop. U. S. D. A). (*Arkansas Sta. Bul. 460* (1945), pp. 45, *illus. 4*).—"The purpose of this study has been to bring together a statement of the conditions, methods, and practices used in producing, canning, and marketing northwestern Arkansas tomatoes, to indicate the more efficient procedures being used, and to determine the quality and competitive position of tomatoes canned in the area." The operations of 77 tomato producers were surveyed during the fall and winter of 1940–41, and operators of 48 canneries were interviewed during the winter and spring of 1940–41. A total of 485 usable schedules were returned by buyers in 304 counties in 16 States. The farms on which tomatoes were produced and the tomato enterprise are described. The canneries and their operations are discussed and analysis made of the cost of canning tomatoes. The section on marketing discusses the Ozark pack, the marketing channels and practices, market area for Arkansas canned tomatoes, and the competitive position of Arkansas canned tomatoes. Some of the findings were:

The average production per farm in 1940 was 4 acres, yielding 3.3 tons per acre. An average of about 140 to 150 hr. of man labor per acre was required. About four-fifths of the growers contracted their tomatoes generally at \$10 to \$11 per ton. Seventy-five percent of the canners contracted for 90 percent or more of the tomatoes bought, and nearly one-third grew part of the tomatoes packed. The approximate average costs per No. 2 equivalent case of tomatoes for major items were: Cans 51 ct., tomatoes 26 ct., labor 10 ct. in addition to labor of operator or hired manager, other miscellaneous manufacturing costs 11 ct., selling costs 7 ct., and overhead plant costs 2.5 ct. Seventy-seven percent of the tomatoes packed by the canners studied were reported by the canners as standard grade. Practically all other grades reported were above standard. Of the buyers reporting the Ozark region as their usual source of purchases, 95 percent were located in the eight States in the first two tiers of States west of the Mississippi River and south of Minnesota. "In comparison with other competing areas, Arkansas has advantages in transportation costs in the western part of the market area, while in the northeastern part rates are favorable to Indiana. Along the Gulf Coast transportation costs favor the Maryland area. . . . Northwestern Arkansas is a production area of standard grade canned tomatoes. Color, and other factors associated with it, limits most of the tomatoes to standard grade. A good standard pack may well be the basis for any program for the area, until varieties and cultural practices have overcome present handicaps to production of highest quality tomatoes."

**Agricultural geography of the Philippine Islands: A graphic summary**, R. G. HAINSWORTH and R. T. MOYER (*U. S. Dept. Agr., Off. Foreign Agr. Relat.*, 1945,

pp. 72+, illus. 45).—The 45 maps and charts, with the accompanying 23 tables and text, cover among other things the size and location of the Islands, the population, the relief, climate, vegetation, soils, land resources and utilization, land tenure, total and cultivated acreages per farm, the various food crops for domestic consumption, the different export crops, the food supply, the distribution of livestock and poultry, and exports to and imports from the United States and other countries.

**Foreign Agriculture [February-March 1946]** (*U. S. Dept. Agr., Foreign Agr.*, 10 (1946), Nos. 2, pp. 17-32, illus. 6; 3, pp. 33-48).—No. 2 consists of an article, Ecuador's Agriculture and the War, by K. H. Wylie (pp. 18-32), discussing, among other topics, the development of the agriculture of the country; its crop pattern; the export, domestic food, and raw material crops; the government policies affecting agriculture; the livestock; the effects of World War II; and the postwar problems.

No. 3 includes an article, Chilean Agricultural Policy, by O. Moore (pp. 34-45), dealing with the trade in agricultural products, the status of agriculture, land tenure, prewar and wartime measures affecting agriculture, and the transitional and postwar prospects for Chile. A second article, United Kingdom Production and Marketing Policy for Sheep, by D. D. Jones (pp. 45-48), discusses the prewar and wartime controls, the trends in number of sheep, and the official postwar plans.

**Improving farm labor efficiency**, E. F. REBMAN (*Michigan Sta. Spec. Bul.* 334 (1945), pp. 18, illus. 2).—The amount of work accomplished per man during 1943 on individual farms in the farm-accounting project in central Michigan ranged from 40 to 165 percent of the average of 289 productive man-work units. With a view to ascertaining the causes of the differences, this analysis was made of 32 farms in south-central Michigan that had an average labor efficiency of 370 productive man-work units per man during 1943 as compared with 14 farms with an average of 185 units.

"In general, the farmers who had high labor efficiency had larger businesses, had more livestock, had more crops, had more and larger machinery, had a better farm layout, were younger men, and had more incentives to accomplish more work."

**Egg and poultry marketing practices in West Virginia**, M. A. ABRAHAMSEN (*West Virginia Sta. Bul.* 323 (1945), pp. 39, illus. 2).—"The purpose of this study was to obtain first-hand information with respect to the marketing methods followed by West Virginia farmers in disposing of their eggs and poultry. Attention also was given to the buying and selling methods followed by the various kinds of agencies handling eggs and poultry." Records relating to egg and poultry marketing were furnished by 203 farmers in four counties (Berkeley, Monongalia, Upshur, and Wood) that had 25 or more laying hens on January 1, 1944. The importance and characteristics of the egg and poultry enterprise in the State, the seasonal distribution of sales, egg prices, etc., are described. The marketing agencies, the distribution of sales among them, producers' opinions regarding the prevailing markets, the buying and selling practices of purchasing agencies, etc., are discussed, and some suggestions made for improving production methods and marketing practices and for increasing the operating efficiency of receiving agencies.

**Air transport of agricultural perishables**, R. W. HOECKER ET AL (*U. S. Dept. Agr., Misc. Pub.* 585 (1946), pp. 44, illus. 4).—This publication, dealing with postwar adjustments in the marketing of agricultural products, was prepared by the Working Group on Conversion of Marketing Facilities and Methods of the Interbureau Committee on Postwar Programs. It discusses the present development of air cargo, the present and estimates of future air cargo rates, new developments in air transportation, facilities for handling air cargo, and the economies of air transportation. Some savings in refrigeration costs and case studies of possible economies in air transportation of strawberries, tomatoes, and lettuce are shown. The retention of food value by air shipment, use of the airplane for quick-freezing foods, and potential domestic cargoes of fruits, vegetables, flowers, and livestock and poultry products are discussed. Other sections deal with seasonal factors in air transportation,

potential domestic cargo of industrial products, air transportation in foreign trade, and the competitive position of the air-freight carrier.

**Membership relations in farmers' cooperatives**, A. L. LARSON (*Oklahoma Sta. Cir.* 122 (1946), pp. 8, illus. 4).—The kinds of information on operation of the organization desired by the members and the information which the organization needs about its members are discussed, as are also methods for presenting information to members and for obtaining data on their attitudes.

**Crops and Markets [January 1946]** (*U. S. Dept. Agr., Crops and Markets*, 23 (1946), No. 1, pp. 72, illus. 1).—Among the numerous tables included are ones showing the acreages, yields, and production, by States, and for the United States, of different crops in 1945, with comparisons with other periods; summary tables showing estimated acreages planted and not harvested by years 1929–45, acreage of fruits 1929–45, utilization of corn 1944 and 1945, total harvested acreage of principal crops, etc.; the employment of farm labor by geographic divisions, January 1, 1945, with comparisons; farm wage rates by States, January 1, 1945, and 1946; prices received and paid by farmers; and average monthly prices received by farmers for important crops 1908–45. Livestock reports include tables on egg production, hog-corn ratios, milk production, etc. Market reports of the usual types are included for cotton, dairy and poultry products, feed, grain, livestock, meats, etc. A short article (pp. 44–45) discusses the cost of producing field crops in 1944, with tables showing by States or regions the estimated gross and net costs per acre for corn, wheat, oats, and cotton; and the net cost per bushel for the grains and per pound for cotton.

**Farm production, farm disposition, and value of cotton and cottonseed, and related data, 1928–44, by States**, H. L. RASOR and E. S. MINOR (*U. S. Dept. Agr., Bur. Agr. Econ.*, 1945, pp. 41+).—Data for the years 1943 and 1944 are added to the tables in a publication of the same title covering the years 1928–42 (E. S. R., 91, p. 759).

**Current Farm Economics [February 1946]** (*Cur. Farm Econ.* [Oklahoma Sta.], 19 (1946), No. 1, pp. 23, illus. 4).—Included are the monthly review of the agricultural situation, the usual tables of prices and price indexes, and the article, Membership Relations in Farmers' Cooperatives, noted above.

## RURAL SOCIOLOGY

**Planing programs for veterans in rural areas**, E. R. HOSKINS (*[New York] Cornell Sta. Bul.* 825 (1945), pp. 57+, illus. 1).—This study, based on the educational records and work experiences of 800 young men in service, selected from the honor rolls of 3 rural areas in central New York, "represents a large group of servicemen from a particular geographical area. It provides not only a basis and a program for the postwar adjustments of an appreciable group of men and for a relatively large area, but also a pattern by which other communities may approach similar postwar problems of adjustment. It designates a definite group of men with certain qualifications, and includes the total resources of the area. It appraises the educational facilities and other resources within these communities and opportunities for nearby employment. It emphasizes the need for refresher courses and the new opportunities of education and employment within the area and in nearby cities. It suggests the policies of reemployment for the area. In brief, this study provides a basis for local and larger-area planning whereby agencies of education and employment services may be made available effectively for returning veterans."

**A demographic study of the American Negro**, T. L. SMITH. (La. State Univ.). (*Social Forces*, 23 (1945), No. 3, pp. 379–387).—"This paper is a summary of the data concerning the demographic situation and trends among the American Negro population."

## AGRICULTURAL AND HOME ECONOMICS EDUCATION

Conference report on the contribution of extension methods and techniques toward the rehabilitation of war-torn countries, Washington, D. C., September 19-22, 1944 (*U. S. Dept. Agr., Ext. Serv. and Off. Foreign Agr. Relat.*, 1945, pp. 239+).—This is the report on a conference called by the Extension Service and the Office of Foreign Agricultural Relations, jointly, to bring together available information on extension methods and to analyze past experiences in extending scientific information to farm people, so that this fund of knowledge might be made applicable to people in war-torn areas. The conference was organized around 9 areas with a committee reporting for each, and a tenth committee which concerned itself with the experience and contributions of private agencies in the field of extension.

**OES eleventh annual survey**, G. ADAMS. (U. S. D. A.). (*Jour. Home Econ.*, 38 (1946), No. 3, pp. 159-161).—Research findings published by the State agricultural experiment stations in 1944-45 are listed here under these classifications: Food selection and preparation; food preservation; nutritive value of foods; family economics; and home management, housing, and household equipment.

## FOODS—HUMAN NUTRITION

**Food values under the cream layer of a quart of milk**, L. M. DORSEY. (Univ. Maine). (*Milk Dealer*, 34 (1945), No. 6, pp. 49-50).—Based on the nutritive value of whole milk (E. S. R., 83, p. 270), this study gives calculations and comparisons concerning skim milk. The energy value is estimated at 505 calories per quart; mineral matter content is slightly higher than that of whole milk on this basis; and trace elements such as manganese, cobalt, copper, molybdenum, fluorine, and possibly others are recognized. Although the fat-soluble vitamins are lessened in amounts when the cream is removed, appreciable quantities still are found present because ordinary skimming processes do not produce a true skimmed milk. Protein contents of a quart of under milk are slightly higher than in whole milk.

**Human milk studies, XIX-XXVII** (*Amer. Jour. Diseases Children*, 70 (1945), No. 3, pp. 135-199, illus. 20).—Studies in continuation of this series (E. S. R., 73, p. 887), bearing on the nutritive value of human milk, include the following: XIX—Implications of Breast Feeding and Their Investigation, by I. G. Macy, H. H. Williams, J. P. Pratt, and B. M. Hamil (pp. 135-141); XX—The Diet of Lactating Women and the Collection and Preparation of Food and Human Milk for Analysis, by M. Kaucher, E. Z. Moyer, A. J. Richards, H. H. Williams, A. L. Wertz, and I. G. Macy (pp. 142-147); XXI—A Simple Technic for the Manual Expression of Mother's Milk, by V. Davies (pp. 148-149); XXII—Nicotinic Acid, Pantothenic Acid, and Biotin Contents of Colostrum and Mature Human Milk, by M. N. Coryell, M. E. Harris, S. Miller, H. H. Williams, and I. G. Macy (pp. 150-161); XXIII—Free and Total Thiamine Contents of Colostrum and Mature Human Milk, by C. E. Roderuck, H. H. Williams, and I. G. Macy (pp. 162-170); XXIV—Free and Total Riboflavin Contents of Colostrum and Mature Human Milk, by C. E. Roderuck, M. N. Coryell, H. H. Williams, and I. G. Macy (pp. 171-175); XXV—Ascorbic Acid and Dehydroascorbic Acid in Colostrum and Mature Human Milk, by B. Munks, A. Robinson, H. H. Williams, and I. G. Macy, with the assistance of M. Leshner, M. E. Harmon, J. K. Brody, J. Anderson, and R. Rust (pp. 176-181); XXVI—Vitamin A and Carotenoid Contents of Colostrum and Mature Human Milk, by M. Leshner, J. K. Brody, H. H. Williams, and I. G. Macy (pp. 182-192); and XXVII—Comparative Values of Bovine and Human Milks in Infant Feeding, by J. M. Lawrence, B. L. Harrington, and L. A. Maynard (pp. 193-199) (Cornell Univ.).

**Fruit and vegetable products and by-products**, W. V. CRUSS. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Food Mfr.*, 25 (1946), No. 7, pp. 203-206).—The author

gives an outlook into California's horticultural industries in regard to the threat of future overproduction of fruits, vegetables, and other products. Attention is called to some of the more important fruit and vegetable products that appear to offer promise of new usages. These products include those which can be frozen satisfactorily, made into fruit candies, bakery products, fruit beverages, ice creams and ices, children's sieved foods, and dehydrated products and those which can be utilized for such byproducts as citric acid, pectin, concentrates, stock feeds, and oils from citrus fruits.

**The preservation of freshness in vegetables and fruits from harvest to consumption,** E. P. BRASHER, G. M. GILLIGAN, C. W. WOODMANSE, and E. M. RAHN. (Del. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Food Mfr.*, 25 (1945), No. 6, pp. 168-170).—The results of this study indicate that the use of cracked ice or ice refrigeration in marketing the fruits and vegetables considered offers a means of reducing losses due to weight-shrinkage and spoilage, and enhances the retention of ascorbic acid, freshness, and palatability. "Only in the case of tomatoes and peaches did refrigeration seem slightly superior to that of snow ice for retaining appearance. When stored at room temperature, lima beans were unfit for human consumption after 1 day; sweet corn, kale, and cantaloups, 2 days; and tomatoes, 4 days."

**Legume and cereal sprouts as a dietary substitute for fresh vegetables,** W. A. ANDREAE, E. A. CHALMERS, and W. D. McFARLANE (*Sci. Agr.*, 25 (1945), No. 8, pp. 504-523, illus. 6).—A detailed description is given of several methods developed for sprouting cereal and legume seeds in bulk. Wooden tubs were best for sprouting Windsor broad beans, vetch, soybeans, and cereals; shallow screen bottom trays were best for peas. An open bag, for use in mobile camps, was acceptable for all types of seeds. Recipes for the use of the sprouts are presented. "The beans were best served as a vegetable, thick soup, or in stew; the peas in salad; the vetch in meat or tomato mixtures; soybeans in vegetable dishes or in salads; and cereals in porridge or with rice."

"It was estimated that one serving (approximately 6 oz. as vegetable, 2 oz. as salad) of Windsor broad beans, vetch, and pea sprouts would supply half the daily requirement of vitamin C. The amount of riboflavin is considered to be insignificant."

**Improving peanut butter quality,** J. G. WOODROOF and H. H. THOMPSON. (Ga. Expt. Sta.). (*Food Packer*, 26 (1945), No. 12, pp. 35-37, 56-57, 60, illus. 3).—Essentially noted elsewhere (E. S. R., 94, p. 828).

**Jellied fruit candies,** W. V. CRUESS. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Food Mfr.*, 25 (1946), No. 6, pp. 166-167).—Candies made with pectin, sugar, and either fruit puree or juice may be as adaptable for cutting and wrapping as ordinary candy bars. A typical formula that has been used experimentally in two commercial candy factories is 40 lb. fruit puree, 30 lb. glucose sirup (or invert), 30 lb. cane sugar, 20 oz. powdered pectin, and 8 oz. citric acid, dissolved in 2 pt. of water. Directions for mixing are given, and suggestions for substitutions include replacing the 8 oz. of citric acid with 1 gal. of fresh lemon juice or, if fruit juice is used, replacing the 40 lb. of fruit puree with approximately 5 gal. of the juice. The usual coating for these candies is confectioners' coarse sugar.

**Oxidative deterioration of fats in cereal products,** H. O. TRIEBOLD. (Pa. State Col.). (*Oil and Soap*, 22 (1945), No. 12, pp. 334-336).—An address.

**Toxicity of rancid fats,** F. W. QUACKENBUSH. (Purdue Univ.). (*Oil and Soap*, 22 (1945), No. 12, pp. 336-338).—An address.

**Determination of shelf life of packaged cereals,** C. E. FELT, A. C. BUECHELE, L. F. BORCHARDT, R. C. KOEHN, F. A. COLLATZ, and F. C. HILDEBRAND (*Cereal*

*Chem.*, 22 (1945), No. 3, pp. 261-271, *illus.* 3).—A puffed corn cereal and a puffed oat cereal were packaged under commercial conditions in cartons containing standard single-waxed cereal glassine liners. They were distributed to 12 cities and stored beginning in April. Examinations were made at biweekly intervals for eating quality and moisture content.

The shelf life of the products was determined by this field study and by theoretical mathematical calculation based on moisture content, vapor pressure, temperature, and weather conditions in the areas under consideration. With one exception, good agreement was obtained between the calculated and actual results.

The authors conclude that "the shelf life of a packaged cereal varies widely, depending upon the season, upon the section of the country in which the package is placed, and, to a lesser extent, upon the hygroscopic properties of the product itself."

**Cakes and cookies—recipes for different altitudes**, W. E. PYKE and M. BROWN (*Colorado Sta. Bul.* 489 (1946), pp. 36, *illus.* 11).—Tested recipes and corrections for their application at certain altitudes are presented. The important features of altitude cookery are given in technical terms, and less technical information is also noted for home usage. The leavening correction, applying usually to baking powder or soda, is accomplished by decreasing its content when the sugar-flour ratio in the recipe remains unchanged. As the altitude at which the cake is to be baked increases, the water content should be increased, generally accomplished by providing an increase in the milk or egg content. The sugar-water ratio is related to the kind of shortening used—hydrogenated shortening, lard, or butter. Hydrogenated shortenings are divided into two types—the ordinary and the high-water-tolerant; the latter gives a more effective distribution of water and a smaller amount is required. When natural shortenings are used, most of the water-furnishing ingredients should be mixed into the batter a little at a time to prevent severe curdling. At a 10,000-ft. elevation, the internal temperature attained within a baking cake will be at least 18° F. lower than at sea level due to lowered boiling points, making the structural strength of the flour and eggs much less. Egg added as a form of liquid would provide additional strength to counteract the tenderizing effect of altitude. Suggestions for measurements, equipment, and general baking and mixing methods are discussed.

**Practical cookery and the etiquette and service of the table** (*Manhattan: Kans. State Col.*, 1945, 21. ed., rev., pp. 506, *illus.* 19).—This book, a revision of an earlier edition, is a compilation of principles of cookery and recipes with suggestions for etiquette for various occasions.

**Imitation clove oil effective in spicing pickles**, F. W. FABIAN and V. HARRIS. (*Mich. State Col.*). (*Food Indus.*, 17 (1945), No. 6, pp. 88-90, *illus.* 2).—Solutions of natural clove oil, imitation clove oil, and three clove oil constituents were used to spice sweet pickles (1 : 1,000 dilution and a duplicate set with 1 : 2,000 dilutions) and allowed to stand for a 30-day period. At the end of this period, the liquor was drained off the pickles and total liquor and pickle washings were assayed as such by distilling in the Clevenger apparatus.

Results showed that imitation clove oil is absorbed by the pickles equally as well as the natural clove oil in both high and low dilutions, and apparently there was no great difference in the absorption between the three components of the imitation clove oil. Work on the solubility of the essential oils of whole cloves showed that of the pickling materials used in manufacture, acetic acid was the best solvent—2 percent extracted about 25 percent of the oil, while 2 percent salt extracted only about 10 percent and a 35-percent-by-weight sugar solution only about 3.5 percent. Since the ether-soluble portion of the pickles has a greater affinity for the clove oil than the liquor in which it is suspended, the greater amount of the oil would be taken up by

the pickles; about 25 percent of the oil was found in the liquor and about 75 percent in the pickles for both the natural and imitation clove oils.

**New germicides for food processors**, G. J. HUCKER. (N. Y. State Expt. Sta.). (*Canning Trade*, 68 (1946), No. 29, p. 7).—Quite recently there has been made available a series of compounds which show considerable promise in checking slime-producing organisms which collect on dairy and food plant equipment. The quaternary ammonium compounds, appearing under a number of trade names, are odorless in the small concentrations which are used in routine sterilizing procedures; are noncorrosive; readily soluble in water; nontoxic; and unaffected by light, excess heat, or long storage. Their sterilizing properties are lost, however, when mixed with soaps, with many cleaning powders, and synthetic detergents. It has been found that a number of the spore-forming bacteria (particularly those associated with flat sour spoilage) are completely killed in concentrations varying from 1 : 5,000 to 1 : 15,000 upon a 10-min. exposure; concentrations as high as 1 : 25,000 will kill over 95 percent of the organisms in pure culture of common non-spore-forming types,

**Bacteriological studies relating to thermal processing of canned meats**, [I]–III, C. R. STUMBO, C. E. GROSS, and C. VINTON (*Food Res.*, 10 (1945), Nos. 3, pp. 260–272, illus. 5; 4, pp. 283–302).—A series of studies has been made on the influence of various factors, such as curing agents and concentration of spores, upon the heat processing necessary to prevent spoilage of canned meat.

[I]. *Laboratory methods employed for studying factors which influence the thermal processes required to prevent bacterial spoilage of canned meats*.—In this preliminary paper, a detailed illustrated description is presented of a method devised to study the thermal resistance and growth of bacteria in canned meat.

Heat-resistant spores of a putrefactive anaerobe were isolated from spoiled, cured, and canned meat and served as the test material. Small tubes containing various samples of mixed ground pork and spore suspensions were heated at 220°, 230°, 240°, and 250° F. to determine the thermal death time of the spores.

The advantages of the method are considered to be: Its use with a wide variety of meats which have been treated or processed under different conditions; the compactness of the method, as small tubes were used and a large number of them could be conveniently incubated; the meat could be mechanically introduced, and the spores readily cultured with little danger of contamination; and progressive spoilage of the processed meat could be observed through the glass walls of the tubes during incubation.

II. *Influence of meat-curing agents upon thermal resistance of spores of a putrefactive anaerobic bacterium in meat* (pp. 283–292).—The curing agents commonly employed for curing meat (sugar, salt, sodium nitrate, and sodium nitrite) were studied separately or together. They exerted no influence on the heat processes necessary to sterilize meat inoculated with known concentrations of spores of a putrefactive anaerobe similar to *Clostridium sporogenes* and *C. botulinum* (see above). “The higher the concentration of spores in the meat, the more severe were the heat processes necessary to sterilize it.”

III. *Influence of meat-curing agents upon growth of a putrefactive anaerobic bacterium in heat-processed meat* (pp. 293–302).—The various inoculated and processed tubes of meat were stored at 28° C. and examined periodically over a 1-yr. period. The authors conclude that “the data would seem to support the following statements: (1) Sugar (1 lb./100 lb. of meat) alone was ineffective in preventing spoilage of the meat; (2) sodium nitrate (2¾ oz./100 lb. of meat) alone was ineffective in preventing spoilage; (3) sodium nitrite (¼ oz./100 lb. of meat) alone was ineffective in preventing spoilage but did appreciably delay germination; (4) salt in a concentration of 3½ lb./100 lb. of meat seemed to inhibit spoilage of all but a

few tubes of meat for at least 1 yr., while in a concentration of  $1\frac{1}{2}$  lb./100 lb. of meat it has not inhibited spoilage to the same degree; (5) salt and sodium nitrite together; salt and sodium nitrate together, or salt, sodium nitrite, and sodium nitrate together have thus far proved very little if any more effective in preventing spoilage than salt alone; and (6) the data show that over a period of 1 yr. sodium nitrate, either alone or in combination with other curing ingredients, has not appreciably influenced spoilage and, therefore, growth of putrefactive anaerobe  $S_2$  in the meat."

**Canning beef**, J. G. WOODROOF and I. S. ATKINSON (*Georgia Sta. Cir.* 150 (1946), pp. 8, illus. 4).—The results reported here are from two series of experiments run in 1944 and 1945. Using a single animal divided into halves, one side was cut into steaks, roasts, and stew meat and canned while fresh; the other half was aged at  $36^{\circ}$  to  $38^{\circ}$  F. for 8 days before cutting and processing. One year later, the cans opened for examination (previously heated in boiling water) showed that aging improved the texture and flavor of the steaks, searing improved the flavor, and precooking by boiling destroyed aroma and flavor. Processing at 10-lb. pressure developed the highest flavor and best texture; best processing time was found to be 60–70 min. for steaks and 80–90 min. for roasts and stew meat.

**Examination of canned apple juices**, J. FORGACS, W. A. RUTH, and F. W. TANNER. (Univ. Ill.). (*Food Res.* 10 (1945), No. 3, pp. 227–237).—The analyses of several varieties of apple juice at canning and after storing for 2 yr. at room temperatures revealed that many different types of bacteria and other microorganisms were present—rod-shaped bacteria being the most prevalent. Changes in the total acidity and pH were evident at the time the experiment was discontinued; although no close correlation existed between them, hydrogen-ion concentration decreased while acidity (calculated as malic acid) increased; refractometer readings decreased during storage. The problem of clouding was studied, although it was not directly accounted for. Regarding the examination of cans, results showed that some cans were normal in appearance, while others were springers or flippers. Pitting was observed in most swelled and normal cans, but varied considerably and was confined to the seams and bottom.

**Home canning, I–II.** (Mass. State Col.). (*Food Res.*, 10 (1945), No. 3, pp. 197–226, illus. 2.)

I. *Survey of bacteriological and other factors responsible for spoilage of home-canned foods*, R. G. Tischer and W. B. E. Esselen, Jr. (pp. 197–214).—A detailed description is given of the methods and technics used in determining spoilage in home-canned foods, and the results are tabulated. In all, 293 samples of sound and spoiled home-canned foods were examined to determine: (1) Appearance of container, (2) appearance of food, (3) vacuum or pressure, (4) odor, (5) pH value, (6) bacteria observed with the microscope, and (7) presence of viable microorganisms.

Bacteriological culture tests appeared to be the most reliable criterion of spoilage. More than half of the 146 samples submitted as sound contained viable microorganisms, indicating faulty canning technic and the possibility of spoilage, while 97 percent of the samples submitted as spoiled gave some evidence of spoilage. The spores of four putrefactive anaerobes isolated from spoiled jars of asparagus, lima beans, and snap beans survived heating for 30 min. at  $110^{\circ}$  C. ( $230^{\circ}$  F.) and 320 to 820 min. at  $100^{\circ}$  C.

The authors conclude from these results that about three-fourths of home-canning spoilage is due to understerilization and one-fourth to improper sealing. The boiling-water-bath method of processing was not adequate to destroy certain types of bacteria present in many low-acid vegetables. While a pressure canner correctly used was satisfactory for processing, understerilization could result if it is misused.

A survey of the spoilage actually encountered by home canners who submitted samples showed that approximately 2 percent spoilage was observed by 90 families who canned 22,544 jars of food in 1942.

II. *Determination of process times for home-canned foods*, W. B. Esselen, Jr. and R. G. Tischer (pp. 215-226).—A method is described in which the theoretical process times were determined for home-canned asparagus, beets, carrots, corn, green beans, peas, spinach, and squash in pint jars. The processing temperatures used were 100° and 115.6° C.

Results showed that in a pressure canner at 115.6° C. the theoretical process times might be somewhat shorter than the present recommended process times. In a boiling-water bath (100°), the process times ranged from 5½ to 12 hr.—considerably longer than the times recommended at present for home canning.

In the pressure-cooker type of canning, the relatively long come-up time and slow air-cooling period are responsible for much of the sterilizing value of the process (18 to 35 percent occurring during cooling alone). In the boiling-water-bath method, 90 to 98 percent of the lethal value occurs during the actual processing—the effect of come-up and cooling periods being relatively small.

The authors indicate that particular stress should be placed on correct operation and maintenance of pressure canners to obtain the maximum sterilizing value from a given process.

**New methods produce superior dehydrated cut fruits, I-III.** (Univ. Calif. et al.). (*Food Indus.*, 17 (1945), Nos. 2, pp. 94-97, 178-184, illus. 3; 5, pp. 96-98, 180-188, illus. 2; 6, pp. 84-87, illus. 3).—This article, part 1 by H. J. Phaff, R. L. Perry, and E. M. Mrak; part 2 by H. J. Phaff, G. L. Marsh, E. M. Mrak, and C. D. Fisher; and part 3 by H. J. Phaff, E. M. Mrak, R. L. Perry, and C. D. Fisher, presents the principles of sulfuring fruits under large-scale commercial experimentation. Three varieties of apricots were prepared for dehydration by blanching 1½ to 4 min. in a continuous blancher, predrying, and sulfuring 3 to 3½ hr. (9 lb. of sulfur burned per ton of cut fruit). Freestone peaches were dehydrated in a manner similar to apricots, although the blanching time varied from 4 to 7 min. and predrying and sulfuring required a longer time (amount of sulfur reduced to 5 lb./ton). In contrast to the dehydration of apricots and freestone peaches, the clingstone peaches were sulfured after blanching without being subjected to a preliminary drying period. Due to the firmness of the flesh, the peaches did not have a tendency to bleed in the sulfuring house, although, it was necessary to allow the fruit to cool to about 120° F. before sulfuring. The sulfuring period required 3 hr., and 7 lb. of sulfur were used per double car of fruit. Whole clingstone peaches may be successfully dehydrated when adjustments of the sulfuring procedure are made. Dehydration of pears required about 26 to 30 hr. at a finishing temperature of 140°, after 12 to 16 min. of blanching, and sulfuring for 8 hr. (12 to 15 lb. of sulfur for each pair of single cars of fruit). "Because of the high sulfur dioxide retention during dehydration as compared with sun drying, the bulk storage of unprocessed dehydrated fruit is superior as far as darkening is concerned. However, when compared under identical storage conditions the keeping qualities are equal."

**The dehydration of kale**, J. S. CALDWELL, C. W. CULPEPPER, B. D. EZELL, M. C. HUTCHINS, and M. S. WILCOX. (U. S. D. A.). (*Canner*, 101 (1945), No. 25, pp. 13-14, 16, 28, 30, 32).—Lots of three varieties of kale were blanched by different treatments and for varying lengths of time. Drying was begun at 175° and completed at 150° F., reducing the moisture content to 4.5 percent. After dividing into two portions, one lot was packed in hermetically sealed containers in carbon dioxide and stored at 32°, and the other was placed in nonairtight containers and stored at 70°-75°. "When examined after 2 months' storage, all samples of Blue Curled

Scotch and Dwarf Green Scotch, except those that had been sulphured or dried raw, were very good to excellent in quality; Dwarf Siberian was slightly less good in both color and flavor. . . The material stored in carbon dioxide at 32° was slightly superior in flavor after 2 mo. to that stored in air at 75°. . . . Approximately half of the original content of each vitamin was retained after dehydration and storage for 5½ mo. in air at 75°, slightly more in carbon dioxide at 32°."

The plant leaves were divided into groups on the basis of stage of development, and determinations made upon the vitamin content showed that ascorbic acid was maximum in amount in the youngest leaves which had not yet unfolded and decreased progressively with maturity. The carotene content of these young blades was relatively low, but their petioles showed high carotene before elongation began.

**Quick test for peroxidase aids in dehydration control**, E. H. LUCAS and D. L. BAILEY. (Mich. Expt. Sta.). (*Food Indus.*, 17 (1945), No. 2, pp. 82-83, illus. 1).—Essentially noted elsewhere (E. S. R., 91, p. 503).

**Instructions on processing for community frozen-food locker plants**, M. B. MATLACK (U. S. Dept. Agr., Misc. Pub. 588 (1946), pp. 52, illus. 4).—Processing methods are given for the preservation of foods by freezing and include their preparation, packaging, freezing, thawing, and cooking. Suggestions for the care of frozen foods after removal from the frozen-food locker, sanitation problems, and packaging materials (including a list of manufacturers) are also noted.

**Histological characteristics, tenderness, and drip losses of beef in relation to temperature of freezing**, R. L. HINER, L. L. MADSEN, and O. G. HANKINS. (U. S. D. A.). (*Food Res.*, 10 (1945), No. 4, pp. 312-324, illus. 4).—Longissimus dorsi muscle of beef was frozen at 18°, 0°, -10°, -40°, and -114° F. in air without forced circulation. The histological changes occurring with different rates of freezing were investigated. This study included only meat frozen and examined within 24 to 36 hr.

Freezing at 18° produced large interfibrillar ice areas which caused the fibers to bunch together. No intrafibrillar ice crystals or areas were noted. As the freezing temperature was lowered, the size of ice crystals and ice areas became smaller. Intrafibrillar freezing and fiber-wall damage was visible at 0°, and both became more extensive as the freezing temperature decreased. At -114°, the fibers split longitudinally into several sections and intrafibrillar ice crystals were very extensive and small.

Various methods for preparing the tissue for fixing and staining are described.

Tenderness tests were made on beef samples aged 5 days, cut 1½ in. thick, and frozen at the above temperatures. Tenderness was found to increase as freezing temperature was lowered and the time shortened. This was believed to be due to increased fiber rupture caused by intrafibrillar ice as well as to stretching and rupturing of the interstitial connective tissue.

Drip during subsequent thawing decreased as freezing temperatures were lowered. The authors assume that increased intrafibrillar freezing and rupturing of fibers permits the proteins to reabsorb a large proportion of the water originally frozen in the meat.

**Freezing muscadine grapes**, J. G. WOODROOF and I. S. ATKINSON (*Food Packer*, 26 (1945), No. 12, p. 48).—Essentially noted elsewhere (E. S. R., 94, p. 538).

**The use of calcium salts in freezing McIntosh apples**, J. J. POWERS and W. B. ESSELEN, JR. (Mass. Expt. Sta.). (*Fruit Prod. Jour. and Amer. Food Mfr.*, 25 (1946), No. 7, pp. 200-202, 217, illus. 3).—Normal colored and green McIntosh apples were washed, peeled, cored, and cut into ½ in. slices and held in 0.1 percent sodium chloride brine until treated with varying solutions of calcium chloride. Concentrations from 0.03 to 1.5 percent of calcium chloride were desirable—the

amount of calcium used and the length of treatment depending upon such factors as the original firmness of the apples, the length of time they had been in storage (fresh and cold storage apples were tested), and the degree of firmness desired. These calcium treatments were found to be successful in preventing excessive softness or mushiness in the green or ordinary McIntosh apples. Evaluations of the effectiveness of calcium chloride as a firming agent upon frozen, canned, and fresh sliced apples were made after readings on the penetrometer jelly-strength tester were taken on each of the three groups.

**Electronics in food processing—blanching by electronics involves new principles,** J. C. MOYER. (N. Y. Stat Expt. Sta.). (*Food Packer*, 27 (1946), No. 2, pp. 35-36, illus. 2).—Preliminary experiments (E. S. R., 94, p. 533) with electronically blanched vegetables presents a basis for this study, which points out that dielectric heating would be superior as a blanching agency.

**Incidence and distribution of *Clostridium botulinum* in soils of Illinois,** M. T. JONES and F. W. TANNER. (Univ. Ill.). (*Food Res.*, 10 (1945), No. 3, pp. 238-245).—Results indicated that 7.2 percent of 604 soil samples from 88 counties produced positive toxic cultures. About 25 percent of the counties in Illinois had toxin-producing soil samples, with the southern counties showing over 2½ times as many positive tests as the northern counties (36.5 v. 14). The toxin was identified as type B. The danger of *Clostridium botulinum* producing toxin in home-canned foods unless proper precautions are observed is emphasized.

**A symposium on the effects of soil elements on food,** T. J. BROOKS (*Tallahassee: Fla. State Dept. Agr.*, [1946], pp. 175).—This volume brings together for convenient reference many studies that bear on the problem of food values in relation to the soil elements. These studies, credited to the original source, cover the following topics: Soils (pp. 11-12); Physical Requirements (pp. 13-14); Soil and Health (pp. 15-16); Soil Fertility and Human Nutrition (pp. 17-19); Health from the Ground Up, by R. Beach (pp. 20-23); Experiment Station Research on the Vitamin Content and the Preservation of Foods, by G. Adams and S. L. Smith (pp. 24-40) (U. S. D. A.) (E. S. R., 91, p. 218); Soils and Food, by C. G. Henry (pp. 41-57); Soil Mineralization (pp. 58-61); The Minor Elements Play No Minor Role in Florida, by H. Mowry (pp. 62-64); Pasture Grass Improved by Adding Minor Minerals, by J. C. Brossier (pp. 65-68); Notes on Animal Nutrition (pp. 69-74); Soil-Builders, by V. **Magnesium content of meats,** V. TOSCANI (*Food Res.*, 10 (1945), No. 6, pp. 461-464).—The meats previously studied for proximate and some mineral values by Toscani et al. (E. S. R., 73, p. 268) have been assayed for magnesium. The 71 samples included beef, lamb, and veal muscle meat, and beef tongue, liver, kidney, and brain. The magnesium values, in terms of milligrams per 100 gm., moist weight, averaged from 19.3 to 25.5 mg. for the various muscle tissues, tongue, and liver. The

lowest value was found in lamb, and the highest in veal. Beef brain and kidney averaged 13.0 and 14.0 mg., respectively. These values are considered to be in good agreement with previously published data.

**Response of rats to boron supplements when fed rations low in potassium,** J. T. SKINNER and J. S. McHARGUE. (Ky. Expt. Sta.). (*Amer. Jour. Physiol.*, 143 (1945), No. 3, pp. 385-390, illus. 1).—Rats were fed a basal diet low in potassium (51 p. p. m.) and containing negligible amounts of boron (0.45 p. p. m.), plus boron supplements of 100, 250, 500, and 1,000 p. p. m. as boric acid or 1,000 p. p. m. as borax. Some of the animals receiving borax were also fed 100 or 250 p. p. m. supplements of K. The survival time of 54 pairs of rats under 7 sets of conditions are tabulated.

Results showed that rats receiving either boric acid or borax survived longer than pair mates receiving no boron when a low-potassium diet was fed. After 21 days, the boron-supplemented rats contained 47 percent more glycogen in their livers than the control animals. The authors believe that "maintenance of stores of body fat was favored by liberal supplementation of the low-potassium rations with boron compounds."

**Fluorine in milk, plant foods, and foods cooked in fluorine-containing water,** H. V. and M. C. SMITH and M. VAVICH (*Arizona Sta. Mimeog. Rpt.*, 77 (1945), pp. 7).—In a series of experimental periods ranging from 2 to 13 days in length, two cows, one Jersey the other Guernsey, were given drinking water containing from as little as 0.2 p. p. m. to as much as 500 p. p. m. of fluorine. Analyses of the milk obtained from these cows showed that there was a small but definite increase in the fluorine content of the milk when NaF was added to the drinking water. In no case, however, did the fluorine content of the milk exceed 0.5 p. p. m. These results suggested that fluorine is not transmitted in toxic quantities to milk even when the lactating cows are drinking water which has a fluorine concentration far above that causing mottled enamel in children's teeth. Water consumption by the cows decreased sharply as the fluorine content of the water reached the higher levels. It was also observed that most of the fluorine ingested by the cows was excreted by the kidneys.

Cereals and legumes were grown on soils treated with CaF up to soil concentrations of fluorine as high as 500 p. p. m., and vegetables were grown in soils treated with NaF up to fluorine concentrations as high as 3,200 p. p. m. The fluorine content of these plants was higher than that of plants grown in control plots receiving no fluorine; however, the amount deposited in the plants was not proportional to the amount in the soil. The amount of fluorine absorbed varied with the type of plant and the part of the plant analyzed. Beets and sweetpotatoes, for example, absorbed more than snap beans and tomatoes, and wheat stalks and leaves more than the wheat grain. Since natural soils contain only traces of fluorine and since the excessively enriched soils produce relatively small increases in the plant fluorine content, it is reasoned that plant foods grown on Arizona soils are not dangerously high in fluorine content.

Vegetables cooked in water containing added fluorine (5 and 24 p. p. m.) absorbed some of the fluorine. "It is not a wise policy, therefore, to cook in fluorine waters cereals, beans, and other dry foods which absorb large amounts of water during the cooking process. Again, although vegetables show relatively small increases in fluorine content as compared to cereals when they are cooked in fluorine waters, it is important that as little fluorine water as possible be used."

**The choline content of pure varieties of wheat, oats, barley, flax, soybeans, and milled fractions of wheat,** D. GLICK (*Cereal Chem.*, 22 (1945), No. 2, pp. 95-101, illus. 1).—The reineckate method previously described (E. S. R., 93, p. 249) was used for the determination of choline. Pure varieties of wheat, oats, barley, flax, and

soybeans grown in known localities were tested. Results show that hard winter, hard spring, and soft winter wheats averaged, respectively, 0.79, 0.91, and 0.88 mg./gm. (dry weight basis). Other average values were oats, 1.14; barley, 1.10; flax, 1.07; and soybeans, 2.37.

Various milling fractions of wheat were also assayed, and it was found that commercial bleaching had no effect on flours of different degrees of extraction.

"In the relationship between the degree of extraction and the percentage of constituent in wheat, a parallelism was observed for choline, as found in the present investigation, and lipid phosphorus. . . . It would appear that all of the choline in wheat exists in the form of lecithin."

It was noted that a large proportion of the total choline and lipid phosphorus is present in the more refined wheat flours.

**Nutrition and chemical growth in childhood.**—II, Original data, I. G. MACY (*Springfield, Ill.: Charles C. Thomas, 1946, vol. 2, pp. 433-1460+, illus. 706*).—Volume 1 of this study of chemical changes in growth and development (E. S. R., 88, p. 851) details the methods and technics used and presents average data for children. The present volume contains all the facts and figures for each of the 21 normal children (13 boys and 8 girls) who participated in this study by the Research Laboratory of the Children's Fund of Michigan. A foreword by L. Reynolds and a supplement by J. O. Holmes are included. The material presented includes the medical histories and pictures of the 21 subjects; the chemical analyses of the food, feces, and urine\* for consecutive balance periods over a period of months for the group of children, and for certain of the children at different age levels; anthropometric measurements; hemato-chemical determinations; actual size reproductions of roentgenograms; medical and dental examinations; basal metabolism determinations; and psychometric evaluations. The supplement presents data for 12 normal children collected in the department of home economics, Illinois Experiment Station. An appendix gives comparative values for abnormal children studied by the Research Laboratory of the Children's Fund of Michigan.

**Some factors influencing the food intake of preschool children,** C. L. JUSTICE, M. L. MATTSON, and C. SCHUCK. (Purdue Univ.). (*Jour. Amer. Dietet. Assoc., 22 (1946), No. 2, pp. 128-133*).—The food which 26 nursery school children ate at lunch showed that more food was consumed under self service (with the exception of milk) than was consumed under standard service. Data collected for 433 individual lunches showed that for three out of four menus, calorie and protein intakes averaged higher with self service; intakes of these nutrients increased with age. The study included observations on the influence of activity, age, rate of growth, sex, season, and type of diet on consumption. Food intakes of boys per kilogram and per inch exceeded those of girls of the same age. Winter and spring intake averages were smaller than those of the preceding fall, and calorie consumption was higher when the menus contained meat.

**Study of the dietary level of 100 families,** F. HARDY. (Wash. State Col. et al.). (*Jour. Home Econ., 37 (1945), No. 6, pp. 351-355*).—Information relative to the nutritive level of the diets of 100 families in Snohomish County, Washington, was obtained by checking the homemaker's records and menus. Thirty-six families met the recommended allowances of the National Research Council for every dietary essential, disregarding preparation and cooking losses of water-soluble and heat-labile vitamins in making calculations. Fourteen families had an intake of less than 75 per cent of the recommended allowance for one or two dietary essentials. More than one-third of the families were below the recommended level of calcium, more than one-fourth in calories and riboflavin, more than one-fifth in niacin, one-sixth in ascorbic acid, and one-tenth in iron and thiamine. Of the 19 farm families studied,

58 percent met recommendations as compared with 60 percent of the 30 other rural families and 69 percent of the 51 city families studied. The families with income levels above \$3,500 a year were found to be divided—half had diets below the recommendation. Of the \$1,500 to \$2,500 and \$2,500 to \$3,500 income groups, about two-thirds of the families had diets below the recommended levels in one or more factors. Home food production improved the diets, especially their calcium and ascorbic acid intakes.

**A further analysis of food selection of 80 families in Lubbock, Texas, M. W. LAMB and M. T. CORRINGTON** (*Jour. Amer. Dietet. Assoc.*, 22 (1946), No. 2, pp. 134–138).—Dietary quality, income level, and occupation influence the selection and quantity of foods consumed by average families in this community. Conclusions drawn from the study indicated that food selection improved with an increase in family income up to \$4,000 or more. Professional groups made the best food selection in type and variety of the occupation groups studied, which also included labor, skilled trade, and white collar workers. The greatest variation was in selection of protective foods such as fruits, fresh and canned vegetables, whole grain cereals, butter, margarine, and milk.

**Seasonal changes in food consumption and rate of growth of the albino rat, H. L. CAMPBELL** (*Amer. Jour. Physiol.*, 143 (1945), No. 3, pp. 428–433, illus. 5).—A large number of rats were maintained on the same diet over a period of years. Statistically significant differences in food intake varying with the season were noted—the largest intake being in the winter months and the smallest in the summer months. Over 900 adult rats, 82 to 173 rapidly growing rats 28 to 56 days of age, and separate groups of young male and female rats were studied.

The importance of choosing animals so as to represent all season of the year is emphasized by the author.

**Digestibility of human foods and animal feeds as measured by experiments with rats, G. S. FRAPS** (*Texas Sta. Bul.* 675 (1945), pp. 19).—"Results of 508 tests of the digestibility of foods and feeds by rats are summarized. The rats digested slightly less protein than did the chickens from all the feeds, but digested a little more protein than did the chickens from human foods. The rats digested less fat but more crude fiber and more nitrogen-free extract than the chickens. The digestibility of protein and of nitrogen-free extract by rats and humans averaged practically the same. Rats digested smaller percentages of fats than the humans on an average."

**The food value of a further batch of edibles estimated by chemical methods, K. MITRA and H. C. MITTRA** (*Indian Jour. Med. Res.*, 33 (1945), No. 1, pp. 91–95).—This is a continuation of a series of studies by the authors (*E. S. R.*, 92, p. 575) on the proximate composition and Ca and P values of foods utilized in India. This report lists two kinds of grain foods; seven kinds of flesh foods—including immature shrimps, winged white ants, frog, field rat's meat, turtle's egg, and fresh water mussel; five kinds of fruit; nine varieties of mushroom; six leafy vegetables; casein from cow and buffalo milk; as well as nine miscellaneous products such as sugar from cane, date palm, coconut palm, and palmyra palm. Hindi or local names, English names (when available), and Latin names are given.

High calcium values were noted for mussels and immature shrimps.

**Biological value of proteins from muscle meat of cow, buffalo and goat, K. MITRA and H. C. MITTRA** (*Indian Jour. Med. Res.*, 33 (1945), No. 1, pp. 87–90).—Rats were fed a basic diet of corn starch, sugar cubes, coconut oil, salt mixture, and calcium carbonate. The meat supplements, in the form of a dry powder, were fed at a level necessary to provide 10 or 15 percent protein.

Results showed that at the 10 percent protein level, the biological value of beef muscle meat was superior to both buffalo and goat meat, with values of 68.6, 59.5, and 60.4, respectively. At the 15 percent level, the values were 53.7, 46.4, and 46.7 for the three meats, and the differences were not considered significant.

The relative digestibility coefficient of beef muscle meat was also higher, being 97.3 and 98.4 at the 10 and 15 percent levels, respectively, compared with 94.7 and 97.1 for buffalo meat and 95.2 and 94.2 for goat meat at the comparable protein levels.

**The effect of feeding succinylsulfathiazole to rats receiving purified diets high in carbohydrate, protein, fat, or protein and fat,** L. D. WRIGHT, H. R. SKEGGS, and K. L. SPRAGUE (*Jour. Nutr.*, 29 (1945), No. 6, pp. 431-439, illus. 2).—Rats were fed a diet high in either carbohydrate, protein, and fat, or both protein and fat, and to which 5 percent succinylsulfathiazole (SST) was added.

The rate of growth, bacterial flora in the feces, and the fecal elimination and liver storage of folic acid, biotin, and pantothenic acid were measured. Results showed the weight gains continued for a longer period of time in rats fed SST in high protein diets than in animals receiving the drug in high carbohydrate or high fat diets. The bacterial flora of the feces was not demonstrably altered in number or kind of organisms by changes in the composition of the diet. The superior condition of the rats ingesting high protein diets showed only slight correlation with the fecal elimination of folic acid, biotin, and pantothenic acid. The inclusion of SST in all the diets was accompanied by a reduction in the hepatic stores of folic acid and biotin—most marked in the rats on the high fat and carbohydrate diets.

Of the determinations made, the hepatic stores of pantothenic acid showed the best correlation with the condition of the animals.

**The excretion of pyridoxine, "pseudopyridoxine," and 4-pyridoxic acid in the urine and sweat of normal individuals,** B. C. JOHNSON, T. S. HAMILTON, and H. H. MITCHELL. (Univ. Ill.). (*Jour. Biol. Chem.*, 158 (1945), No. 3, pp. 619-623).—Four young adult males were maintained for 8 hr. per day under hot moist conditions for 5 days each week. They were fed a normal diet with or without added pyridoxine (8 mg./day). Analyses were made of sweat and urine for pyridoxine, pyridoxal, and 4-pyridoxic acid.

Results showed that 50 percent of the pyridoxine supplement given orally was recovered in the sweat and urine in one of the three forms tested. On the normal or supplemented diet, 85 percent of the total metabolites excreted in the urine was in the form of 4-pyridoxic acid, 4-4.5 percent as pyridoxine, and 7-8 percent as pyridoxal. Only a small amount of the three metabolites appeared in sweat, but the percentage distribution of these three compounds was similar to that found in urine.

The possible functional form of pyridoxine in the body is discussed. See also a note by Huff and Perlzweig (p. 148).

**Effects of methods of blanching, storage, and cooking on calcium, phosphorus, and ascorbic acid contents of dehydrated green beans,** M. S. EHEART and M. L. SHOLES. (Va. Expt. Sta.). (*Food Res.*, 10 (1945), No. 4, pp. 342-350).—Landreth Stringless Green Pod bush beans were planted and harvested at four different dates. Five methods of blanching were used: (1) Tap water—18 min.; (2) tap water +  $\text{NaHSO}_3$ —18 min.; (3) tap water +  $\text{NaHSO}_4$  and  $\text{Na}_2\text{SO}_4$ —18 min.; (4) steam-blanching—30 min.; and (5) unblanched. After dehydration, samples were stored for 6 mo. in one of four ways: (a) Fruit jars in a refrigerator; (b) cellophane bags in a refrigerator; (c) same as (a) at room temperature; and (d) same as (b) at room temperature. In cooking experiments, the dehydrated beans were boiled 30 min. with or without preliminary soaking.

Under the experimental conditions used, dehydrated beans were found to be as high in phosphorus as raw beans and higher in calcium. However, most of the ascorbic acid had disappeared, since only 6.9 percent of the amount in the raw beans remained in the blanched dehydrated beans after 6 months' storage, and less than 25 percent of the amount in the dehydrated product was retained in the cooked beans.

Greatest factor influencing the vitamin and mineral contents of the raw or dehydrated beans was the date of harvest. Highest values were found in those beans harvested at an early date.

**Ascorbic acid, carotene, chlorophyll, riboflavin, and water content of summer squashes.** A. D. HOLMES, A. F. SPELMAN, and C. P. JONES. (Mass. Expt. Sta.). (*Food Res.*, 10 (1945), No. 6, pp. 489-496).—Studies were made on seven varieties of summer squash commonly grown in the New England States: (1) Cocozella Vegetable Marrow, (2) Zucchini Grey, (3) Early White Bush Scallop, (4) Early Summer Prolific Straightneck, (5) Early Summer Crookneck, (6) Butternut, and (7) Golden Cushaw. Two samples of (2), and three samples of all the other varieties were assayed.

Vitamin values are reported in milligrams per 100 gm., fresh weight. The highest ascorbic acid value, 16.7, was found in (3), while values averaging between 11.2 and 12.2 were obtained in (4), (5), and (7). High carotene values of 6.21 and 3.31 were found in (7) and (6) respectively, while all the other varieties gave values of 0.36 or lower. Best riboflavin results were found in (7) (0.249), and other squashes showing high values were (1) and (5), with 0.173 and 0.119, respectively.

Moisture content ranged from 84.6 to 95.7 percent, with (7) and (6) containing less than 90 percent moisture, 5 averaging 91.76 percent, and the others between 93.77 and 95.75 percent. Chlorophyll values were high in the green varieties only—being 6.07 and 12.25 in (1) and (2), respectively.

**Vitamin retention in quantity cooking of vegetables.** B. K. WATT and M. B. ARAYA. (U. S. D. A.). (*Jour. Home Econ.*, 37 (1945), No. 6, pp. 340-344).—Results from 17 studies on vitamin content of vegetables and vitamin retention after large scale operations are reviewed. Emphasis is placed upon the wide range of values found, the danger of generalization from even a fairly large number of cases, and the need of more information in this field before averages can be established for different methods of food preparation.

**The availability of vitamins from yeasts, I-II.** (Wis. Expt. Sta.). (*Jour. Nutr.*, 29 (1945), No. 6, pp. 373-389, illus. 1).

I. *The absorption of thiamine by human subjects from various types of bakers' yeast.* H. T. Parsons, A. Williamson, and M. L. Johnson (pp. 373-381).—Several samples of commercial compressed bakers' yeast were tested. Approximately 0.5 to 1.0 mg. of thiamine per cake of yeast was contained in the unenriched samples, and from 30 to 300 times as much in the enriched samples.

Measurements of thiamine intake and output indicated that a large portion of the thiamine ingested in the form of fresh unenriched yeast was excreted in the feces. Boiling the yeast before ingestion produced a lower fecal output and an increased urinary excretion. This was attributed to improved absorption of thiamine from the boiled samples. However, with some of the highly enriched samples of yeast, increased urinary excretion occurred when fresh yeast was consumed. No explanation of this reaction was found. The authors conclude "the differences in the absorbability of the thiamine from various fresh yeasts did not seem to be attributable either to the strain of yeast or to the amount of yeast consumed by the subjects."

II. *The accessibility to rats for growth of the thiamine in various types of bakers' yeast.* H. T. Parsons, A. Foeste, and H. Gilberg (pp. 383-389).—The same yeasts

were assayed biologically with rats. Results showed that the thiamine in fresh yeast was relatively unavailable in low potency yeast. Boiling or treatment with alcohol increased the availability of thiamine in these yeasts.

Two samples of high potency yeasts were nearly as effective sources of thiamine in the fresh as in the treated state. The results of the rat assay were considered to be in good agreement with the tests made on human subjects.

**Relative values of carotenes in foods as measured by storage of vitamin A in livers of rats, G. S. FRAPS and W. W. MEINKE.** (Tex. Expt. Sta.). (*Food Res.*, 10 (1945), No. 3, pp. 187-196).—Young rats were fed a vitamin A-free purified diet supplemented with various sources of carotene. The amount stored in the liver was assayed as spectro-vitamin A. The average total storage from 60 µg. of carotene per rat per day ranged from 63.4 to 124.1 µg. per liver with an average of 85.9 µg. The foods tested—carrots, sweetpotatoes, turnip greens, spinach, pumpkin, apricots, beet greens, alfalfa, liver, and butterfat—were assayed in terms of their beta-carotene equivalent. Liver storage values for the vegetables ranged from 16 to 64 percent (average 32 percent), while for beef liver and butterfat, the values were 179 and 145 percent, respectively, of that of carotene in oil. Cottonseed oil, added to the basal ration or directly to the supplement, increased the utilization of carotene from a value of 21 percent to 44 percent for the foods tested. The addition of tocopherol to spinach or pumpkins did not increase the storage of vitamin A in the livers, according to the experiments carried out by the authors. Twenty-four references are listed.

**Constituents of crude carotene of carrots, A. R. KEMMERER and G. S. FRAPS.** (Tex. Expt. Sta.). (*Food Res.*, 10 (1945), No. 6, pp. 457-460).—Fresh and dehydrated carrots from various localities were assayed for crude carotene and  $\beta$ -carotene equivalents according to the method of Kemmerer and Fraps (E. S. R., 91, p. 243). Fourteen known and several unidentified varieties were studied.

In fresh carrots, crude carotene values ranged from 386 to 1,120 p. p. m. (dry weight basis); in dehydrated carrots values ranged from 165 p. p. m. (for samples dehydrated in 1941) to 942 p. p. m. The  $\beta$ -carotene content varied from 42.1 to 73.3 percent,  $\alpha$ -carotene from 19.5 to 42.2 percent, and  $\beta$ -carotene equivalent from 60.1 to 83.6 percent of the crude carotene values. In general,  $\beta$ -carotene averaged roughly 55 percent, and  $\alpha$ -carotene approximately 30 percent of the total crude carotene present in the carrots.

**The vitamin A content of Arizona butter, H. FARRANKOP** (*Arizona Sta. Mimcog. Rpt.* 74 (1945), pp. 3).—This phase of the Arizona study (E. S. R., 91, p. 486), conducted as part of the National Cooperative Study on the vitamin A content of butter, involved analyses of 25 samples of market butter manufactured in Arizona. The samples obtained at intervals from December 1943 through May 1945 were found to contain from 14,754 to 19,880 International Units of vitamin A per pound, with an average of 17,457. These uniformly high values (as compared with the values of 9,974 to 13,058 International Units per pound obtained for 4 samples of nationally distributed brands analyzed in the course of the study) are attributed to the fact that green pasture for the cows is available throughout the year under Arizona climatic conditions.

**The B vitamin content of raw and cooked sweet potatoes, P. B. PEARSON and R. W. LUECKE.** (Tex. Expt. Sta.). (*Food Res.*, 10 (1945), No. 4, pp. 325-329).—Four varieties of sweetpotatoes obtained from three States were studied. Two varieties, Nancy Hall and Porto Rico, were deep yellow and the other two, Triumph and W. M. 3, were very light in color. With the exception of nicotinic acid, which seemed to run higher in the more pigmented varieties, no varietal differences were noted in the distribution of the other B vitamins. In general, the raw sweetpotatoes

averaged 1.39, 0.46, 5.56, and 10.95  $\mu\text{g./gm.}$  of thiamine, riboflavin, nicotinic acid, and pantothenic acid, respectively.

Cooking tests included baking in an oven at 204.4° C. (400° F.) and boiling. In both tests the potatoes were cooked with their skins on. The baked potatoes lost an average of 16.7 percent of their weight, while the boiled potatoes gained an average of 4.9 percent in weight. Results showed that "sweetpotatoes cooked by baking retained 75.5 percent of the thiamine, 88.6 percent of the riboflavin, 85.1 percent of the nicotinic acid, and 76.8 percent of the pantothenic acid. There was less loss of the vitamins when the potatoes were cooked by boiling. Boiled sweetpotatoes retained 92.3 percent of the thiamine, 103.2 percent of the riboflavin, 100.6 percent of the nicotinic acid, and 99.9 percent of the pantothenic acid.

"The riboflavin, nicotinic acid, and pantothenic acid contents of sprouts and the sprouted sweetpotatoes were essentially as high as for unsprouted potatoes, while for thiamine the values were somewhat lower."

**Stability of B vitamins in grape juices and wines**, L. PERLMAN and A. F. MORGAN. (Univ. Calif.). (*Food Res.*, 10 (1945), No. 4, pp. 334-341).—Experimental juices and wines were prepared from Burger grapes. To some of the wines, varying amounts (75 to 250 p. p. m.) of  $\text{SO}_2$  were added either before or after fermentation. Half of the samples were fortified with thiamine, riboflavin, pyridoxine, and pantothenic acid. Samples were stored in clear or dark bottles, in the light at room temperature, and in the refrigerator (40° to 50° F.). Tests were made at 1 and 10 mo. after storage.

Results showed that all of the added vitamins, with the exception of riboflavin, were retained in the wines. Riboflavin was largely destroyed in the clear bottles held in daylight.

Riboflavin and pantothenic acid assays were also made on 11 kinds of aged commercial wines. Values for riboflavin ranged from 6 to 21  $\mu\text{g./100 gm.}$ , and for pantothenic acid 7 to 45  $\mu\text{g./100 gm.}$

**Self-selection studies on coprophagy as a source of vitamin B complex**, C. P. RICHTER and K. K. RICE (*Amer. Jour. Physiol.*, 143 (1945), No. 3, pp. 344-354, illus. 4).—Rats were fed a self-selection diet in which all components of the B complex were either absent or provided for by dried brewer's yeast or dried liver powder or feces collected from normal adult rats.

In the absence of the B complex, loss of weight was rapid, and changes in food selection occurred so that fat was substituted for most of the carbohydrate and protein previously eaten.

Comparisons of growth rates showed that the needed vitamin B complex was supplied equally well by the feces consumed (4.5 gm.) as by the brewer's yeast supplement (2.2 gm.). This amount of feces corresponded to the daily output of 2 to 4 normal adult rats. On the dried liver supplement (2.2 gm.), growth was somewhat slower and certain rats were repelled by the bitter taste. The authors conclude "that for at least 40 to 50 days feces satisfactorily replaced all the components of the vitamin B complex found in yeast or liver powder."

The absence of any bitter or toxic substance in the feces is adduced from the fact that large amounts were consumed over a long period of time with no visible ill effects.

**Thiamine, riboflavin, and nicotinic acid retention in preparation of overseas hams and bacons**, H. P. SARETT and V. H. CHELDELIN, (Oreg. State Col. et al.). (*Jour. Nutr.*, 30 (1945), No. 1, pp. 25-30).—Heavily salted overseas hams and bacons were studied at different stages of preparation—as received, after soaking, and after cooking. The vitamin values were determined by microbiological methods. Thiamine values for whole ham, sliced ham, and bacon were, respectively, 10.1, 10.8, and 3.3

μg./gm. as received; 9.5, 6.2, and 1.7 μg./gm. after boiling; and 8.5, 9.7, and 2.7 μg./gm. after frying. Riboflavin values for the same three samples were 2.5, 2.4, and 1.0 as received; 2.2, 2.0, and 0.75 after boiling; and 2.5, 2.9, and 2.85 after frying. The nicotinic acid content ran from 31.1, 25.5, and 12.6 in the three samples as received; 30.5, 14.4, and 5.5 after soaking; and 35.3, 18.4, and 14.7 μg./gm. after frying. Bacon drippings accounted for 56 percent of the weight of the raw sample, but contained only 8.4 percent of the total nicotinic acid present and no thiamine or riboflavin.

"Average retentions of thiamine, riboflavin, and nicotinic acid after soaking and boiling of whole hams were 72, 79, and 79 percent, respectively. Subsequent frying reduced the remaining vitamins to 55, 67, and 68 percent, respectively, whereas after baking the comparable figures were 50, 79, and 71 percent. . . .

"Soaking of sliced ham left only 59, 85, and 58 percent, respectively, of the original thiamine, riboflavin, and nicotinic acid contents. Retentions after frying these slices were 47, 78, and 52 percent, while after baking 47, 68, and 47 percent, respectively, of the thiamine, riboflavin, and nicotinic acid were found.

"The losses of these vitamins on soaking of overseas bacon were large, leaving only 52, 78, and 42 percent of the original thiamine, riboflavin, and nicotinic acid. The amounts of these vitamins remaining after frying were 20, 72, and 30 percent, respectively."

**The riboflavin content of tea and some results for the pantothenic acid content,** E. A. M. BRADFORD and E. B. HUGHES (*Analyst*, 70 (1945), No. 826, pp. 2-5).—Riboflavin and pantothenic acid were assayed by microbiological methods. Tea infusions, corresponding to the way tea is usually prepared for drinking, were found unsatisfactory for riboflavin assay because of interfering substances present. A creaming procedure is described in which the interfering polyphenols were precipitated by a 2 percent solution of caffeine. Tabulated data are presented on 19 tea samples obtained from different countries and of various blends. Riboflavin values range from 6 to 11 μg./gm. and pantothenic acid from 15 to 40 μg./gm. of tea. The authors calculate that on the basis of 2.0 to 2.5 gm. tea (1 teaspoonful) per cup of infusion, approximately 25 μg. and 75 μg. of riboflavin and pantothenic acid, respectively, can be supplied exclusive of the amounts derived from any milk added.

**The nicotinic acid content of tea,** E. B. HUGHES and T. L. PARKINSON (*Analyst*, 70 (1945), No. 828, pp. 86-87).—Seven of the same tea samples previously assayed for riboflavin and pantothenic acid (see above) were assayed for nicotinic acid by the method of Wang and Kodicek (*E. S. R.*, 92, p. 758). Values ranged from 56 to 94 μg./gm.—averaging about 72 μg./gm.

**Nicotinamide methochloride and its fluorescent derivatives,** P. ELLINGER (*Nature [London]*, 155 (1945), No. 3933, pp. 319-322).—A comprehensive review of the literature on the subject is presented including a discussion of the possible interpretations of the various conflicting results obtained (48 references are listed).

**The thiamine and riboflavin content of the grain and flour of certain varieties of Kansas-grown wheat,** D. E. WHITNEY, H. HERREN, and B. D. WESTERMAN. (Kans. Expt. Sta.). (*Cereal Chem.*, 22 (1945), No. 2, pp. 90-95).—Experimentally grown Turkey, Chiefkan, Blackhull, Pawnee, Comanche, and Tenmarq varieties of wheat from the 1941 and 1942 crops were assayed for thiamine and riboflavin. Nebred wheat was also assayed from the 1942 crop, while riboflavin assays only were made on similar samples from the 1943 crop and on one additional sample—Blackhull X Tenmarq. Experimentally milled long patent flours of 70 percent extraction, with a moisture content of approximately 15 percent and an ash content of about 0.42 percent, were prepared from most of the wheat samples.

Thiamine values found ranged from 3.99 to 5.45  $\mu\text{g./gm.}$  in the wheat and from 0.82 to 1.50  $\mu\text{g./gm.}$  in the flour. Thiamine retention in the flour was calculated to be about 12 to 25 percent of that in the original wheat.

Riboflavin values over the 3-yr. period ranged from 1.00 to 1.69  $\mu\text{g./gm.}$  in the wheat and from 0.65 to 0.96  $\mu\text{g./gm.}$  in the flour. Retention in the flour was calculated to be approximately from 30 to 54 percent. Riboflavin values ran consistently lower for the 1943 wheat samples tested than for the previous 2-yr. samples (1.00 to 1.45 v. 1.25 to 1.69).

**Observations on thiamin content of stored wheat**, E. G. BAYFIELD and W. W. O'DONNELL. (Kans. Expt. Sta.). (*Food Res.*, 10 (1945), No. 6, pp. 485-488).—A study was made of the thiamine content of a number of wheats stored for periods ranging from 5 mo. to 51 yr. Values ranged from 0.29  $\mu\text{g./gm.}$  to 4.19  $\mu\text{g./gm.}$  for the samples stored for more than 10 yr.

Experimental samples were stored under normal (13 percent) and high (15 percent) natural moisture conditions with and without ethylene treatment. Results indicated that significant losses of thiamine occur on storage. Greatest losses occur under abnormal storage conditions of high moisture with consequent high temperature.

**Nuevas valoraciones de vitamina C en alimentos Mexicanos [New values for vitamin C in Mexican foods]**, F. GIRAL and L. M. DE LA TORRE (*Ciencia [Mexico]*, 6 (1945), No. 9-12, pp. 252-254).—In a continuation of the earlier studies of Giral and Viesca Viesca (*E. S. R.*, 90, p. 279), 17 foods not previously reported have been assayed for ascorbic acid. Tabulated data include common and scientific names, parts of plant assayed, and the reduced and total ascorbic acid value in milligrams per 100 gm. fresh and dry weight. Comparisons are made with other reported values; and 24 references are listed including several in German and Spanish.

**A note on the production of vitamin C by sprouting seeds**, L. P. V. JOHNSON, G. A. YOUNG, and J. B. MARSHALL (*Sci. Agr.*, 25 (1945), No. 8, pp. 499-503, illus. 1).—Of 31 varieties of legumes and cereals originally studied, only 17 showed adequate germination or ascorbic acid content to warrant further investigation. Tests made at 15.6, 22.2, and 28.9° C. showed the lowest temperature to give the best results. Only five legumes produced sprouts with ascorbic acid values over 15 mg./100 gm. Sprouting times, with maximum vitamin C production at 15.6°, were Chinese salad bean 3 days, 23 mg./100 gm.; English Broad Windsor bean 7 days, 33 mg.; Arthur pea 5 days, 17 mg.; O. A. C. No. 181 pea 5 days, 18 mg.; and Early Blue, Ottawa No. 21 5 days, 20 mg./100 gm.

**Effect of steam and hot-water blanching on ascorbic acid content of snap beans and cauliflower**, J. L. RETZER, F. O. VAN DUYNE, J. T. CHASE, and J. I. STIMPSON. (Univ. Ill.). (*Food Res.*, 10 (1945), No. 6, pp. 518-524).—Stringless Black Valentine snap beans and an unidentified variety of cauliflower were studied over a 2-yr. period. Bean samples weighing 240 gm. were blanched  $4\frac{1}{2}$  min. in steam, or 3 min. in 8 qt. of boiling water. Cauliflower samples (275 gm.) were blanched  $5\frac{1}{2}$  min. in steam, or 4 min. in 11 qt. boiling water. After cooling, the samples were quick frozen at  $-24^{\circ}$  to  $-30^{\circ}$  C., and after 16-24 hr. stored at  $-17.8^{\circ}$ . Twelve to 20 determinations were made at each stage of the processing, using small samples for each test.

Ascorbic acid values are reported in terms of milligrams per gram edible portion as determined. In the raw beans, values ranged from 0.18 to 0.20 and in cauliflower from 0.81 to 0.90. After blanching, cooling, and freezing, the ascorbic acid content of beans ranged from 0.16 to 0.17, and of cauliflower, from 0.62 to 0.70. The method of blanching did not significantly influence the results. Progressive loss of ascorbic acid occurred in both vegetables on storage. After 9 mo. of freezer storage, the

snap beans and cauliflower had lost approximately 60 to 70 percent of their original total ascorbic acid.

**Effects of different methods of cooking on the ascorbic acid content of cabbage,** I. NOBLE and E. WADDELL. (Minn. Expt. Sta.). (*Food Res.*, 10 (1945), No. 3, pp. 246-254).—Three varieties of cabbage, Marion Market, Danish Ballhead, and Wisconsin Ballhead Yellow Resistant, were tested over a 2-yr. period. Using 240 gm. of shredded cabbage, comparisons of five cooking methods were made: (1) Boiling in excess (960 cc.) water in an open kettle; (2) boiling in excess water (480 cc.) in a loosely covered kettle; (3a) cooking in a minimum amount of water (30-60 cc.) in a tightly covered kettle; (3b) same as (3a), using 60-90 cc. of water; (4) cooking in 60 cc. water in a pressure saucepan; and (5) steaming. Cooking time for each method was experimentally determined, as it was found to vary with the method used as well as the variety or lot of cabbage used.

Results are reported on the first two varieties only. Best color retention and mildest odor were noted with method (1). Strong odor and off-color results occurred with (3a), (3b), and (5), while similar results were found with (4) when the cooking time exceeded 3 min.

Freshly gathered Marion Market and Danish Ballhead cabbages averaged, respectively, 36.2 and 46.9 mg. ascorbic acid per 100 gm. fresh vegetable in 1943, and 40.4 and 44.9 mg./100 gm. in 1942. Considerable unexplainable variation in the percentage retention of ascorbic acid was noted with each method of cooking. Statistical analyses of the data indicated that methods (3), (4), and (5) were most efficient in retaining the ascorbic acid in cabbage (averaging 67 and 46 percent retention for Marion Market and Danish Ballhead, respectively), while the open-kettle method averaged 34 and 30 percent retention for the two varieties, respectively.

**Ascorbic acid content of okra as affected by maturity, storage, and cooking,** M. E. HOLLINGER and D. COLVIN. (La. State Univ.). (*Food Res.*, 10 (1945), No. 3, pp. 255-259, illus. 1).—Two similar varieties of okra were studied—Louisiana Green Velvet and Louisiana White Velvet. Ascorbic acid values were found to be highest (average—42 mg. per 100 gm. moist weight) in the young immature pods  $2\frac{1}{2}$  to 3 in. long and lowest (average—16 mg./100 gm.) in the fully mature pods 10 to  $10\frac{1}{2}$  in. long. Most samples for the storage and cooking tests were harvested when 5 to  $5\frac{1}{2}$  in. long. Losses of ascorbic acid on storage 24 and 48 hr. at room temperature (27.8° to 30° C.) averaged 36 and 54 percent, respectively, on a moist-weight basis. Storage in the refrigerator (3.3° to 4.4°) showed 100 and 92 percent retention of ascorbic acid for the same period.

Cooking methods studied included boiling the whole or sliced okra in variable amounts of water or in tomato juice, frying the sliced pods, and cooking whole pods 2 min. in a pressure saucepan. Best retention of ascorbic acid (82.2 percent) was obtained by the last method. Retention by the other methods used ranged from 44.5 to 75 percent, with the higher results occurring when tomato juice or a minimum amount of water was used.

**Vitamin C in Nebraska potatoes,** H. O. WERNER (*Better Potatoes in Nebr.*, 8 (1945), No. 1, pp. 2-6).—Nebraska potatoes were analyzed for their ascorbic acid content, and results showed that some varieties were superior to others; potatoes from green vines are superior to those from mature or dead plants; and straw-mulched or dryland potatoes have higher values than nonmulched or irrigated potatoes. The amount of ascorbic acid in all potatoes decreased rapidly during storage but more rapidly at low than at high storage temperatures.

**Some factors affecting the ascorbic acid content of tomatoes,** J. P. MCCOLLUM. (Univ. Ill.). (*Amer. Soc. Hort. Sci. Proc.*, 45 (1944), pp. 382-386).—Four strains of tomatoes were experimentally grown and tested. Results showed that no consistent

relationship could be found between ascorbic acid content, total solids, and sugar content. The amount of sunlight on the fruit was the most important factor regulating ascorbic acid production. The need of carefully selected fruits in relation to their exposure to sunlight, and of sampling the whole fruit or sectors taken from opposite angles of each fruit when making ascorbic acid assays, is emphasized. Dense foliage definitely inhibited ascorbic acid production.

**Seasonal changes in the ascorbic acid concentration of Florida grapefruit,** P. L. HARDING. (U. S. D. A.). (*Amer. Soc. Hort. Sci. Proc.*, 45 (1944), pp. 72-76).—A comprehensive study of the many factors affecting the ascorbic acid value of Florida grapefruit, including the effect of seasonal changes, has been reported elsewhere (E. S. R., 93, p. 291). The present report assembles information on the ascorbic acid content of grapefruit as affected by seasonal conditions, variety, root-stock, location of the grove, cultural practices, and size and maturity of the fruit.

**Nutritive value of canned foods.—VII [a], Effect of commercial canning and short-time storage on ascorbic acid content of grapefruit juice,** J. R. WAGNER, M. IVES, F. M. STRONG, and C. A. ELVEHJEM. (Wis. Expt. Sta.). (*Food Res.*, 10 (1945), No. 6, pp. 469-475).—This special study on grapefruit juice is part of a more complete cooperative study on canned foods in general (E. S. R., 94, p. 397).

The effect of commercial canning practice on the ascorbic acid content of grapefruit juice was studied at 12 canneries in the Rio Grande Valley. Results were in good agreement with those previously obtained by Moore et al. (E. S. R., 94, p. 409) and Ross (E. S. R., 92, p. 453). Retention of vitamin C ranged from 92.2 to 99.6 percent and averaged 96.7 percent for all plants. After 40 days' storage at about 72° F., an average of 91.3 percent of the ascorbic acid found in the freshly canned juice was still retained.

**The vitamin C content of guavas,** H. J. WEBBER. (Calif. Citrus Expt. Sta.). (*Amer. Soc. Hort. Sci. Proc.*, 45 (1944), pp. 87-94).—Published and unpublished data from several sources have been tabulated to present additional evidence of the extraordinary richness of guava fruits in ascorbic acid.

**Acute and chronic ascorbic acid deficiencies in the Rhesus monkey,** J. H. SHAW, P. H. PHILLIPS, and C. A. ELVEHJEM. (Wis. Expt. Sta.). (*Jour. Nutr.*, 29 (1945), No. 6, pp. 365-372, illus. 2).—The animals were fed a purified diet composed of 74 percent sucrose, 18 percent washed casein, 4 percent salt mixture, and 4 percent cottonseed oil; 3 percent of a 1 : 20 liver extract was added at the expense of the entire ration. Vitamin supplements consisted of thiamine, riboflavin, pyridoxine, calcium pantothenate, nicotinic acid, inositol, *p*-aminobenzoic acid, and vitamin D fortified halibut-liver oil. Control animals received in addition 7.5 mg. of ascorbic acid per kilogram of body weight per day.

The monkeys on the ascorbic acid-free diet developed an acute deficiency in 30 to 50 days. Symptoms observed were: Gradual loss of about 10 percent body weight over a 2-week period, followed by more rapid loss of weight, loss of appetite, and roughening of the fur without loss of hair. Tenderness in the leg joints was evident. No gingival changes could be observed.

Chronic ascorbic acid deficiency was induced by the addition of 0.25 mg. of ascorbic acid per kilogram body weight per day, and other symptoms appeared. Gingival lesions occurred with necrosis of the gums, alveolar resorption, and in some cases a high incidence of caries. Tenderness and swelling of the joints was more pronounced, and bone resorption occurred at the bone-cartilage junctions, especially at the end of the long bones in the legs. An extensive loss of hair and dermatitis which occurred could be prevented by the addition of biotin to the diet.

The authors conclude "these data indicate that the signs of acute and chronic ascorbic acid deficiencies in the monkey are distinctly different. They may partially

explain the differences observed in experimentally produced and spontaneous scurvy in man."

**Blood regeneration in pyridoxine-deficient rats**, A. KORNBERG, H. TABOR, and W. H. SEBRELL (*Amer. Jour. Physiol.*, 143 (1945), No. 3, pp. 434-439).—Compared with pyridoxine-fed litter mates, pair-fed pyridoxine-deficient rats occasionally develop a moderate degree of anemia. This can be exaggerated by repeated hemorrhage. In recovery periods of 2, 4, 6, 10, and 22 days following the third hemorrhage, impaired erythropoiesis is evident in the pyridoxine-deficient animal. The addition of folic acid to the diet improves the blood picture in both the pyridoxine-supplemented and pyridoxine-deficient animals, but does not materially alter the relative values in the two groups. The erythropoietic inadequacy of the deficient animals is prevented by pyridoxine even when the administration (100 µg. daily) is begun only 2 days before the start of hemorrhage.

## TEXTILES AND CLOTHING

**How the war affected civilian textiles**, B. V. MORRISON, H. M. FLETCHER, P. B. MACK, E. C. MORSE, E. L. PHELPS, and E. E. STOUT. (U. S. D. A. coop. Pa. State Col., Tenn., Minn., and Wash. Expt. Stas., et al.). (*Jour. Home Econ.*, 38 (1946), No. 1, pp. 21-30).—This study was initiated in 1944 to determine the quality of wartime fabrics which consumers found on retail markets in five sections of the country. Confining purchases to 5 types of staple cotton materials, 5 types of commonly used rayon fabrics, and 4 types of wool and part-wool materials, a representative of the U. S. D. A. Bureau of Human Nutrition and Home Economics bought 3 fabrics of each of the 14 types of materials to represent the best, medium, and poorest qualities.

Most fabrics sold as gabardine were found to be jeans or "middy" twills; salespeople often misrepresented the type and fiber content of fabrics. Gingham showed fewer warp and filling yarns to the inch than did peacetime gingshams of similar weights, the counts averaging 77 and 87 warp and 58 and 72 filling yarns per inch for the respective periods. The wartime chambrays purchased in Minnesota and the District of Columbia had a sufficiently high average warp and filling breaking strength for good wear. Several of the poorest quality chambrays had few yarns per inch in one direction or other. Few good quality percales were found; only one material approximated an 80-square. Before the war, the prices paid for percales in six northeastern states varied between 12 and 29 ct. (1941) compared to 19 and 85 ct. per yard in 1944. The amount of sizing in cotton fabrics varied; eight of the chambrays studied had less than 5 percent, while some had over 10 percent of non-fibrous material; gingshams ranged from 1 to 17 percent; percales contained 5 percent or more. Few of the 1944 cotton fabrics held their color satisfactorily when they were washed, exposed to light, or wet with perspiration. The effect of laundering on the cotton fabrics varied from stretching 1 to 3 percent (broadcloths and gabardines) to 10 percent shrinkage in the gingshams.

Rayons were found generally more plentiful and comparable to prewar fabrics than were the cottons. The color fastness to light, washing, perspiration of practically all rayon fabrics was poor.

In general, the breaking strength of the all-wool fabrics was comparatively low, with a low nonfibrous content. Twenty-nine of the wool and wool-mixed fabrics faded by mild washing, and more than half faded badly by exposure to a carbon arc light for 80 hr.

**Effects of temperature and humidity on cellulosic materials with special reference to tire cord**, J. M. McNEILL (*U. S. Dept. Agr., Libr. List 24 (1946) pp. 9*).—Lists of 41 annotated references and 14 patents are included.

**Simple improvements increase capacity of Colorado A & M wool laboratory,** E. BERTONE (*Colo. Farm Bul. [Colorado Sta.]*, 7 (1945), No. 6, pp. 12-13, illus. 1).—Use of mesh cotton laundry bags instead of screen bottom trays saved two-thirds the time needed to scour a wool sample, and pretreating the dusted wool in water before scouring resulted in an estimated saving of one-third in soap.

**New ideas for clothing make-overs,** C. L. SCOTT. (U. S. D. A.). (*Jour. Home Econ.*, 37 (1945), No. 9, pp. 550-553, illus. 3).—Suggestions are made for using knit goods, leather, and fur in made-over garments.

## HOME MANAGEMENT AND EQUIPMENT

**Postwar equipment,** A. E. BARAGAR. (Nebr. Expt. Sta.). (*Jour. Home Econ.*, 38 (1946), No. 1, pp. 11-15).—This discussion, based on market surveys, points out that the first equipment appearing on the market after war shortages will resemble prewar models, as manufacturers can furnish these models more rapidly by using their prewar machinery. Emphasizing that the home economist should be ready to give counsel on when to buy and suggestions as to who should buy, the author considers equipment of the future in terms of the consumer's designs and needs.

**If you're shopping for home equipment,** A. E. BARAGAR, E. KNOWLES, E. C. McCracken, L. J. PEET, P. B. POTTER, G. M. REDFIELD, and E. and L. SATER. (U. S. D. A. et al.). (*Jour. Home Econ.*, 38 (1946), No. 3, pp. 137-148).—This symposium is a shopping guide for refrigerators, home freezers, washing machines, kitchen ranges, electric roasters, mixers, toasters, coffee makers, pressure cooker saucepans, pressure cookers, electric irons, and vacuum cleaners.

**Planning the kitchen,** M. BUDOLFSON. (Coop. U. S. D. A.). (*Iowa Sta. Bul. P77* (1945), pp. 557-575, illus. 14).—Suggestions are made for improving kitchens by rearranging equipment, changing storage arrangement, adding new equipment, and making structural changes which involve rebuilding of the room. Plans for arrangements of U-shape, L-shape, and corridor-shape kitchens are illustrated. Working heights, preparation units, sink units, and china and cooking utensil storage plans are recommended for arranging cabinets conveniently for tasks to be done and equipment to be used.

**Fifty farm kitchens,** C. FITZSIMMONS and N. L. PERKINS. (Univ. Ill.). (*Jour. Home Econ.*, 37 (1945), No. 9, pp. 567-570).—A study of kitchen arrangements used by 50 Illinois farm families was made to determine the types of activities carried on there, the kinds of equipment used, and the suitability of the rooms for the activities. Fourteen distinct types of activity were found, including dining, resting, laundering, playing, dressing, preparation of produce for market, and bathing, which were in addition to the food preparation activities. The smallest number of activities carried on in any kitchen was 4 and the largest 18. The home owner families showed the highest average score and the narrowest range in the analyses made of the provisions for performing activities in the kitchens, although families of hired men showed about the same range and average score as the owners who adjusted to the homes in which they lived without making changes.

**Relation of posture to fatigue in ironing,** E. E. KNOWLES (*Jour. Home Econ.*, 37 (1945), No. 9, pp. 584-587, illus. 4).—Twenty-three homemakers were studied in order to determine what factors were responsible for fatigue caused by ironing. Films taken of 11 women were analyzed by projecting the images on polar co-ordinate paper to calculate the "angle of bend." The study revealed that ironing at the standard 31-in. board height increased the angle-of-bend from 18 to 149 percent above that when preferred heights were used. Standard physiological testing devices, a specially designed cardiometer, and mechanical platforms were used

to determine whether metabolic, respiratory, heart rates, or other body processes were affected by posture. The women who ironed at the 31-in. height showed a rate of increase above those shown when ironing at preferred heights; force exerted rose from 2.4 to 48 percent; weight distribution and postural shifting, from 0 to 2 percent; caloric requirements, from 14 to 32 percent; heart rate, from 28 to 30 percent; pulmonary ventilation, from 10 to 51 percent; and blood pressure, from 2 to 21 percent.

The author concludes that "body height cannot be the criterion for the selection of a working height."

## REPORTS AND PROCEEDINGS

**Fifty-eighth Annual Report of the Vermont Experiment Station [1945],** J. E. CARRIGAN. (Partly coop. U. S. D. A. et al.). (*Vermont Sta. Rpt. 1945, pp. 9-35, illus. 5*).—This report, compiled and edited by M. F. Lavallard as a part of Annual Report No. 1 of the College of Agriculture, University of Vermont, includes a summary of the work done on each project during the year, including data on soils and fertilizers as to the value of sawdust and shavings as bedding material for cattle, boron need in Vermont soils, and phosphorus fixation and availability; pasture and hay crops, including genetics studies with zigzag clover and other legumes, effect of climatic factors and breeding studies on pasture grasses and clovers, influence of seed mixtures and fertilizers on pastures, maintenance of permanent haylands, effect of hay-drying methods on conservation of carotene and grade of hay, soil erosion studies, value of birdsfoot trefoil, and chemical weed killers; cultivated crops, including studies of potato scab and potato leafroll, fertilization of field beans and silage corn, and tests of varieties of lima beans, edible soybeans, and sweet corn, field corn, field beans, soybeans, and oats; woodland crops, including factors affecting sap flow and sugar content of sugar maple trees and logs; dairying, including insulation in dairy barns, effect of method of feeding and prolonged use of colostrum on calves, methods of detecting mastitis infection, and fluctuation in the weight of dairy cattle; farm management and agricultural economics, including data on the business management of Vermont towns, and factors affecting land use in Vermont; and home management, including saving time in housework.

**Ontario Agricultural College and Experimental Farm, Guelph, Ontario—Report of the President for the year ending March 31, 1945,** G. I. CHRISTIE (*Ontario Agr. Col. and Expt. Farm Ann. Rpt., 70 (1944), pp. 97, illus. 38*).—In addition to administrative data, this report notes progress in studies on silage corn harvesting cost, use of cobalt sulfate to cure wood chewing by calves, inheritance of hernia in pigs and relation of length and shape of face to thickness of back fat, pasture capacity, riboflavin content of eggs, hoof-and-horn meal for poultry, metabolism of tyrosin by chicks, pullorum organisms in eggs, effect on bacteria of adding tomato juice in canning non-acid vegetables, storage rot of potatoes, control of water-core in turnips, tests of fungicides for apples and potatoes, sprays for poison-ivy, soil management, plow-sole applications of fertilizers, mineral and vitamin values of Canadian cheese, control of moisture in cheese and butter and of color defects in butter, tests of DDT and hexachlorobenzene, control of turnip aphid, improvement of wheat, barley, and potatoes, storage of vegetables and apples, varieties of squash for freezing, linseed meal for poultry, and magnesium in poultry rations.

## MISCELLANEOUS

Available bibliographies and lists (*U. S. Dept. Agr., Libr. List 25 (1946), pp. 3*).

**Colorado Farm Bulletin** [September-October, November-December 1945] (*Colo. Farm Bul. [Colorado Sta.]*, 7 (1945), Nos. 5, pp. 15, illus. 16; 6, pp. 15, illus. 7).—In addition to articles noted elsewhere in this issue, No. 5 contains More Sugar Beets, Wheat, Barley, and Vegetables—Colorado's Postwar Goal, by R. T. Burdick (pp. 2-3, 11); Experimental Results with DDT, by G. M. List (pp. 4-5, 14); Facts About DDT, by M. G. Payne (p. 5); and Possibilities of Profit From Winter Feeding—Big Meat Demand Important Factor, by R. T. Burdick (pp. 10-11).

**Mississippi Farm Research** [January 1946] (*Miss. Farm Res. [Mississippi Sta.]*, 9 (1946), No. 1, pp. 8, illus. 2).—In addition to several articles noted elsewhere in this issue and the usual weather notes, this number contains The National Livestock Situation, by D. W. Parvin (p. 1); Branch Station Expansion Program (pp. 1, 7), previously noted (*E. S. R.*, 94, p. 847); Tests of Corn Hybrids and Varieties in Mississippi, by R. C. Eckhardt, W. A. Douglas, and A. L. Hammer (pp. 1, 2-3), also to be published as a station bulletin; Bedding Sweetpotatoes in Relation to Planting Requirements, by W. S. Anderson (pp. 1, 3); Soybean Varieties and Dates of Planting, by P. R. Henson and R. B. Carr (pp. 4-5, 6, 7), also to be published as a station bulletin; Bloat in Cattle, by J. W. Scales (pp. 1, 7); and Phosphate for Late-Planted Cotton, by J. L. Anthony (p. 8), in which results for a single season indicated that "should cotton be planted as late as June 1, it would not be a bad idea to increase phosphate applications over those that might have been used under cotton planted at an earlier date."

**Bimonthly Bulletin** [January-February 1946] (*North Dakota Sta. Bimo. Bul.* 8 (1946), No. 3, pp. 43).—In addition to articles noted elsewhere in this issue, a review of Wyoming Station Bulletin 273 (*E. S. R.*, 94, p. 463), and miscellaneous notes, this number contains Oats Rusts in 1945, by T. E. Stoa (pp. 30, 32); North Dakota Farm Prices, by P. V. Hemphill (pp. 40-42); and Research Achievements, U. S. Department of Agriculture (pp. 42-43).

## NOTES

---

**California University and Station.**—Dr. Robert L. Usinger, assistant professor of entomology and assistant entomologist, has returned from service with the malaria control work of the U. S. Public Health Service and has been assigned to headquarters at Berkeley.

**Purdue University and Indiana Station.**—Following the diversion of part of the poultry farm to campus expansion, a farm of 130 acres about 2.5 miles distant has been purchased for research with chickens and turkeys.

Recent appointments include in chemistry Dr. Edwin T. Mertz as assistant professor and in veterinary science Drs. Floyd V. Washko and Harold D. James for research in swine diseases.

**Maine University and Station.**—According to a note in *Poultry Science*, Dr. Thomas G. Culton of the Louisiana Station has been appointed assistant professor of poultry husbandry and assistant poultry husbandryman in the station. Cecil E. Howes has been appointed instructor in poultry husbandry.

**Maryland University and Station.**—Dr. Charles H. Mahoney has resigned as head of the department of horticulture to engage in commercial work.

**Michigan College and Station.**—A tract of 227 acres of rolling land near Tipton in southeastern Michigan has been given to the college by H. A. Fee of Adrian together with the income from an endowment for its maintenance. The tract is known as Hidden Lake Gardens and has been extensively improved with greenhouses, a rock garden, and a large amount of plant material. Clarence H. Hoxsie has been appointed superintendent.

Other recent endowments include \$5,000 for research on the spearmint and peppermint industry, \$1,350 for research on the value of the addition of dried baker's yeast to cereal products, \$1,000 for research on turkeys, \$500 from the American College of Dentists for continuance of the studies of tooth decay in rats, and \$300 for studies on fungicides.

**Washington College.**—Dr. Gale H. Conner has been added to the staff in veterinary medicine.

**Wisconsin University and Station.**—Leonard A. Salter, Jr., associate professor of agricultural economics and assistant agricultural economist since 1940, and secretary of the Regional Land Tenure Research Committee, was, together with his wife and son, fatally burned in the LaSalle Hotel fire in Chicago on June 5. He was born in Marlboro, Mass., September 29, 1911, and graduated from the Massachusetts College in 1932. He had also been associated with the Connecticut University and Storrs Station and had been Connecticut State director of rural rehabilitation for the Federal Emergency Relief Administration.

B. D. Leith, professor of agronomy and superintendent of the Hill Farms since 1929, has retired.

Dr. G. K. Underbjerg has been added to the research staff in veterinary science, and Dr. William H. Sewell, formerly of the Oklahoma College and Station, to that in rural sociology.

**Association of Land-Grant Colleges and Universities.**—Announcement is made that the 1946 annual convention will be held in Chicago, December 16 to 18, and preliminary meetings are scheduled for December 13 to 15.

## RECENT WORK IN AGRICULTURAL SCIENCE<sup>1</sup>

---

### AGRICULTURAL AND BIOLOGICAL CHEMISTRY AND MICROTECHNIC

Studies of the composition of the wheat kernel, I-II. (U. S. D. A. coop. Ohio Expt. Sta.). (*Cereal Chem.*, 22 (1945), No. 5, pp. 351-371, illus. 3).

I. *Distribution of ash and protein in center sections*, V. H. Morris, T. L. Alexander, and E. D. Pascoe (pp. 351-361).—By a process of microdissection applied to central portions of wheat kernels cemented upon microscope slides and fractionated as drillings and cuttings by means of small, motor-drive dental drills, the authors obtained four pure endosperm fractions and two bran fractions. Of these, the ash and protein contents were determined. A hard red winter wheat (Tenmarq) and a soft red winter wheat (Trumbull) were used, each sample being a composite from several crops grown in various localities.

The lowest concentration of ash was found in the fraction defined as the "cheek endosperm" fraction of both varieties, with the "center" endosperm fractions about 0.05 percent higher. The concentration of ash in the peripheral endosperm zone was considerably greater than in the cheek or center fractions, although the magnitude of the difference was not the same for both varieties. Concentrations ranged from 0.246 to 0.400 percent in endosperm fractions of the Tenmarq samples and from 0.206 to 0.564 percent in Trumbull fractions. The ash content of the total endosperm of the center section was 0.359 and 0.417 percent for Tenmarq and Trumbull, respectively. In the bran fractions, Tenmarq was 0.86 percentage points higher than Trumbull, 6.42 compared to 5.56 percent.

The distribution of protein in the various fractions was much the same as that of ash except that the lowest concentration was found in the center endosperm, with the cheek fraction somewhat higher. The increase from the endosperm to the bran was much less. The protein content of the peripheral endosperm zone was 13.6 and 10.9 percent for Tenmarq and Trumbull, respectively, as compared with 8.9 and 6.8 percent in the center zone.

<sup>1</sup>The publications abstracted in these columns are seldom available for distribution by the Office of Experiment Stations. In general, application should be made to the Office of Information of the U. S. Department of Agriculture, Washington 25, D. C., for publications of the Department; to the directors of the State agricultural experiment stations, as listed on page 8 of the cover of this issue, for publications of the several experiment stations; and to publishers of books and journals for material issued by them. Microfilms and photostatic copies, the latter legible without magnifying equipment, may be purchased from the Library, U. S. Department of Agriculture, Washington 25, D. C. Rates and other details will be supplied by the Library on request.

The rate of increase in concentration of ash and protein in the peripheral zone as compared to the central zone was about the same for both constituents. The principal difference in distribution was in the bran coat. In these tissues the protein content was about 1.4 times that of the whole endosperm, in contrast to the ash content which was 13 to 18 times that of the endosperm.

The relatively wide difference in concentration of ash and protein in the two zones into which the endosperm was separated is considered to offer considerable support to the idea of an increasing gradient in the concentration of these constituents from the center of the endosperm to the bran coat.

II. *Distribution of certain inorganic elements in center sections*, V. H. Morris, E. D. Pascoe, and T. L. Alexander (pp. 361-371).—Applying a spectrographic procedure, described in manipulative detail, to the wheat kernel fractions above defined, the authors found that on an ash basis, potassium was higher in concentration in the peripheral than in the central zone; phosphorus and calcium about the same in the two zones; and sodium, manganese, and copper lower in the peripheral zone. The results of the determinations of iron and of magnesium gave no consistent indications. Comparing concentrations in the endosperm as a whole with those in the bran coat, magnesium and manganese were higher in bran ash, and phosphorus and potassium were about the same in the two tissues; sodium, calcium, iron, and copper were higher in the endosperm. On a dry-matter basis, the peripheral zone contained higher concentrations of phosphorus, potassium, calcium, and probably magnesium than did the central zone. The data for the remaining elements were inconsistent. Of the relatively large differences in total ash shown to exist between the central and peripheral-endosperm zones phosphorus and potassium accounted for a considerable part of the higher ash in the latter zone. The composition of the bran resembled that of endosperm in that both phosphorus and potassium were major constituents. It differed, however, in that magnesium also was a major constituent, the concentration equalling about half that of potassium.

Effects of variety and environment on the analyses of germinated wheat and barley, E. KNEEN and H. L. HADS. (Nebr. Expt. Sta.). (*Cereal Chem.*, 22 (1945), No. 5, pp. 407-418).—In four barley varieties from three localities, the  $\beta$ -amylase activities of the ungerminated grains and the  $\alpha$ - and  $\beta$ -amylase activities of the germinated samples were influenced both by variety and by environment of growth. There was an interstation relationship between barley nitrogen, barley total  $\beta$ -amylase, and the  $\alpha$ - and  $\beta$ -amylase activities of the germinated samples.

In several varieties of hard red winter wheat, also, the  $\beta$ -amylase activities of the ungerminated grain and the  $\alpha$ - and  $\beta$ -amylase activities of the germinated samples were dependent on both variety and environment of growth. There was an interstation relationship between wheat nitrogen and wheat total  $\beta$ -amylase and between either of these properties and the  $\beta$ -amylase activities of the germinated samples. On an interstation basis, a tendency of those germinated samples having high total  $\beta$ -amylase also to have high  $\alpha$ -amylase activity was evident. No relationship between the  $\alpha$ -amylase activities of the ungerminated wheats and any other property, either of the ungerminated or the germinated samples, was apparent.

“With hard red winter wheats, as with barley, a prominent factor in the selection of samples for the development of  $\alpha$ - and  $\beta$ -amylase by malting should be the environment of growth. The indication is that wheats from locations conducive to the production of high-nitrogen grain would be superior in this respect. Among those grown at any one location, a further selection may be

**Effect of moisture content, temperature, and length of storage on the development of "sick" wheat in sealed containers,** E. P. CARTER and G. Y. YOUNG. (U. S. D. A.). (*Cereal Chem.*, 22 (1945), No. 5, pp. 418-428).—Sick wheat was produced artificially by storing sound wheat containing different amounts of moisture in sealed quart jars at various temperatures in temperature-controlled cabinets, the proportion of sick kernels in general increasing with the moisture content of the grain, the temperature of storage, and the length of the storage period. There was no visible fungus growth on the wheat such as usually takes place when moist wheat is exposed in the open air, except in a few jars, and these were discarded. Wheat containing 12.2 percent moisture stored at 40° C. developed sick wheat symptoms when stored 279 days or longer, but not when stored at a lower temperature. A small percentage of sick wheat was produced in 32 days in wheat containing 18.6 percent moisture when stored at 5°, and up to 100 percent sick kernels when stored at higher temperatures and for longer periods of time. The development of the sick wheat condition in general was accompanied by loss in viability and increase in fat acidity.

**Preliminary studies with the extensograph,** P. P. MERRITT and C. H. BAILEY. (Minn. Expt. Sta.). (*Cereal Chem.*, 22, (1945), No. 5, pp. 372-391, illus. 1).—Replicability of extensograph tests was good when a standard procedure involving the use of unleavened doughs was employed. Tests repeated on the same dough rather than single tests after varying rest periods are recommended. Oxidizing action of potassium bromate and potassium iodate effected a decrease in extensibility and in the area enclosed by the curve, and an increase in resistance to extension. Two and three successive testings of doughs treated with potassium bromate effected greater reduction in area of curves than did the corresponding tests of doughs containing potassium iodate. A positive loaf volume response to potassium bromate was obtained with a strong and medium-strength flour but not with a weak flour. Reducing agents such as sodium sulfite and sodium thiosulfate increased in extensibility and decreased in resistance to extension of doughs. Curve area was increased slightly by moderate dosages of sodium sulfite and decreased by sodium thiosulfate. Reducing action of sodium sulfite had little effect on the loaf volumes of a strong and medium-strength flour but increased the loaf volumes of a weak flour. The effects of potassium bromate and sodium sulfite added together showed a variable degree of mutual compensation. Leavening action of yeast decreased all dimensions of extensogram curves but was partially counteracted by the addition of either potassium bromate or sodium sulfite to the formula. The effects of shortenings varied with the flour. In general, they increased extensibility but had no uniform effect on resistance or curve area. Nonfat milk solids decreased extensibility and resistance to extension with flours of low protein content. A dosage of 3 gm. of nonfat milk solids per 100 gm. of flour increased curve area and stabilized doughs against the effect of repeated tests to a greater extent than a dosage of 6 gm. per 100 gm. of flour. Prolonged mixing decreased the extensibility and curve areas of fermented doughs at baking time and tended to decrease resistance and curve areas to extension. Lengthened fermentation decreased resistance and curve areas when measured at the end of the proof period.

"Age-index" values of doughs may be computed from a formula involving the protein content of the flour and measurements characterizing the extensogram. These values may prove useful in predicting the bromate requirements of doughs.

Chemical studies of pineapple (*Ananas sativus* Lindl), I-II (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 10, pp. 1646-1652).—The first two papers of this series are concerned, respectively, with the general composition of the volatile oil obtainable from fresh pineapples, including a comparison of the oils from the summer and from the winter crops, and with the identification, as the methyl ester of  $\beta$ -methylthiolpropionic acid, of a sulfur compound found in very small quantity in the oil fractions of higher boiling point.

I. *The volatile flavor and odor constituents of pineapple*, A. J. Haagen-Smit, J. G. Kirchner, A. N. Prater, and C. L. Deasy (pp. 1646-1650).—The summer fruit was found to have a volatile oil content of 190 mg. per kilogram of the trimmed fruit, the winter fruit 15.6 mg. per kilogram, the difference between summer and winter fruit oils consisting largely in the presence of much more ethyl acetate and ethanol (119.6 mg. and 60.5 mg. per kilogram, respectively) in the summer than in the winter oil. In addition to ethyl alcohol and ethyl acetate, the following compounds were found in the summer fruit: Acetaldehyde, ethyl isovalerate, methyl *n*-propyl ketone, ethyl *n*-caproate, ethyl acrylate (probably), acetic acid, an ethyl ester of a  $C_5$  unsaturated acid, some methyl ester of the same acid, and an ethyl ester of a  $C_7$  keto acid. The winter fruit contained, besides ethyl acetate, the following: Acetaldehyde, methyl isocaproate, methyl isovalerate, methyl *N*-valerate, a methyl ester of a  $C_5$  hydroxy acid, and methyl caprylate. Both the winter and summer fruit contained a sulfur compound in the higher boiling fractions. Except for the ethyl acetate, the esters investigated in the winter oil were methyl esters. In the summer fruit, only one methyl ester was found.

II. *Isolation and identification of a sulfur-containing ester in pineapple*, A. J. Haagen-Smit, J. G. Kirchner, C. L. Deasy, and A. N. Prater (pp. 1651-1652).—A sulfur-containing ester,  $CH_3SCH_2CH_2COOCH_3$ , was isolated from the higher-boiling volatile material from pineapple fruit pulp. This compound was converted by oxidation to the sulfone, m. p. 93.6°-94° [C.], which was identified by synthesis.

The chemical composition of the adult human body and its bearing on the biochemistry of growth, H. H. MITCHELL, T. S. HAMILTON, F. R. STEGGERDA, and H. W. BEAN. (Univ. Ill.). (*Jour. Biol. Chem.*, 158 (1945), No. 3, pp. 625-637).—Assays were made on the body of a normal adult male 35 yr. of age weighing 70.55 kg. The chemical composition was found to be as follows:

Water, 67.85; fat (ether extract) 12.51; crude protein ( $N \times 6.25$ ) 14.39; ash, 4.84; calcium, 1.596; phosphorus, 0.771; and gross energy (heat of combustion) 1.930. Individual analyses of the skeleton, musculature, skin, and many visceral organs are reported. On the assumption that the integration of calcium accretions during the growing period equals the calcium content of the adult organism, the data from these analyses have been considered in a discussion of calcium requirements for growth. A bibliography of 39 references is included.

Studies on protein denaturation.—I, Electrophoretic study kinetics at neutrality of heat denaturation of  $\beta$ -lactoglobulin, D. R. BRIGGS and R. HULL. (Minn. Expt. Sta.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 11, pp. 2007-2014, illus. 4).—At a pH value near seven and in a buffer solution having an ionic strength of the order of 0.1, the heat denaturation of  $\beta$ -lactoglobulin was found to involve at least two processes. The products of these could be distinguished and their ratios could be measured because of the difference between their electrophoretic mobilities.

The first process (or group of processes) which was initiated only at temperatures above 65° [C.], was not accompanied by any appreciable

change in electrophoretic mobility of the protein, but was accompanied by an approximately four-fold increase in particle weight and an increase in frictional ratio. Preliminary calculations indicated the over-all activation energy for this process to be of the order of 48,000 calories, on the assumption of a first order reaction, for the temperature change from 70° to 75°.

The second process, which could take place only after the first had occurred, proceeded at temperatures below that at which the first was initiated. The second process was accompanied by a marked increase in electrophoretic mobility over that of the native protein or that of the product of the first process. It was also accompanied by a further increase (probably unlimited) in particle weight but no marked further increase in frictional ratio. This second process, at temperatures of 70° and below and in phosphate buffer of pH 6.9, ionic strength 0.1, proceeds with a constant activation energy of about 28,000 calories and a temperature coefficient between 60° and 70° of about 3.6 ( $Q_{10} = 3.6$ ). It followed accurately the concentration-time characteristics of a second order reaction. Above a temperature of 75° this process was markedly repressed as the temperature was increased, until at 99° it did not take place at all. Increase in pH or decrease in ionic strength of the solution, in which the heat denaturation was carried out, depressed the rate of this reaction. It is believed probable that this process was markedly influenced by the electrokinetic potential of the particles of the primary denatured protein. There was no evidence that the first denaturation process was affected in this way.

The configuration of the pyranose rings in polysaccharides, K. J. PALMER and M. B. HARTZOG. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 10, pp. 1865-1866).—In an X-ray study of pectin, its derivatives, and other compounds containing the uronic acid unit, the authors found an identity period of 15.0 a.u. in oriented fibres of sodium alginate. In pectic acid fibers, the identity period was close to 13.0 Å. Conclusions drawn from these observations with regard to the type of pyranose ring present, projection per unit along the fiber axis, and chain symmetry, all with reference to fiber identity period, are tabulated. It is further concluded that "(1) the galacturonide chain would appear less flexible than the others, since in both pectic acid and sodium pectate the screw symmetry remains three-fold; and (2) alginic acid and sodium alginate not only have chains of different screw symmetry but the pyranose rings apparently have different configurations."

Allyl ethers of carbohydrates.—III, Ethers of glucose and galactose, E. A. TALLEY, M. D. VALE, and E. YANOVSKY. (U.S.D.A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 11, pp. 2037-2039).—The preceding papers of this series (E. S. R., 94, pp. 568, 713) have been concerned with the preparation of allyl ethers of a variety of polyhydroxy compounds, including nonreducing carbohydrates but no reducing sugars. Because of side reactions in strongly alkaline solutions used for etherification, the reducing sugars gave low yields of mixed products. Glucosides were, therefore, prepared and used as intermediates, the anhydrous sugars being treated for the preparation of the intermediates with anhydrous allyl alcohol in which dry hydrogen chloride had been dissolved. Etherification of  $\alpha$ -allyl glucoside and of  $\alpha$ -allyl galactoside was then carried out in the usual way by the action of strong sodium hydroxide solution and allyl bromide. Penta-allyl ethers were thus prepared for the first time from  $\alpha$ -allyl glucoside and galactoside and  $\beta$ -allyl glucoside tetraacetate. Also a penta-allyl ether was prepared directly from glucose. The properties of these compounds are described.

The action of hydrogen peroxide on carbohydrates, J. H. PAYNE and L. FOSTER. (Univ. Hawaii). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 10, pp. 1654-1656).—A quantitative investigation of the action of hydrogen peroxide on glyceric aldehyde, erythritol, *d*-arabinose, *d*-glucose, and sucrose showed that hydrogen was a characteristic reaction product in every instance. A satisfactory reaction mechanism placed the origin of the hydrogen in formaldehyde produced in the oxidative degradation of the compounds. Glyceric aldehyde apparently underwent a dismutation reaction in the presence of low concentrations of hydrogen peroxide.

1,4-Anhydro-D,L-xylitol, J. F. CARSON and W. D. MACLAY. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 10, pp. 1808-1810).—Xylitol was dehydrated with benzenesulfonic acid or sulfuric acid to yield a mixture of dehydration products from which a pure anhydroxylitol was isolated in crystalline form. Anhydroxylitol was characterized by the preparation of three crystalline derivatives, the tribenzoate, tricarbanilate, and the mono-trityl diacetate. By oxidation with periodic acid and sodium metaperiodate, anhydroxylitol was shown to contain a 1,4 oxygen ring and was designated as 1,4-anhydro-D,L-xylitol.

The thermal degradation of pectin, R. C. MERRILL and M. WEEKS. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 12, pp. 2244-2247, illus. 1).—The large initial decrease in viscosity of pectin solutions on heating was found to be due mainly to the breaking of primary chemical valence bonds rather than to the destruction of a secondary aggregate. This was indicated by the irreversibility of degradation, the absence of a pronounced effect of urea and temperature (up to 50 percent) on the viscosity of dilute pectin solutions, the fact that the loss in relative viscosity was found to be closely associated with a decrease in the intrinsic viscosity of the pectin, and the magnitude of the value for the activation energy of the loss in viscosity with heating time ( $28,000 \pm 6,000$  calories per mole).

An X-ray diffraction investigation of sodium pectate, K. J. PALMER and M. B. HARTZOG. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 12, pp. 2122-2127, illus. 4).—The results of an X-ray diffraction investigation of oriented sodium pectate fibers are recorded. The authors' interpretation of these results indicates that the galacturamide chain has the configuration of a three-fold screw axis and that the chains are arranged in closest packing, the structure having pseudo hexagonal symmetry. The identity period in the fiber direction was found to be 13.1 a. u. This fiber identity period is somewhat less than the value found for some cellulose derivatives in which the chain has the configuration of a three-fold screw axis. This difference in identity periods is discussed in terms of molecular models. On adsorption, sodium pectate in equilibrium with air at a relative humidity of 40 percent was found to contain 18 percent water. A considerable portion of this water was located in the crystalline portion of the material. The non-uronide material (18 percent) was shown to have no detectable influence on the X-ray pattern.

Hydroxylation of mono-unsaturated fatty materials with hydrogen peroxide, D. SWERN, G. N. BILLEN, T. W. FINDLEY, and J. T. SCANLAN. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 10, pp. 1786-1789).—A new and rapid general reaction for the quantitative hydroxylation of long-chain, mono-unsaturated, aliphatic compounds is described.

The oxidizing agent, performic acid, was not isolated but was prepared and utilized in situ by dissolving the unsaturated compound in formic acid and adding hydrogen peroxide. Because of the rapidity of the reaction and

the mild conditions, only 1 mole of hydrogen peroxide was required for each mole of mono-unsaturated compound. Substantially identical results were obtained when acetic acid containing catalytic quantities of sulfuric acid was substituted for formic acid in the mixture with hydrogen peroxide. The oxidizing agent in this was peracetic acid. It was concluded that either of the two hydroxylation methods described should be suitable for the industrial production of hydroxylated fatty acids and related compounds. Application of these reactions to red oil (commercial oleic acid) gave good yields of 9,10-dihydroxystearic acid, m. p. 92°-94° [C.].

The fatty acids of corn oil, F. J. BAUR, JR., and J. B. BROWN. (Ohio State Univ.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 11, pp. 1899-1900).—The authors distilled the fatty acid esters, without previous separation of the acids into saturated and unsaturated fractions, through a fractionating column packed with glass helices and electrically heated. They calculated the composition of the several fractions from iodine number, molecular weights, and thiocyanometric equations. The C<sub>18</sub> fraction was also studied by a low-temperature crystallization procedure developed in their laboratory. The results differ from previous analyses mainly in their finding of a substantially larger content of linoleic acid and a correspondingly lower content of oleic acid. Their specimen of the oil contained 56.3 percent of linoleic acid, 30.1 percent of oleic acid, 8.1 percent of palmitic acid, 2.5 percent of stearic acid, 1.7 percent of acids having more than 18 carbon atoms, 1.2 percent of hexadecenoic acid, and 0.1 percent of myristic acid.

The organic acid content of raw cotton fiber: Isolation of l-malic acid and citric acid from cotton fiber, E. R. MCCALL and J. D. GUTHRIE. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 12, pp. 2220-2221).—The authors point out that a typical sample of oven-dry raw cotton fiber contains about 94 percent cellulose, 1.3 percent protein, 1.2 percent pectic substances, 1.2 percent ash, 0.6 percent wax, and 0.3 percent sugars, leaving about 1.4 percent of the weight of the fiber undetermined. The high content of alkaline ash and other properties indicated the probable presence of "considerable quantities" of the common organic plant acids in the fiber as salts, probably, of sodium, potassium, magnesium, and calcium. The percentages of malic, citric, and oxalic acids, and of unidentified organic acids, were determined in four samples, the malic acid content indicated being about 0.5 percent, that of the unidentified acids about 0.3 percent, of citric acid about 0.7 percent, and of oxalic acid about 0.004 percent. Quantities sufficient for identification were isolated of malic and of citric acids.

The effect of unsaturated fatty acids on *Lactobacillus helveticus* and other gram-positive micro-organisms, E. KODICEK and A. N. WORDEN (*Biochem. Jour.*, 39 (1945), No. 1, pp. 78-85, illus. 6).—*L. helveticus* (*L. casei* E) was grown in Barton-Wright and Booth's medium (E. S. R., 91, p. 250) and in a similar medium made fat-free by chloroform extraction. A total of 53 compounds were added to test their effects on the acid production of the organism. Among the compounds studied were fatty acids, sterols, vitamins, synthetic estrogens, and certain substances which alter surface tension.

Inhibition of growth and acid production of *L. helveticus* occurred with oleic, linoleic, and linolenic acids, while the methyl esters of these compounds were inactive. The degree of inhibition obtained depended upon the concentration of bacteria, the length of incubation, the amount and nature of the fatty acid added, and the presence of other liquids in the medium. The inhibition was reversed by lecithin, cholesterol, calciferol, lumisterol,  $\alpha$ -tocopherol,  $\alpha$ -tocopherol acetate, and calcium chloride. The inhibitory action of stilboestrol, hexoestrol, and dienoestrol could not be reversed by the addition of lecithin or cholesterol.

Linoleic acid inhibited the growth of several gram-positive bacteria, but was inactive in the case of *Proteus vulgaris* and *Escherichia coli*.

The possible mechanism of this inhibitory action is discussed, and attention is drawn to the surface activity of the compounds able to reverse the inhibition. "For the microbiological assay of riboflavin it is recommended that a standard inoculum be employed, that incubation be of 72 hr. duration, and that the material under test be extracted with chloroform."

Chemical nature of the insecticidal principle in mamey seed, M. A. JONES and H. K. PLANK. (P. R. Fed. Expt. Sta.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 12, pp. 2226-2267).—Among plants producing insecticidal compounds and already established in the Western Hemisphere, the species *Mammea americana*, the mamey tree, has been found to contain substances highly toxic to insects in some of its parts, of which the kernel of the mature seed was found the most effective. The color tests for rotenone were found to be negative. The ground, dried seed had a marked paralytic effect suggestive of the presence of pyrethrins or of similar compounds, and material extracted by petroleum spirit could be purified as are pyrethrin extractives. In a pyrethrin determination however, a color change characteristic of the pyrethrins did not occur and biological tests "indicated that the toxicity could not be due to actual pyrethrin content," though it may be caused by a somewhat similar type of substance. It was demonstrated definitely that the toxicity is that of a compound or compounds containing no nitrogen.

Dehydrochlorination of 1-trichloro-2-o-chlorophenyl-2-p-chlorophenylethane (*o,p'*-DDT isomer), S. J. CRISTOL and H. L. HALLER. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 12, pp. 2222-2223).—1-Trichloro-2-o-chlorophenyl-2-p-chlorophenylethane (*o,p'*-DDT) was shown to react with refluxing ethanolic alkali to give 1,1-dichloro-2-o-chlorophenyl-2-p-chlorophenylethylene and *o,p'*-dichlorodiphenylacetic acid. Reaction with barium hydroxide in ethylene glycol at 175° [C.] gave larger proportions of the acid. *o,p'*-Dichlorodiphenylacetic acid was synthesized by the acid-catalyzed condensation of *o*-chloromandelic acid and chlorobenzene. The methyl ester and the decarboxylation product *o,p'* dichlorodiphenylmethane were prepared.

The synthesis of some organic compounds of gold, C. W. DENKO and A. K. ANDERSON. (Pa. State Col. et al.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 12, p. 2341).—Of gold alkylxanthates of the form R-O-C=S S-Au, the authors prepared the esters in which R = methyl, ethyl, *n*-propyl, *i*-propyl, *n*-butyl, and *i*-butyl by treating the corresponding alcohol with carbon disulfide and potassium hydroxide to form the potassium R xanthate and slowly adding a gold trichloride solution to excess of the xanthate solution. By a similar treatment of  $\alpha$ -thiobutyric and  $\alpha$ -thioglycolic acids, univalent gold was made to replace the hydrogen of the hydrosulfuryl group. Of these gold compounds, prepared for physiological experiments, the xanthate derivatives were water soluble, pale yellow, and heat labile. Of the thio-acid derivatives, the sodium potassium and ammonium salts were water soluble, the calcium salts insoluble. The strontium salt of the thioglycolic acid derivative was also insoluble in water.

The continuous thermal isomerization of  $\alpha$ -pinene in the liquid phase, T. R. SAVICH and L. A. GOLDBLATT. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 11, pp. 2027-2031, illus. 4).—The isomerization of  $\alpha$ -pinene in a continuous liquid phase process was investigated over the temperature range 200°-500° [C.]. The data indicated that the reactions took place throughout this temperature range in the same manner as had been observed by other investigators in batch experiments over the temperature range

189.5°-285°. The yield of pidentene decreased and the yield of allo-ocimene increased with increasing temperature. The cyclization of allo-ocimene to  $\alpha$ - and  $\beta$ -pyronene occurred throughout the range investigated. If the contact time was limited to that required for substantially complete conversion of  $\alpha$ -pinene, the polymerization reaction became relatively unimportant at reaction temperatures somewhat above 300°. At incomplete conversions of  $\alpha$ -pinene, the  $\alpha$ -pinene was partially racemized. At a given temperature the same products were obtained in roughly the same yields for both vapor phase and liquid phase reaction.

The preparation of  $\beta$ -carotene of a high degree of purity, J. DEVINE, R. F. HUNTER, and N. E. WILLIAMS (*Biochem. Jour.*, 39 (1945), No. 1, pp. 5-6, *illus. 1*).—A brief description is given of the various treatments used to obtain 28 gm. of purified  $\beta$ -carotene starting with 1 kg. of carotene concentrate obtained from alfalfa meal. The crude concentrate in cotton seed oil had an  $E_{1\%}^{1\text{cm}}$  value of 127 at 460 m $\mu$ . in chloroform. A final 2 gm. sample further purified by 5 recrystallizations gave spectroscopic values in cyclohexane, chloroform, hexane, and benzene appreciably higher, according to the authors, than those recorded in recent literature.

Autoclaving and waxing help preserve carotene of hay (*Wisconsin Sta. Bul.* 468 (1945), pp. 43-44).—Loss of carotene from alfalfa and cereal grass was largely prevented by autoclaving the material, pressing it into blocks, and sealing these with a flexible wax. The process is regarded as too expensive to come into general use on the average farm, but may be found economically adaptable to the production of vitamin supplements for livestock feeding.

Ascorbic acid and some related compounds as oxidizing agents in doughs, R. M. SANDSTEDT and B. D. HITES. (Nebr. Expt. Sta.). (*Cereal Chem.*, 22 (1945), No. 3, pp. 161-187, *illus. 16*).—The ascorbic acid analogs *d*-gluco- and *d*-arabo-ascorbic acids were ineffective as oxidizing agents in doughs. The oxidized analogs were somewhat more effective but not as effective as dehydro-*l*-ascorbic acid. Reductone, reduced or oxidized, had no oxidizing action. It was concluded that the presence of an enediol group next to a carbonyl group in a compound is no assurance that the compound will act as a chemical flour improver. Oxidation of ascorbic acid in flour extracts was effected by a heat-labile enzyme similar to that reported in other plant extracts but a heat-stable catalyst which was quite effective in the oxidation was found also to be present. The heat-stable factor was not inactivated by glutathione. The activity of both the heat-labile and heat-stable factors varied with the flour grade. Oxidation in boiled extracts was affected by light intensity, indicating that, in the presence of light, riboflavin may be a third factor promoting oxidation of ascorbic acid in flour extracts. The dehydro-ascorbic acid reductase system appeared to oxidize hydrosulphy groups of the flour extract. There was found to be a considerable quantity of reducing material in flour extract which was oxidized by iodine but not by dehydro-ascorbic acid. In the concentrations and at the pH values used in this investigation, preformed dehydroascorbic acid was unable to oxidize glutathione except in the presence of dehydroascorbic acid reductase. Oxidation of glutathione did take place in boiled extracts in the presence of active ascorbic acid oxidation. The ascorbic acid oxidase of flour had little action on the analogs of ascorbic acid. The heat-stable catalyst effected the oxidation of the analogs and *l*-ascorbic acid at essentially the same rate, however. The dehydroascorbic acid reductase-hydrosulphy system was unable effectively to reduce the oxidized analogs. The comparative oxidizing actions of ascorbic acid and

its analogs may be explained by their relative ability or inability to take part in the enzymatically induced oxidation of certain reducing groups which are present in flour.

**Apparatus for the rapid determination of chlorophyll and carotene, R. B. GRIFFITH and R. N. JEFFREY.** (Ky. Expt. Sta.), (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 7, pp. 448-451, *illus.* 2).—By the use of an apparatus here described the authors found it possible to determine total chlorophyll, percentage chlorophyll a, and  $\beta$ -carotene, and to estimate xanthophyll concentration within an hour from the time a leaf sample was removed from the plant. The standard deviation of the total chlorophyll and carotene results obtained by this method was less than 2 percent of the means and that of the percentage chlorophyll less than 0.3 percent of its mean. Total xanthophyll determinations were less accurate than those previously reported. The apparatus is said to eliminate possible loss from the many transfers in the older procedure, to decrease the amount of apparatus required, to increase the speed of determinations, to be easily constructed, and to be self-cleaning.

**Apparatus for rapid removal of solvents, W. F. BARTHEL and H. L. HALLER.** (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 8, p. 529, *illus.* 1).—Evaporation takes place in vertically placed, steam-jacketed bulb tubes, the upper, designated the boiler, being separated from the lower section, called the stripper, by a constriction and ball valve. A collecting flask for the solute is attached to the lower end of the stripper. The solution to be evaporated is admitted through a stopcock from a reservoir bulb at the top of the tube called the boiler. A condenser system and receiver for the solvent and a water boiler with immersed resistance wire heating unit and a steam condenser to return the boiler water to its boiler complete the assembly. A detailed description and scale drawing show the construction and manner of operation of the setup. It was run under reduced pressure for solvents having boiling points over from 70° to 80° C., and was found capable of removing nitromethane from pyrethrin solutions of a concentration of 10 percent or less at the rate of 1.5 l. per hour.

**Glass-surfaced magnetic pump for circulating liquids in a high-vacuum system, G. D. OLIVER, W. G. BICKFORD, S. S. TODD, and P. F. FLYNN.** (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 3, pp. 158-159, *illus.* 3).—The authors describe a single-action pump of which the plunger consists of a glass tube containing a sealed-in mild steel armature held in place by asbestos plugs at either end, and so ground into its glass barrel as to permit it to be moved freely and smoothly by electromagnetic solenoids fitting closely about the outer surface of the barrel. The detail of the construction of the pump proper is shown in a drawing. The entire assembly, including a four-tube power rectifier providing current for the solenoids, an eddy-current flasher motor automatically controlling the pumping rate, hand switches for non-automatic operation, etc., is shown in a photographic illustration. The circuit diagram of the bridge rectifier used is also reproduced with the article.

**Ozonizer capable of producing a constant amount of ozone, F. L. GREENWOOD.** (Minn. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 7, pp. 446-447, *illus.* 1).—It was found that by maintaining a constant transformer primary voltage and a constant oxygen flow, and by cooling the water in the Berthelot tubes, the conventional laboratory ozonizer can be designed to maintain ozone production constant to 0.1 percent ozone (by volume) over a period of 12 hr. or longer. The primary voltage of the transformer was held constant at 114 volts by means of a commercially

available voltage equalizer, the secondary voltage being 10.30 kv.; the water in the cooling tubes was controlled by passing through them a cold water stream regulated by a constant hydrostatic head device; and a constant rate of gas flow was achieved by inserting in the gas line between the oxygen tank and the ozonizer a T-tube, to which was attached a glass tube which dipped into a tube (60 cm. long) of sulfuric acid; the depth to which the glass tube penetrated the sulfuric acid was capable of rapid change by means of a rack and pinion. After about 3 to 4 hr. of operation, an oxygen flow of from 10.3 to 10.6 l. per hour was ozonized to the extent of from 5.6 to 5.7 percent. A fully dimensioned drawing of the form of Berthelot tube used accompanies the paper.

**Apparatus for determination of rate of oxygen absorption with special reference to fats,** M. H. MENAKER, M. L. SHANER, and H. O. TRIEBOLD. (Pa. State Col.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 8, pp. 518-519, illus. 5).—The apparatus described makes a continuous and automatic record of the oxygen absorbed by the sample, at the same time maintaining constant pressure in the reaction chamber, irrespective of atmospheric pressure variations.

The constant-temperature oven was made from a baking oven by adding a fan to provide air circulation and a mercury-over-toluene thermostat. Pressure control was obtained by means of a regulator of the mercury manometer type with electrical contact in the arm communicating with the absorption vessel to open, by action of a relay circuit, a solenoid-operated valve in the connection between the absorption vessel and the oxygen reservoir when the pressure in the absorption vessel fell. In the flask serving as an oxygen reservoir, a float resting upon a mercury column supported by the pressure of the oxygen was connected to the pen of a revolving record drum. Scale drawings show the relation of parts in the complete assembly and construction of the pressure regulator and of the pressure control valve system. The electrical circuits required are shown in a wiring diagram.

**A simple automatic media dispenser,** A. A. ANDERSON. (U. S. D. A.) (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 7, pp. 463-464, illus. 3).—The device described consists essentially of a 20-cc. syringe with its tip cut off, valves made by cutting a thin slice nearly off the smaller end of a rubber stopper and boring the main portion of the stopper longitudinally, suitable tubing connections to the supply vessel and the delivery tube, and a 5-in. wooden drive wheel provided with a sliding eccentric connection to the shaft operating the syringe plunger, adjustment along the slide of the degree of eccentricity of the drive shaft linkage being the means for setting the apparatus for the desired delivery volume. A 1/30 h. p. motor with 20 : 1 reduction gear and further large pulley ratio reduction in the belt drive to the wooden drive wheel permits operation at from 25 to 40 strokes per minute.

**Determination of sodium and potassium in silicates: An improved method,** G. G. MARVIN and L. B. WOODLAYER (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 9, pp. 554-556).—The use of hydrofluoric and perchloric acids as a decomposition mixture was investigated. It was shown that, by the use of this mixture, the major difficulties of both the Berzelius and the J. Lawrence Smith methods of decomposition could be avoided and most of their advantages retained. A procedure whereby the solution obtained from the acid decomposition could be purified preparatory to an alkali analysis was devised. Data on synthetic and National Bureau of Standards samples were obtained.

**Colorimetric determination of potassium,** M. F. ADAMS and J. L. ST. JOHN, (Wash. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 7, pp. 435-436, illus. 3).—The photometric determination of potassium as chloroplatinate was found reliable and convenient. A precision of 2 percent could be attained with samples containing 0.2 mg. of potassium or more. The iodoplatinate method was found about 100 times more sensitive, but slow changes of color were observed. It was concluded that appreciable errors can be eliminated only by careful calibration under well-defined conditions.

**Titration of boric acid in the presence of mannitol,** M. HOLLANDER and W. RIEMAN, III. (Rutgers Univ.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 9 pp. 602-603).—The authors call attention to the rather wide variations in recommended mannitol concentrations for boric acid titration, and report upon a study of effects of concentration of boric acid and of mannitol upon the pH value of the acid solution and of the solution at the equivalence point, upon the slope of the titration curve at the equivalence point, and upon the titration error. They found that a sharp end point with phenolphthalein as indicator required the titration curve to have a slope of at least 3.0 pH units per cubic centimeter at the equivalence point; and that if the mannitol is present in large excess with reference to the boric acid, a concentration of about 0.35 mole of mannitol per liter of solution at the equivalence point will yield both a small titration error and a sharp end point.

**Determination of fluoride in water: A modified zirconium-alizarin method,** W. L. LAMAR (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 3, pp. 148-149).—A convenient, rapid colorimetric procedure using the zirconium-alizarin indicator acidified with sulfuric acid for the determination of fluoride in water is described. This acid indicator was found to be stable indefinitely, and to be more useful than other zirconium-alizarin reagents previously reported. The use of sulfuric acid alone in acidifying the zirconium-alizarin reagent made possible the maximum suppression of the interference of sulfate. Control of the pH of the samples eliminated errors due to the alkalinity of the samples. The fluoride content of waters containing less than 500 p. p. m. of sulfate and less than 1,000 p. p. m. of chloride could be determined within a limit of 0.1 p. p. m. when a 100-cc. sample was used.

**Quantitative determination of bases by means of calomel: Application to lime in commercial calcium arsenate,** L. M. MARKWOOD, H. D. MANN, and R. H. CARTER. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 9, pp. 570-571).—It was shown that the reaction between bases (except ammonium hydroxide) and excess calomel, evidenced by immediate blackening, proceeds quantitatively with the formation of soluble chloride in amount stoichiometrically equivalent to the quantity of base present. After removal of dissolved mercury by means of zinc, the soluble chloride could be determined by argentometric titration. Results obtained by this method in the determination of free lime in calcium arsenate agreed well with those by an acidimetric method. The calomel method was found to have the following advantages over the acidimetric method: The end point is sharp even in the presence of magnesium hydroxide, and the method is applicable in the presence of dyes. By employing a base in excess, calomel may be determined.

**Optical and X-ray diffraction studies of certain calcium phosphates,** W. F. BALE, J. F. BONNER, H. C. HODGE, H. ALDER, A. R. WREATH, and R. BELL (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 8, pp. 491-495, illus. 1).—The X-ray diffraction data, the melting points, the crystallographic systems, and the indices of refraction of 11 calcium phosphates are reported.

These are divided into four groups: A primary calcium phosphate and three derivatives, a secondary calcium phosphate and three derivatives, two tertiary calcium phosphates, and hydroxylapatite.

**Determination of nitrogen, phosphorus, and potassium in leaf tissue: Application of micromethods, R. H. COTTON.** (Pa. State Col.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 11, pp. 734-738, illus. 1).—The Fiske and Subbarow colorimetric procedure for blood phosphorus was adapted to leaf analysis. Several methods of determining phosphorus are compared, and fundamental data are presented on colorimetric phosphorus determinations in which molybdic acid was used. The dipicrylamine micromethod for determining potassium in leaf tissue is more time-consuming than the turbidimetric cobaltinitrite procedure, but gave relatively high precision.

**Determination of tryptophane, phenylalanine, and methionine: A rapid procedure, W. C. HESS and M. X. SULLIVAN** (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 11, p. 717).—In an investigation of the effects of hydrolysis methods, it was found that the results for tryptophane are substantially the same whether the alkaline hydrolyzate or intact protein is analyzed. The phenylalanine contents of squash-seed globulin and casein are likewise the same as those previously obtained by the same method. The methionine content of casein is the same as that determined following hydrolysis with 20 per cent hydrochloric acid, while the value for squash-seed globulin is but slightly higher.

**Determination of nitrogen in pyridine ring-type compounds by the Kjeldahl method, R. L. SHIRLEY and W. W. BECKER** (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 7, pp. 437-438).—Mercury alone or mercury plus selenium oxychloride was found a satisfactory catalyst for the Kjeldahl determination of the nitrogen content of compounds containing a refractory ring-type nitrogen, as in pyridine nicotine, nicotinic acid, or quinoline. A digestion-time study showed that 3 to 4 hr. are required for complete digestion of these compounds by the mercury catalysts.

Copper sulfate and selenium oxychloride yielded extremely low results, even on prolonged digestion.

**Isolation of constituents of cane juice and blackstrap molasses by chromatographic methods, W. W. BINKLEY, M. G. BLAIR, and M. L. WOLFROM.** (Ohio State Univ.). (*Jour. Amer. Chem. Soc.*, 67 (1945), No. 10, pp. 1789-1793). Inositol (m. p. 225° [C.]) was isolated from sugarcane juice (as inositol hexaacetate) and from cane blackstrap molasses. The presence of phytin in cane molasses was detected by biochemical methods. D-Mannitol was isolated in small amount from a normal sample of cane molasses but was found to be absent in normal cane juice. D-Glucose (as  $\beta$ -D-glucose pentaacetate) was isolated from cane molasses. It was demonstrated that a commercial sample of baker's yeast was able to dephosphorylate phytin.

The use of ion exchange resins in a method of deacetylation is described.

**Rapid determination of starch: Factors for starches and comparison with acid and enzymic hydrolysis methods, J. P. NIELSEN and P. C. GLEASON.** (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 3, pp. 131-134, illus. 1).—This paper presents factors for calculation, from measurements of the color developed in the iodine reaction, of the percentage of starch in various vegetables with potato starch as standard; compares results by the proposed method with those by an enzyme procedure; describes minor revisions that increase the accuracy of the original method; and describes its application to dehydrated foods. Data to show that the enzyme procedure used for comparison is not applicable to all types of starches are

given. Acid hydrolysis was used to establish calculation factors for certain pure starches. Several thousand samples analyzed for starch content by the proposed procedure included fresh, frozen, dehydrated, and canned vegetables and apples.

**[Quantitative estimation of hemicelluloses]** (*Massachusetts Sta. Bul.* 428 (1945), p. 24).—Preliminary experiments indicated that sodium chlorite could be made an effective reagent for the separation of the holocellulosic component of non-woody plant tissue in a form suitable for the quantitative estimation of the hemicelluloses. The process is said to be long, but was found to be simple, to demand but little attention, and to eliminate other operations more tedious and lengthy. It was possible to prepare in this way a product which contained the hemicelluloses and was substantially free from lignin.

**Determination of the methyl ester content of pectin**, C. H. HILLS, C. L. OGG, and R. SPEISER. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 8, pp. 507-510, illus. 2).—Sources of error in the Zeisel and saponification methods for determining the methyl ester content of pectin were discovered, and improved procedures are presented. A third method, utilizing the specific action of pectase for hydrolyzing pectin methyl ester, is recommended for general use as more rapid than the Zeisel method and involving fewer sources of error than the saponification method.

**Quantitative determination of *d*-xylose by selective fermentation**, L. E. WISE and J. W. APPLING (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 3, pp. 132-134).—A simple microbiological method which permits the determination of 12 to 50 mg. of xylose in the presence of glucose, mannose, arabinose, and glucuronic acid, with an accuracy of 96 to 104 percent is described. It depends on the use of *Hansenula suaveolens* (N. R. R. L. No. 838), which ferments xylose quantitatively but not arabinose, rhamnose, fucose, and glucuronic acid. Inasmuch as N. R. R. L. No. 838 also ferments glucose, the hexoses must be fermented prior to its use. Such fermentation is affected by *Saccharomyces carlsbergensis* (N. R. R. L. No. 379), which has only a very slight action on xylose (an error for which correction may be made).

**Spectrophotometric determination of alpha-eleostearic acid in freshly extracted tung oil: Determination of extinction of coefficients in oil solvents**, R. T. O'CONNOR, D. C. HEINZELMAN, A. F. FREEMAN, and F. C. PACK. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 8, pp. 467-470, illus. 2).—The authors report upon a study made of the procedure for estimating  $\alpha$ -eleostearic acid in freshly extracted tung oil by direct spectrophotometric measurements. Extinction coefficients for the pure acid in oil solvents are reported. A possible explanation of the discrepancies in the value of this coefficient in ethyl alcohol (partial deterioration during storage) was to some degree supported by storage experiments. The extinction coefficients in hydrocarbon solvents were used to determine the  $\alpha$ -eleostearic acid content of some tung oil samples. The spectrophotometric procedure used was found to be more direct, much simpler, considerably more rapid, and very probably, because of these factors, more accurate than chemical methods.

**Determination of itaconic acid in fermentation liquors**, M. FRIEDKIN (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 10, pp. 637-638).—A method for the direct determination of itaconic acid in fermentation liquors containing other acids and glucose involved the use of aqueous bromine buffered at pH 1.2 to ensure the selective absorption of bromine by the itaconic acid. The principal advantage claimed for the bromine absorption method is that itaconic acid can be determined directly in fermentation liquor containing glucose and many acids known to be mold metabolites.

Aconitic acid, an unsaturated acid which has been suggested as a possible precursor of itaconic acid, can be determined directly in fermentation liquor containing glucose and many acids known to be mold metabolites and does not interfere. Another advantage is that bromine absorption values, when compared to total acidity values, indicate relative purities of experimental fermentations with respect to itaconic acid production. Analyses with aqueous bromine buffered at pH 3.0 resulted in apparent purities exceeding 100 percent. These high values were usually associated with fermentations that showed much pigmentation and low acid production. Though no purity index above 100 was encountered when the analysis was conducted at pH 1.2, it is pointed out that unsaturated pigments should be considered as possible interfering substances in evaluating the results of the bromine absorption method.

**Ring and ball softening points of resins: A constant-temperature air-bath method.** V. E. GROTLISCH and H. N. BURSTEIN. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 8, pp. 476-480, illus. 5).—The usefulness of softening points and methods used in their determination are discussed. Objections to the present methods and criteria for improved methods are pointed out. The determination of softening point is discussed from a theoretical point of view. It is shown that any method of obtaining this value, to be practical, must ignore to a great extent the principle of measuring the transition point while no change occurs in the internal temperature of the system.

An air-bath method of test for softening point operated at constant temperature is described, together with experimental data. A method for computing the correction to be applied for correlating values obtained at different bath temperatures is presented. The corrected softening point values were found to be in close agreement with usual E28-42T ring and ball values. The data presented show the application of the method over a range of softening points between approximately 70° and 170° C. The apparatus used consisted mainly of standard equipment used in making A. S. T. M. ring and ball tests. A scale drawing of a special ring holder is shown. In a recommended procedure, more rapid than the regular A. S. T. M. E-28-42T method and applicable to a wide range of softening points and resin types from rosin to high-melting synthetic resins, results could be duplicated within 1.0°.

**A study of methods for determination of riboflavin** (*Massachusetts Sta. Bul.* 428 (1945), p. 47).—Biological (1), microbiological (2), and fluorophotometric (3) methods used in determining riboflavin were compared in a study of the riboflavin content of beans, milk, kale, and fish. Low values were noted in baked beans assayed by method (2). Certain modifications of methods (2) and (3) were necessary before good agreement among all three methods could be reached.

Method (3) gave low results when the riboflavin standard was assayed separately. The addition of the standard riboflavin solution to the extract of the food sample was necessary in order to obtain results comparable to those obtained by the other procedures. Enzymatic digestion of the sample appeared to be unnecessary. In method (3), the use of florosil and the oxidation step with  $\text{KMnO}_4$  were not essential. In method (2), the removal of fat or the addition of an irradiated extract to the blank and to the standard curve produced no change in the riboflavin values obtained.

No loss of riboflavin occurred when frozen baked beans, blanched kale, or steamed fish were stored over a 6-mo. period.

**Agar-streak method for assaying antibiotic substances,** S. A. WAKSMAN and H. CHRISTINE REILLY, (N. J. Expt. Stas.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 9, pp. 556-558).—It was found that the agar-streak method for assaying antibiotic substances is rapid, does not require a sterile sample, permits testing unknown substances against several bacteria or fungi at one time, and can be used to test substances in nonaqueous solutions. Although it is less precise and less rapid than some other methods it had marked advantages, especially in screening tests with a large number of organisms and in isolation procedures of the antibiotic substances.

**Spectrographic determination of some metallic elements in food and feces,** J. K. BRODY and D. T. E. WING. (Mich. State Col., et al.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 10, pp. 627-631, illus. 3).—A direct current arc method is described. Special attention was given to a study of the effects of the extraneous elements encountered in food and fecal samples. A specially devised buffer solution permitted sodium, potassium, magnesium, calcium, and phosphorus to vary over a considerable concentration range without influencing the ratio of certain lines of the metallic elements to an internal standard bismuth line. When this buffer solution was used, good comparisons between spectrograph and chemical results were obtained. Other advantages pertaining to the development of working curves and to corrections for background are attributed to the buffer solution.

**Estimation of sucrose and lactose in binary mixtures with particular application to sweetened condensed milk,** H. H. BROWNE. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 10, p. 623, illus. 1).—The method here described is based upon the fact that the addition of sodium bisulfite decreases the optical rotation of the aldose sugars in a manner such that the optical rotation of a mixture of two sugars of which one is an aldose can be made a linear function of the concentration of each sugar. The author's procedure consists essentially in the determination of the percentage of total sugars by means of the refractometer and the measurement of the optical rotation of a solution containing a known percentage of total sugars in the presence of sodium bisulfite. Actual determination of the two sugars was made from a graph of the data obtained by dissolving the sugars in the ratios given in sugar dilution flasks, adding 30 gm. of sodium metabisulfite per 10 gm. of sugar, making up to the 110-cc. mark with distilled water, letting stand (stoppered) about 2 hr. at 20° C., and then reading the rotation. It was found that when the rotations corresponding to the two 100 percent points were plotted and then connected by a straight line, the intermediate points all lay practically on this line.

**Colorimetric method for determination of DDT,** E. L. BAILES and M. G. PAYNE. (Colo. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 7, pp. 438-440, illus. 1).—Purified DDT (0.1 gm.) was dissolved and made up to 50 cc. with benzene, and 10 cc. of this solution were heated in a constant-temperature water bath at 66° C. for 5 min. Then the solution was treated with 0.5 gm. of anhydrous aluminum chloride, and the mixture was heated for 1 hr. at 66°. The complex was decomposed with 3 cc. of water, and 30 cc. of benzene were added. This product was treated with 1.5 gm. of anhydrous calcium chloride and allowed to stand until the turbidity disappeared. The benzene layer was decanted into a 100-cc. volumetric flask. The residue was washed with small portions of benzene to remove the last traces of color, added to the volumetric flask, and diluted to volume with benzene. The percentage transmission was read in the photoelectric colorimeter. If the benzene layer was turbid, as often occurred in fruit strippings, it was

necessary to allow it to stand before reading. A temperature above 66° decreased the intensity of color; the reaction was completed in 1 hr. The color developed as soon as the complex was decomposed with water and the product dissolved in benzene. Samples of fruit could be stripped with small quantities of benzene diluted to a definite volume and an aliquot part treated according to the above procedure. The colored substance so developed had its maximum light absorption at 420 m $\mu$ . Developed in ethylene chloride in place of benzene, the color had maximum absorption at 530 m $\mu$ .

**Colorimetric determination of DDT:** Color test for related compounds, M. S. SCHECTER, S. B. SOLOWAY, R. A. HAYES, and H. L. HALLER. (U. S. D.A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 11, pp. 704-709, illus. 5).—A colorimetric method developed for the estimation of small quantities of DDT down to about 10  $\mu$ g. involves intensive nitration and the production of colors by the nitrated products in benzene plus methanolic sodium methylate. It was found that this color reaction can also be used as a test for degradation products of DDT and some compounds related to it.

Various possible contaminants caused more or less rapid fading of the color, especially impurities in technical benzene yielding hydrogen sulfide on distillation, and sulfur from rubber stoppers not freed from sulfur by boiling with strong sodium hydroxide solution before use. The presence of water in the benzene used to dissolve the nitrated residue, or that of water or sodium hydroxide in the sodium methylate solution, also caused rapid fading. The identity of the nitration products yielding the color was not determined.

**Determination of 1-trichloro-2,2-bis(p-chlorophenyl)ethane in technical DDT,** S. J. CRISTOL, R. A. HAYES, and H. L. HALLER. (U. S. D. A.). (*Indus. and Eng. Chem., Analyt. Ed.*, 17 (1945), No. 8, pp. 470-472, illus. 1).—The authors point out that technical DDT consists essentially of a mixture of 1-trichloro-2,2-bis (p-chlorophenyl)ethane (p,p'-DDT) and 1-trichloro-2-o-chlorophenyl-2-p-chlorophenylethane (o,p'-DDT), with small amounts of by-product and describe a method for the determination of 1-trichloro-2,2-bis (p-chlorophenyl)ethane, which is the most effective insecticidal component present, in technical grades of DDT as well as in dusts containing DDT. The method involves crystallization from a saturated solution of 1-trichloro-2,2-bis (p-chlorophenyl)ethane in 75 percent aqueous ethanol and is apparently reliable to within 1 percent when a small empirical correction is added.

**Quantitative estimation of DDT and of DDT spray or dust deposits,** F. A. GUNTHER. (Calif. Citrus Expt. Sta.). (*Indus. and Eng. Chem., Analyt. Ed.*, 17 (1945), No. 3, pp. 149-150).—A method for the quantitative estimation of the amount of DDT in a sample containing it is based upon the quantitative dehydrohalogenation of DDT under suitable manipulative conditions. A specific application to the determination of spray or dust deposits is discussed in detail. Data to show both the accuracy and the reproducibility of the method are presented, and possible sources of error are discussed.

**Determination of petroleum oil spray deposits on citrus leaves,** J. B. REDD. (Fla. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 10, pp. 621-623).—In studying the insecticidal efficiency and phytocidal value of petroleum oil spray deposits on citrus, it was necessary to determine accurately the amount of oil deposited by oil sprays and the amount retained by the foliage over a period of several weeks. In order to eliminate the error introduced by the extraction of variable amounts of plant waxes and at the same time retain the advantages of gravimetric measurement, it is proposed to sulfonate the extract in petroleum ether, separate the petroleum ether containing the unreacted oil, and weight the residue after evaporating the ether.

**Determination of sulfur dioxide in fruits, J. D. PONTING and G. JOHNSON.** (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 11, pp. 682-686, illus. 1).—The authors consider none of the various methods reviewed to be satisfactory for the analysis of fruits sampled in the frozen state if the samples contain, as is usual, oxygen and active oxidizing enzymes. For rendering the sulfur dioxide nonreactive toward iodine titrating solutions, they found acetone to give an end point not as good as that provided by formaldehyde. They developed a method in which the sulfur dioxide content of frozen fruits and of other types of fruit can be determined rapidly by extraction by blending in buffered sodium chloride solution (which stabilizes sulfur dioxide against enzymic and autoxidation), filtration, treatment with alkali to dissociate combined sulfur dioxide, and acidification and titration with iodine, with and without added formaldehyde, which binds sulfur dioxide.

**Varietal responses to certain baking ingredients essential in evaluating the protein quality of hard winter wheats, K. F. FINNEY and M. A. BARMORE.** (Kans. Expt. Sta. coop. U. S. D. A. and State expt. stas.). (*Cereal Chem.*, 22 (1945), No. 3, pp. 225-243, illus. 4).—Baking test data of flours from the crops from 1938 to 1942 indicated that a formula for testing varieties of hard winter wheats should contain adequate amounts of milk, malt, and potassium bromate; that milk solids buffer the oxidative effects of bromate and also serve to buffer the detrimental effects resulting from overdosages; that varieties differ in bromate requirement and response; and that with such formulas commercial varieties are evaluated in agreement with trade opinion. It is considered an important advantage of such rich, highly bromated formulas as that proposed by the authors that all varieties tend to produce bread having equally good crumb structure and hence scoring alike as to grain but differing in loaf volume according to the protein content and protein quality of each variety. For most varieties of hard winter wheat, loaf volumes increased rapidly at first and then more slowly with increasing proportions of potassium bromate until the optimum was reached, after which there was a decline. A variation of 1 mg. either way from the optimum when using the rich formula was found not likely to result in serious discrepancies.

**The effect of mixing speed and dry milk solids on bread volume, E. C. SWANSON and E. G. BAYFIELD.** (Kans. State Col.). (*Cereal Chem.*, 22 (1945), No. 3, pp. 214-224, illus. 3).—The behavior of three flours with 0, 2, 6, and 12 percent of dry milk solids, with seven mixing speeds in the Swanson-Working mixer and with four speeds in the Hobart-McDuffee mixer, was studied. A Tenmarq sample was also studied at seven mixing speeds in the Working mixer. Data were collected on optimum mixing times and on loaf volumes. At all speeds of all machines, optimum mixing time increased with increasing milk solids, but the increase was very small at high speeds. In general, at all speeds and levels of milk solids, Tenmarq required longer mixing times than Chiefkan, and the commercial flour held an intermediate position. Loaf volumes for Chiefkan were consistently reduced by added milk solids, but those for the other two flours were improved. In all three mixers Tenmarq yielded maximum loaf volumes at intermediate levels of milk solids.

**Optimum vs. fixed mixing time at various potassium bromate levels in experimental bread baking, K. F. FINNEY and M. A. BARMORE.** (Kans. Expt. Sta. coop. U. S. D. A. and State expt. stas.). (*Cereal Chem.*, 22 (1945), No. 3, pp. 244-254, illus. 4).—For flours from several varieties of hard red winter, and from one variety of hard red spring wheat in each of 3 yr., mixing time and potassium bromate compensated for each other to some extent but were by no means completely interchangeable. With inadequate bromate,

overmixing improved the bread, probably because the deleterious effects of overmixing are more than offset by the beneficial effects of the oxidation induced by the additional mixing. With optimum or near-optimum bromate levels either undermixing or overmixing reduced the loaf volumes and crumb scores, the decrease being proportional to the departure from the optimum mixing time. The data afforded a satisfactory explanation of the conflicting results previously reported for overmixed dough. It appeared that overmixing produced a deleterious effect, but if the dough was not sufficiently oxidized these effects could be obscured by the beneficial effects of the additional oxidation provided by the longer mixing time. Undermixing irrespective of oxidation produced lower loaf volumes and poorer bread than the flour was capable of producing. These relations appeared to be especially important in work designed to characterize and evaluate varieties of hard red winter wheat which varied a great deal with respect to mixing and bromate requirements.

**Effect of fermentation, rest periods, and formula ingredients on mixogram patterns,** J. A. JOHNSON and C. O. SWANSON. (Kans. Expt. Sta.). (*Cereal Chem.*, 22 (1945), No. 3, pp. 204-214, illus. 6).—The mixogram patterns obtained on no-rest doughs, continuous mixing, differed markedly from those obtained after rest or fermentation periods. The patterns of the mixograms obtained on flour-water doughs after rest periods of 3 hr. were nearly the same as those obtained from sponge doughs after 3 hr. of fermentation. The rest period and the fermentation process each markedly shortened the time to reach the mixogram peak and increased the steepness of the ascending and of the descending slopes. Thus, the rest periods produced about as great an effect on patterns as the process of yeast fermentation. When all the ingredients were present in the sponge during the fermentation period, the height and the band width were increased—sodium chloride having the greatest effect, potassium bromate and shortening having none. The effect of yeast, sugar, and malt was small but that of milk moderate. Mixogram patterns from sponge doughs of the various varieties differed less than those from no-rest doughs, but the varietal effect can be clearly observed. While the mixing times of Tenmarq and Turkey were shortened in the fermented sponge doughs, they still remained longer than for Chiefkan and Early Blackhull.

**Some factors causing dark-colored maple sirup,** F. W. HAYWARD and C. S. PEDERSON (*New York State Sta. Bul.* 718 (1946), pp. 14, illus. 13).—The authors note that the principal characteristic considered in the grading of maple sirup is the color, the lighter-colored sirup having usually the more delicate maple flavor. They find that the color depends upon the alkalinity of the sap and by the small and variable quantity of invert sugar which is always present, the darkening of the sirup being accompanied by a lowering of the pH value and of the reducing-sugar content. It was further found that "growth of bacteria causes increased alkalinity and inversion of sucrose, which, in turn, result in darker-colored sirup. The bacteria grow even at temperatures slightly above the freezing point and cause significant deterioration in color. Cleanliness of equipment and rapid handling of the sap, therefore, are very important factors in production of high quality, light-colored maple sirup."

**The storage of maple sirup,** F. W. HAYWARD (*New York State Sta. Bul.* 719 (1946), pp. 8, illus. 6).—The author finds that maple sirup may be held in storage successfully if it be carefully packed and kept under suitable conditions. To minimize darkening, the storage temperature should be as low as is practicable, a cool, dry cellar being very suitable. Storage temperatures should be low to minimize darkening. Containers should be filled hot and full in order to exclude oxygen which will discolor sirup, and in order to prevent

mold growth, which will cause off-flavors and inversion of sugar. Maple sirup may be reheated for canning without appreciable change in character.

[Chemical investigations of hemicelluloses] (*Massachusetts Sta. Bul. 428 (1945), p. 25*).—In purified hemicellulose preparations from corncobs and from rye straw, xylose appeared to be the principal sugar. A uronic acid, believed to be glucuronic acid, was also present in both samples. Glucose was present but galactose could not be detected. Acetylation indicated that the corncob hemicellulose had two hydroxyl groups (theoretical acetyl content, 39.81 percent; found, 39.73 percent). The data obtained indicated that the xylose units probably are linked through the 1,4 positions and that the preparation was quite pure. Hemicellulose from rye straw did not acetylate satisfactorily. The "repeating units" appeared to be of from 25 to 40 units in length, corresponding to an approximate molecular weight of from 3,000 to 6,000. Hydrolytic and polariscopic studies indicated that the xylose units in both hemicelluloses had a pyranose structure with a  $\beta$ -type linkage between units. Alkali-ability numbers were about equal and were comparable to those of commercial samples of cornstarch. Complete hydrolysis of both hemicelluloses could be obtained with 4-percent sulfuric acid in approximately 4 hr., whereas the usual time is about 15 hr. This shorter time of hydrolysis decreased the destruction of uronic acids.

[Investigation of agricultural waste products—lignin] (*Massachusetts Sta. Bul. 428 (1945), p. 25*).—Pure lignin was added to finely ground samples of silage, timothy hay, cornstalks, and oat hay, thoroughly mixed, inoculated with a soil suspension and allowed to incubate at about 32° C. for several months. The lignin contained 64.2 percent of carbon and 5.6 percent of hydrogen and was added in amounts equivalent to about 14 percent of the plant material. Added nitrogen was supplied in the form of 1 gm. of ammonium carbonate to each 100 gm. of the organic material and total and ammoniacal nitrogen, solids and the pH value were determined at intervals. Tentative results indicated that there was a greater loss of organic matter from the cornstalks and oat hay in the presence of added lignin; timothy hay and silage decomposed at about the same rate with or without lignin. In general, ammonification was retarded in the presence of lignin. Added lignin did not appear to alter materially the rate of aerobic decomposition of plant substances when sufficient nitrogen was available.

## AGRICULTURAL METEOROLOGY

Dynamic meteorology, J. HOLMBOE, G. E. FORSYTHE, and W. GUSTIN (*New York: John Wiley & Sons; London: Chapman & Hall, 1945, pp. 378 +, about 150 illus.*).—This volume is intended as a basic textbook in theoretical meteorology for students preparing for a professional career in meteorology; it may also be helpful in such applied sciences as geophysics, aerodynamics, hydrology, and pure physics. The aim is to provide a theoretical background for understanding the physical behavior of the atmosphere and its motions. Only material considered indispensable to the practical meteorologist and weather forecaster is included. Starting from the fundamental concepts of physics, the book develops the thermodynamical and hydrodynamical principles by which atmospheric phenomena and the evolution of the weather may be explained.

The teaching of meteorology in colleges and universities: Recommendations of the Committee on Meteorological Education of the American Meteorological Society, H. R. BYERS ET AL. (*Amer. Met. Soc. Bul., 27 (1946), No. 3, pp. 95-98*).

Regarding the evaluation of periodicity in extended meteorological series, C. BENEDICKS (*Svenska Vetensk. Akad. Arkiv Mat., Astron., och Fys.*, 32 (1945), No. 1, Sect. B, Art. 2, pp. 7, illus. 2).—The simple periodical analysis made implied that a periodicity occurring in an otherwise random material is best revealed when using averages, the basis of which approaches the half period. The general character of the curve obtained by the author using 21-yr. averages for the temperature indexes of Hellmann-Pettersson proved fairly similar to the exposition of mean temperatures given by A. Ångström. It appears advisable in long meteorological series to investigate the 45-yr. period found by the author, using consecutive averages on the basis of 22 or 23 yr.

Calibration and characteristics of a sensitive hot-wire anemometer, T. A. STEEVES, A. E. CHADDERTON, and W. H. COOK (*Canad. Jour. Res.*, 23 (1945), No. 3, Sect. F, pp. 192-197, illus. 3).—"A wet test meter was used to measure the air supplied to a small wind tunnel that could be adjusted to provide up-, down-, or side-draughts for the calibration of a sensitive hot-wire anemometer. The readings on the instrument used were independent of the direction of air flow and the orientation of the instrument at velocities in excess of 10 ft. per minute. At lower velocities separate curves were obtained for different instrument orientations and directions of air movement. Air flows as low as 1 ft. per minute can be estimated with useful accuracy provided the direction of air movement is known."

The errors of cup anemometers in fluctuating winds, F. J. SCRASE and P. A. SHEPPARD (*Jour. Sci. Instruments*, 21 (1944), No. 9, pp. 160-161, illus. 1).—"The overestimation of mean wind speed in a variable wind is investigated for Sheppard and Meteorological Office patterns of the 3-cup anemometer. Comparison of Schrenk's theory with observation shows satisfactory agreement for hemispherical cups. Conical cups overestimate mean wind speed to a much smaller extent than hemispherical cups and are to be preferred therefore when unsteady winds, e. g., natural winds, are to be measured. For a given cup form, overestimation appears to be a minimum mass per unit area of cup; other parameters such as cup diameter and arm length are of secondary importance."

Dial wind indicators, R. L. IVES (*Amer. Met. Soc. Bul.*, 27 (1946), No. 3, pp. 117-120, illus. 4).—The author describes and illustrates electric-clock relay controlled indicators of wind speed and direction designed to operate at predetermined time or interval and to retain the record of conditions at that time for a definite period.

Mesure de l'humidité relative de l'atmosphère, E. BRUN (*Fruits d'Outre Mer*, 1 (1946), No. 7, pp. 195-200, illus. 4).—The author discusses relative humidity as such, its absolute measurement and measurement by the usual methods, and new apparatus for the purpose.

Size of raindrops, V. N. KELKAR (*Indian Acad. Sci. Proc.*, 32 (1945), No. 6, Sect. A, pp. 394-399, illus. 6).—In this note the author describes the results of measurements of sizes of raindrops deduced from the areas of splashes produced by them on glazed paper coated with ink and dried before use. The method is believed competent to measure the intensity of precipitation in very short intervals, the number of drops per cubic meter of air in a shower together with their size distribution, and the distribution of drop size from different parts of a rain cloud.

Monthly Weather Review [October-December 1945] (*Mo. Weather Rev.* [U. S.], 73 (1945), Nos. 10, pp. 167-183, illus. 10; 11, pp. 185-199, illus. 11; 12, pp. 201-229, illus. 15).—In addition to meteorological, climatological, solar radiation, and sunspot data in each number, No. 12 contains articles on

The Weather of 1945 in the United States (pp. 201-205) and Preliminary Report on Tornadoes in the United States During 1945 (pp. 207-209), both by J. L. Baldwin.

[Highlights in Ohio weather for 1944 and 1945], J. T. McCURE (*Ohio Sta. Bimo. Bul.* 239 (1946), pp. 47-52).—Climatological data are presented in text and tabular forms.

Seasonal precipitation range in the United States, S. S. VISHNER (*Ecology*, 27 (1946), No. 1, pp. 81-87, illus. 8).—A sort of summary of the findings on seasonal precipitation contrasts is presented in a table showing the approximate amount of range in the central or core parts of each of 12 precipitation regions; this makes it somewhat more obvious that the common range averages for the entire country about 4 in. in each season and is largest in the Deep South, where it is 7 in. The extreme ranges average for the 12 regions is nearly 10 in., the South again being least fortunate with 16 to 18 in. The ratio between range and average precipitation is least—for the average of the country—in summer and, fortunately, greatest in the fall. The South Pacific coast region has an average ratio even greater than that of the Great Basin. The Upper North is most fortunate. There is a steady southward increase of the ratio in each of the longitudinal belts. Hence, in this important respect, the southern part of the country is less fortunate than the northern.

Foreshadowing this winter's (1945/6) precipitation in the northern Rocky Mountains and North Pacific States region, I. I. SCHELL (*Amer. Met. Soc. Bul.*, 27 (1946), No. 3, pp. 131-132).

Geographic variation in annual rainfall on Oahu, C. K. WENTWORTH (*Hawaii Univ., Res. Pub. No. 22* (1946), pp. 14+, illus. 4).—Variations of interstation annual rainfall ratios from the mean were determined over 35 yr. for all the pairs of stations included in 13 stations—or 78 pairs and 2,730 ratios. Extreme ratios ran as high as 3.0 indicating that a given station in relation to another may receive as much as three times—or as little as a third of—the expected amount. For the best-correlated pairs, the most probable deviation was less than 10 percent; for the least well correlated, it was near 45 percent. In the majority of station pairs, plotting on log-probability paper revealed a close adherence to the normal curve, with no systematic evidence of skewing; the few pairs deviating from this pattern are believed to be inclusive of any generic natural tendency. The closest correlation existed between stations fairly close together, so as to be influenced by unit storms of a few miles in diameter and similarly located with reference to windward or leeward slopes, high or low elevations, and other topographic conditions. Given a station not over 5 to 10 miles away and similarly situated the probable rainfall at a new or lapsed station can be estimated from a valid interstation ratio with a probable deviation of not over about 20 percent. Only the very high rainfall stations (like Luakaha) have probable deviations annually from their own mean which are smaller than this. All the others, with rainfall less than about 100 in. annually, have large enough annual variations so that reference to other stations and use of interstation ratios result in an improved estimate.

A new formula for precipitation effectiveness, J. SETZER (*Geog. Rev.*, 36 (1946), No. 2, pp. 247-263, illus. 11).—While investigating soil genesis in São Paulo, Brazil, the author mapped certain climatic elements of this and neighboring regions. The maps provided a clue to differences in the physical and chemical properties of the soils originating from similar rocks under different climates and also guided the development of certain ideas on the negative or positive effects of climatic factors on various important crops

grown on the principal soil types of the State. From the data of 110 meteorological stations, the author prepared annual and seasonal rainfall maps, maps for the rainiest and least rainy months, and similar ones dealing with mean temperatures. In compiling them, interpolations were necessary and pedologic conditions were also taken into consideration. Besides these and other climatic maps, maps of São Paulo were drawn in accordance with Köppen's international classification, Serebrenick's Brazilian classification, and Thornthwaite's classification based on temperature efficiency and precipitation effectiveness. Use of the last suggested the possibility of deducing a new formula for precipitation effectiveness, based on the well-known law of Van't Hoff. The author believes that the empirically derived geometrical progression here presented and discussed gives a more rational climatic classification. "Whatever the progression employed, it must be empirically obtained; for the influences of humidity and temperature bear on so many interacting phenomena that the possibility of simple mathematical elaboration is virtually precluded. The question is that of the influence of those climatic factors over a large and complex combination of phenomena and their interactions, so that only an empirical treatment can be satisfactory. The bases, however, can be established by a well-known general chemical law."

**Effect of climate on the performance of grapes in Michigan:** Some 1945 observations, R. E. LOREE (*Michigan Sta. Quart. Bul.*, 28 (1946), No. 3, pp. 173-175).—A brief summary is presented of the effects on grapes of the unfavorable climatic conditions of 1945, with an interpretation and recommendations. Size of crop, maturity at harvest, and quality of fruit of certain varieties at East Lansing are tabulated. Length of season and the amount of summer heat are considered important for grape production; these as well as other factors should be considered in selecting varieties and sites for establishment of young vineyards.

**Effect of low temperatures on the vegetation of the Barrens in central Pennsylvania,** W. S. CLARKE, JR. (Pa. State Col.). (*Ecology*, 27 (1946), No. 2, pp. 188-189).—Hough has shown how frost pockets have affected the vegetation in stream valleys of the northern Allegheny Plateau of Pennsylvania (E. S. R., 93, p. 719); the author briefly describes in this note a similar condition—probably even more extreme—in the region known as the Barrens in the central part of the State.

## SOILS—FERTILIZERS

**Our American land: The story of its abuse and its conservation,** H. H. BENNETT (*U. S. Dept. Agr., Misc. Pub. 596* (1946), pp. 31, about 40 illus.).—This well-illustrated publication points out the extent of the problem of erosion and the serious condition of soils that are depleted as a result. Emphasis is placed again on the treating of land according to its needs and using it according to its capabilities to accomplish soil conservation. A discussion is presented as to what the soil conservation districts are doing to accomplish soil conservation through cooperative effort and long-time planning. The procedure in preparing a farm plan for attaining soil conservation and the principal conservation practices are set forth in detail.

**Experiments in the control of soil erosion in central New York,** G. R. FREE, E. A. CARLETON, J. LAMB, JR., and A. F. GUSTAFSON ([*New York Cornell Sta. Bul.* 831 (1946), pp. 30, illus. 10).—Results presented in this bulletin apply to the rolling, glaciated limestone soils of central and north-western New York and to land eastward along the Mohawk River. Experi-

ments were conducted at the Marcellus and Geneva, N. Y., stations of the U. S. D. A. Soil Conservation Service, in cooperation with the station. The principal soils at the Marcellus station are Honeoye silt loam and Honeoye gravelly silt loam, and the soils at Geneva that were used for experimental work were Ontario sandy clay loam and Dunkirk silty clay loam. Studies of seasonal occurrence of soil erosion indicated that heavy summer thundershowers usually cause the greatest amount of erosion. Detailed information is presented on the periods of excessive rain and the extent of erosion that has taken place as a result of the excessive rainfall. Factors that influence winter and spring erosion are considered. The effects of past erosion were shown from studies of different physical and chemical properties of soil. This erosion has resulted in soil crust formation that gave poor stand and crop growth. Loss of organic matter increases erosion, and erosion removes organic matter because of its lighter weight and because so much of it is in the topsoil. A considerable portion of the bulletin is devoted to the presentation of practical systems of soil management intended to reduce the harmful effect of excessive soil and water losses.

[Soil survey Reports, 1936 Series] (*U. S. Dept. Agr., Bur. Plant Indus., Soils, and Agr. Engin. [Soil Survey Rpts.], Ser. 1936, Nos. 22, pp. 33+, about 10 illus.; 23, pp. 72+, several illus.*).—These surveys were made in cooperation with the State experiment stations as respectively noted: 1936, Nos. 22, the Salt Lake area, Utah, D. S. Jennings et al. (Utah Expt. Sta.); and 23, Martin County, Ind., H. P. Ulrich et al. (Ind. Sta.).

Shall we apply fertilizer with the plow? A. C. CALDWELL, J. M. MACGREGOR, and C. O. ROST (*Minn. Farm and Home Sci. [Minnesota Sta.], 3 (1946), No. 2, pp. 6-7, illus. 3*).—This article presents information obtained on the value of plowing under fertilizers on different soil series in several counties of Minnesota with field corn, alfalfa, soybeans, and navy beans. The results are summarized in recommendations which point out that for most of the better soils, such as the Clarion-Webster soil types, heavy application of fertilizer is not needed to obtain good yields of either field or seed corn. Soybeans likewise failed to give a response on these soils. Alfalfa yields were increased by plowing down fertilizers, but the same results were secured by fertilizer applied broadcast. On the less fertile soil types, plowing under fertilizer was found to give more promising results. One year's results with corn on sandy soils indicated profitable return from small amounts of nitrogen fertilizer plowed under.

Fertilizer recommendations in Mississippi, 1946, C. DORMAN (*Mississippi Sta. Cir. 124 (1945), pp. 11*).—The five grades of mixed fertilizers available for 1946 are considered in relation to crop and soil needs, and fertilizer recommendations are presented for the various soil areas of the State.

Utah fertilizer recommendations for 1946, D. W. THORNE and H. B. PETERSON (*Farm and Home Sci. [Utah Sta.], 7 (1946), No. 1, pp. 1, 9-11*).—In a brief statement prefatory to the specific State recommendations, the author noted that a fertilizer supply better than that of 1945 was to be expected though a somewhat short supply for early spring application was probable; that the past year has brought a rapidly expanding demand for concentrated ammonium phosphate fertilizers (11-48-0 and 16-20-0); and that ammonium nitrate, the physical properties of the fertilizer preparations of this salt having been greatly improved, is now one of the best nitrogen fertilizers to buy. Recommendations are largely concerned with advice as to substitutes for the brands usually purchased. It is noted that ground rock phosphate, though annually produced in Utah or imported, has shown no

value in the States of the arid West. No potassium deficiency in Utah soils having been observed, purchase of fertilizer mixtures containing this element is not recommended.

Band placement of fertilizers near the plant row is recommended as more efficient and economical than the broadcast application and harrowing which have been customary in the State.

Commercial fertilizers report for 1945, E. M. BAILEY (*Connecticut [New Haven] Sta. Bul. 492 (1945), pp. 40*).—This bulletin presents the usual data for 1945 on fertilizer inspection, classification, and analysis.

Fertilizer inspection, analysis, and use, 1944, M. F. MILLER, L. D. HAIGH, E. W. COWAN, and J. H. LONG (*Missouri Sta. Bul. 493 (1945), pp. 43*).—This bulletin presents the usual statistics on fertilizer inspection, analysis, and use, and includes a revised list of approved fertilizer mixtures.

## AGRICULTURAL BOTANY

Proceedings of local branches of the Society of American Bacteriologists (*Jour. Bact.*, 51 (1946), No. 3, pp. 401–410).—Abstracts of the following papers of interest to microbiology are included: Submerged Culture of Molds for Amylase Production, by F. Stewart, R. E. Scalf, and W. H. Stark (pp. 401–402); Mutation of *Aspergillus niger* Van Tieghem by Means of Soft X-Rays, by V. M. Diller, A. A. Tytell, and H. Kersten (p. 404); On the Efficiency of Cotton Plugs in Maintaining Sterility, by O. K. Stark (pp. 404–405); Vitamin Requirements of the Photosynthetic Purple Bacteria, by S. H. Hutner (p. 405); Fungus Deterioration Testing—A Chemist's Contribution, by J. Marshall (p. 406); A Micro-Plate Method for Penicillin Assay, by E. R. Jackson (p. 407); and Production of Antibiotic Substances by Basidiomycetes, by W. J. Robbins, A. Hervey, and F. Kavanaugh (p. 410).

Simple photometric method of determining the rate of bacterial growth, N. V. NEEDHAM (*Nature [London]*, 157 (1946), No. 3986, pp. 374–375, illus. 1).—A compensated photometric circuit—here described and illustrated—has been devised for determining relative bacterial densities. Apart from its value in assaying disinfectants, the apparatus was used by the author in determining how the rate of bacterial growth is affected by time of incubation and by variations in the composition of the medium, in pH, and in size of inoculum.

Sterile milk for background in capsule staining, G. C. WEBER (*Stain Technol.*, 21 (1946), No. 2, p. 75).—Maneval has described a staining technic for demonstration of bacterial capsules, with albumin used as a background (E. S. R., 85, p. 326). The present author suggests sterile litmus milk as proving better for the purpose than albumin.

The antibacterial activity of protamine zinc insulin, C. H. BOLLENBACK and S. W. FOX. (Iowa Expt. Sta. et al.). (*Science*, 103 (1946), No. 2676, pp. 445–446).—The experiments here briefly recorded indicate that protamine is able to act as an antibacterial, even though combined in relatively insoluble form with insulin. The test organisms were *Lactobacillus arabinosus*, *Staphylococcus aureus*, and *Escherichia coli*.

Antibiotic material from *Bacillus licheniformis* (Weigmann, emend. Gibson) active against species of mycobacteria, R. K. CALLOW and P. D. HART (*Nature [London]*, 157 (1946), No. 3985, pp. 334–335).—Fractionation of the crude concentrate of the antibiotic material yielded an active precipitate—free from carbohydrate—with Reinecke's salt, and a polysaccharide fraction devoid of activity; from the Reineckate an amorphous material was obtained which gave a positive Sakaguchi test and had an activity of 800,000 units per

gram. It is believed that more than one antibiotic is present in cultures of *B. licheniformis*.

Bacillin, a new antibiotic substance from a soil isolate of *Bacillus subtilis*, J. W. FOSTER and H. B. WOODRUFF (*Jour. Bact.*, 51 (1946), No. 3, pp. 363-369).—A new antibiotic, bacillin—obtained from a soil isolate of *B. subtilis*—was found highly active against both gram-negative and gram-positive bacteria in certain media. Its differentiation from known antibiotics derived from similar bacteria, conditions relating to its production in solid and in liquid media, purification procedure for obtaining highly potent concentrates, and some chemical properties are described. Crude bacillin concentrates proved moderately toxic for mice and completely ineffective in protecting the animals from virulent bacterial infections. The presence in the medium of blood and other complex natural materials reduces or abolishes the antibacterial properties of bacillin.

Antibacillin, a naturally occurring inhibitor of bacillin, H. B. WOODRUFF and J. W. FOSTER (*Jour. Bact.*, 51 (1946), No. 3, pp. 371-380).—Naturally occurring complex organic materials were found to contain an organic substance, "antibacillin," which counteracted the antibacterial action of the antibiotic bacillin. Inorganic salts and  $H_2S$  also had this property. Antibacillin was liberated on hydrolysis of gelatin or casein. It failed to destroy or combine with bacillin, probably acting competitively with the latter for vital systems in susceptible bacteria. The chemical properties of antibacillin are given, as well as details for the preparation of concentrates of the active fraction from gelatin and from *Penicillium notatum* mycelium.

An antibacterial pigment from *Fusarium javanicum*, H. R. V. ARNSTEIN, A. H. COOK, and M. S. LACEY (*Nature [London]*, 157 (1946), No. 3985, pp. 333-334).—A preliminary report.

Wisconsin research helped supply penicillin (*Wisconsin Sta. Bul.* 468 (1945), pp. 48-52, illus. 1).—A brief summary of investigations by the station which aided in speeding up the manufacture of penicillin, including studies on growth conditions, constituents of the medium, assay methods, and antiseptics for control of contamination.

Metabolic changes in submerged penicillin fermentations on synthetic media, H. KOFFLER, S. G. KNIGHT, W. C. FRAZIER, and R. H. BURRIS. (*Wis. Expt. Sta.*). (*Jour. Bact.*, 51 (1946), No. 3, pp. 385-392, illus. 2).—Addition of ash from corn steep to a medium consisting of lactose, dextrin, and mineral salts caused a remarkable increase in penicillin yields in shake flask fermentations. When phenylacetamide also was added, penicillin yields were even greater, being as high as or higher than those previously obtained on corn steep media. Boric acid may slightly stimulate the penicillin formation. Corn steep ash had a distinct accelerating influence on mold metabolism. *Penicillium chrysogenum* X-1612—grown on ash media—utilized sugars and  $NH_3$  more rapidly and to a much greater extent than on the medium without the added ash. Not only the synthetic processes but also the decomposition was conspicuously accelerated by adding corn steep ash; the rate at which the  $NH_3$  nonbasic N, and basic N fractions were excreted was considerably faster in ash media than without the added ash. During the disintegration of the mold,  $NH_3$  was by far the most abundant N compound determined. The concentration of amino N and basic N compounds was low, and amide N was either absent or present only in traces. The compounds of the nonbasic fraction, however, were excreted in slightly greater amounts—and more rapidly in ash-treated than in ash-free fermentations. Ammonia levels were always considerably lower with the added corn steep ash, and in such media  $NH_3$  was almost completely exhausted during growth of the mold.

The action of sulfonamides on certain fungi pathogenic to man, F. T. WOLF (*Mycologia*, 38 (1946), No. 2, pp. 213-219).—Sulfanilamide was found very fungistatic to *Tricophyton mentagrophytes*, *T. rubrum*, *Epidermophyton floccosum*, *Microsporum canis*, *M. gypseum*, and *Sporotrichum schenckii* in vitro; it had no definite fungistatic action on *Candida albicans*, *C. krusei*, *C. tropicalis*, *C. parakrusei*, *C. pseudotropicalis*, *Cryptococcus neoformans*, *Monosporium apiospermum*, *Hormodendrum pedrosoi*, *H. compactum*, and *Phialophora verrucosa*. Sulfathiazole, sulfadiazine, and sulfaguanidine were not appreciably fungistatic toward any of these fungi under the in vitro conditions used. There are 25 references.

A dictionary of the fungi, G. C. AINSWORTH and G. R. BISBY (*Kew, Eng.: Imp. Mycol. Inst.*, 1945, 2. ed., pp. 431+, illus. 138).—The principal changes and additions in this edition of the work previously noted (E. S. R., 91, p. 390) consist in the listing of new genera (with the years made), a new arrangement of the Phycomycetes, a systematic arrangement of the genera, and short notes on more than 50 important mycologists. Changes made by G. W. Martin in his keys to the fungus families are also included.

Three new Zoopagaceae subsisting on soil amoebae, C. DRECHSLER. (U. S. D. A.). (*Mycologia*, 38 (1946), No. 2, pp. 120-143, illus. 6).—Apart from the descriptions of these three new species isolated from decaying plant material—*Cochlonema agamum*, *Acaulopage lophospora*, and *A. hystricospora*—supplementary comment is supplied on an amoeba-capturing form (*Stylopaga rhabdospora*). Of the three new species the first acts as an endoparasite; the other two are predators.

Illustrations of the fleshy fungi of Iowa—VI, Fleshy poroid forms, J. C. GILMAN. (Iowa State Col.). (*Iowa Acad. Sci. Proc.*, 51 (1944), pp. 191-197, illus. 5).—The five species of fungi illustrated in this contribution (E. S. R., 91, p. 264) are found in two of the families of the larger fungi—the Polyporaceae and the Boletaceae.

Flora fungosa Chilena: Indice preliminar de los huéspedes de los hongos chilenos y sus referencias bibliográficas [Fungus flora of Chile: A preliminary list of the hosts of Chilean fungi, with bibliographical references to them], F. MUJICA R. and C. VERGARA C. (*Santiago: Imp. Stanley*, 1945, pp. 199).—An index of the common and scientific names of the plants is included.

Plants of Hawaii National Park illustrative of plants and customs of the South Seas, O. DEGENER (*Ann Arbor, Mich.: Edwards Bros.*, 1945, pp. 314+, illus. 141).—This book was first published under the title of *Illustrated Guide to the More Common or Noteworthy Ferns and Flowering Plants of Hawaii National Park, with Descriptions of Ancient Hawaiian Customs and an Introduction to the Geological History of the Islands*, appearing in 1930. Since then the author has continued his studies of the flora of the South Seas and of the customs of the South Sea Islanders. Moreover, he lived for 8 mo. with the Fiji Island natives, part of the time as the "adopted father" of a bright Fijian youth, thus learning some of the native lore not generally available to the ordinary white colonial. These continued studies have convinced the author (1) that many of the plants of the Hawaiian Islands grow likewise in other islands of the Pacific or have close relatives there, and (2) that many of the customs of the ancient Hawaiians are identical with those of the present inhabitants of other Pacific islands or may be considered modifications of such customs. On account of the special current interest in the plants and customs of the Pacific, "the present volume has been reproduced as a quick, inexpensive, wartime edition to meet this demand under the new subtitle of 'Plants and Customs of the South Seas.'"

**Ethnobotany of western Washington**, E. GUNTHER (*Wash. Univ. [Seattle] Pubs., Anthropol.*, 10 (1945), No. 1, pp. 61, illus. 1).—The subject matter in the main body of the text—"the plants and their uses"—is arranged on the systematic basis from the Polypodiaceae to the Compositae, with a final short section on miscellaneous plants (fungi, algae, mosses, and a lichen). A chart lists the plants discussed in the text, and a subject index is provided.

**American species of Amelanchier**, G. N. JONES. (*Univ. Ill. (Ill. Biol. Monog.*, 20 (1946), No. 2, pp. 126, illus. 55).—This taxonomic monograph includes a bibliography and description of the genus and keys to flowering and fruiting specimens of the species; descriptions and discussion of the 22 individual entities, involving nomenclatorial change in only one case—*A. arborea alabamensis* n. comb.; and a list of numbered exsiccatae. An index to plant names is provided.

**A seed key to fourteen species of Geraniaceae**, M. MURLEY. (*Iowa Expt. Sta.*). (*Iowa Acad. Sci. Proc.*, 51 (1944), pp. 241-246, illus. 28).—The present contribution on the plant family Geraniaceae is the first publication in a program of seed identification initiated in the seed laboratory of Iowa State College.

**Host specificity amongst root-nodule bacteria isolated from several clover species**, J. M. VINCENT (*Jour. Austral. Inst. Agr. Sci.*, 11 (1945), No. 3, pp. 121-127).—The results are reported for 18 strains of root nodule bacteria, isolated mostly from several clover species growing in recorded locations and tested for ability to fix N in association with 4 host-plant species; in most cases some information was also obtained on the serological constitution of the strains. The data emphasized the importance and complexity of the organism-host relationship. The 18 strains set out against the 4 hosts provided no less than 7—possibly more—patterns of effectiveness. The 4 test hosts may be regarded as differing in their compatibility at least with respect to these 18 strains; subterranean and ball clovers showed a significant agreement in their behavior to the same strains. The findings fail to substantiate the striking field-host to test-host relationship reported by Strong (*E. S. R.*, 77, p. 172), except with respect to isolations from red clover tested with subterranean or ball clover. There is no relationship between effectiveness patterns and what is known of serological behavior, but some likelihood that strains coming from the same area might show a degree of common behavior in their host relationships.

**Studies on germination and seedling growth.**—III, Early growth in relation to certain aspects of nitrogen metabolism in the seedling of barley, R. BROWN (*Ann. Bot. [London]*, n. ser., 10 (1946), No. 37, pp. 73-96, illus. 7).—In this phase of the study (*E. S. R.*, 90, p. 597), two culture series were run—one of the seedlings grown normally attached to the rest of the seed and another of seedlings excised from seeds that had been in contact with water for 2 hr.; both series were cultured under the same conditions and in contact with water over a 96-hr. period. For each series data are given indicating the change with time in dry and fresh weights, gaseous exchange, and levels of total, soluble, protein, residual soluble, total amino, amide amino, and non-amide amino N.

The fresh weight of the isolated seedlings increased rapidly to 48 hr. and then remained more or less constant; that of the attached seedlings increased slowly to 48 hr. and rapidly thereafter. At 48 hr. the fresh weight of the isolated was greater than that of the attached seedlings; this difference was attributed to a higher water availability in the former. The dry weight of the isolated seedlings fell during the first 12 hr. and again—more slowly—

during the final 84 hr. The preliminary decrease is attributed to leaching; the fall during the final period is believed due to respiratory losses. The dry weight and total and protein N of the attached seedlings increased in two phases, the first being one of slow and the second one of rapid increase; the transition from the first to the second phase occurred between 48 and 60 hr. and was probably complete within 6 hr. In the attached seedlings fresh weight increase in the first and second phases, dry weight in the second, total N increase in the first and second, and protein increase in the second are believed to be exponential.

The exponential increase in each phase and the abrupt rise in the relative rate of increase indicate, it is suggested, that absorption of nutrients from the endosperm is largely determined by the growth reactions of the seedling itself. The water content increased in the isolated seedlings up to 48 hr. and in the attached throughout the experimental period, indicating cell extension over corresponding times. The evidence suggests that in cell extension there is a deposition of dry matter and of protein N, the increases occurring exponentially in a system which itself is expanding exponentially. In the isolated seedling at 2 to 36 hr. and again at 60 to 96 hr. amino N increased by the hydrolysis of constituents of the residual soluble N fraction; at 36 to 60 hr. both residual soluble and total amino N increased by protein hydrolysis. These changes were related to simultaneous changes in the growth process. In the attached seedling, residual soluble N remained more or less constant at 2 to 48 hr. and then increased; total amino N increased continually from the beginning of the experiment. In terms of the percentage of each of these fractions of the total soluble N, during the first phase residual soluble N decreased continuously and amino N exhibited a complementary increase; after 48 hr., however, the proportion of each in the total soluble fraction tended to remain constant. These changes are believed to indicate a profound change in the metabolic situation that coincides with the change in growth rate.

The evidence suggests that the respiration rate in both series was determined by the level of nonamide amino acids, and that the accumulation of amide was related to this condition. Changes in rate of water intake and of cell extension did not coincide with changes in the rate of O<sub>2</sub> uptake; it is suggested that cell extension is not limited by the respiration rate. These findings fail to provide any indication as to the origin of the abrupt change in the development of the attached seedling occurring at 48 hr.; it is not determined by the breaking of the seed-coat membranes, since this happens at least 24 hr. earlier. There are 18 references.

Annual increase of underground materials in three range grasses, J. E. WEAVER and E. ZINK. (Univ. Nebr.) (*Ecology*, 27 (1946), No. 2, pp. 115-127, illus. 6).—Separate lots of three range grasses were grown in large steel drums and at the end of each summer their root systems were freed of soil, photographed, and their dry weights obtained. Roots of big bluestem produced 152 gm. dry weight the first year; this increased 72 percent the second summer and 23 percent the third. During the second year increase in weight was greatest in the first 4-in. level; during the third year, in the 4- to 12- and 12- to 24-in. depths. Little bluestem produced 89 gm. of roots the first year and 86 percent the second, after which their weight declined slightly. Most rapid increase the second year was in the surface foot, especially in the first 4 in. Blue grama produced 76 gm. of roots the first year and reached its maximum the second, with increases mostly in the 4- to 12-in. depth but also with 59 percent in the second foot. Big bluestem reached its approximate maximum

root development the third summer; both little bluestem and blue grama, a year earlier. The underground materials produced in 3 yr. were very similar in amounts to those ascertained earlier in typical mature stands in native prairie; they were also very nearly the same in the surface 4 in.—and especially in the surface 12 in.—as the average amounts found by extensive sampling in climax prairie dominated by each species, respectively. Roots alone yielded about 5.5 tons per acre after 3 yr. in big bluestem, 2.7 in little bluestem, and 1.6 tons in blue grama. Of these amounts, 43, 36, and 49 percent occurred in the surface 4 in. and 78, 69, and 80 percent in the first 12 in. The effects of grass roots in producing a granular soil structure, the time required for completing the structure-forming effect, the decrease or loss of soil granulation under continuous cropping to cereals, and the restoration of good structure and fertility by growing perennial grasses are all considered.

Studies in the physiology of leaf growth.—II, Growth and structure of the first leaf of rye when cultivated in isolation or attached to the intact plant, R. S. DE ROPP (*Ann. Bot. [London], n. ser., 10 (1946), No. 37, pp. 31–40, illus. 6*).—In this further study (E. S. R., 94, p. 605), growth of the first leaf attached to the isolated stem tip of rye was compared with that of the first leaf attached to the intact plant. Growth of the isolated first leaf was shown to be due to the development of cells already present; in the absence of roots, cell division in the basal meristem of the leaf failed to occur. Growth of the attached first leaf depended mainly on the activity of the basal meristem during the first 3 days after germination. Differentiation in the attached leaf began at the tip and proceeded toward the base. No clearly defined meristem was observed in the coleoptile; its growth seemed to be mainly from elongation of already existing cells.

Use of a constant-temperature water bath as a culture chamber, J. H. CRAFT (*Iowa Acad. Sci. Proc., 51 (1944), pp. 175–176, illus. 1*).—In the course of experiments on excised leaves of *Bryophyllum calycinum* a need arose for a culture chamber in which light, temperature, and humidity could be controlled simultaneously; the chamber described and illustrated is said to meet these requirements and to be capable of providing a wide range of environments which should make it useful in the culture of micro-organisms.

The physiology of plant growth with special reference to the concept of net assimilation rate, R. F. WILLIAMS (*Ann. Bot. [London], n. ser., 10 (1946), No. 37, pp. 41–72, illus. 9*).—Net assimilation rate is defined as the rate of increase in the dry weight of a plant per unit of active “growing material;” an attempt is here made to evaluate leaf area, weight, and protein as indexes of this “internal factor” for growth. The derivation of the formulas for calculating mean values of relative growth rate and net assimilation rate over specified time intervals is discussed, and the approximate nature of the formula for net assimilation rate is stressed. A method based on graphical interpolation is described for estimating mean values of net assimilation rate in cases where it is known that considerable error may be introduced by direct use of the approximate formula; failure to eliminate such errors may invalidate attempts to relate net assimilation rate to environmental factors.

Following a review of the literature (44 references), a growth experiment with *Phalaris tuberosa* is described; this was limited to the vegetative growth phase, and nutrient treatments comprised two levels each of N and P in all combinations, six harvests being taken at 14-day intervals. Tiller counts showed that early meristematic activity was stimulated more by P than by N, and that the effect of N was delayed and was then greater at the higher

levels of P. These effects were reflected in the dry-weight data for total plant, leaves, and stems, but not in those for roots. Protein N data for the leaves revealed that P is directly concerned in protein synthesis. The data for relative growth rate and net assimilation rates (dry-weight and protein bases) are examined in detail, leaf protein proving more adequate than leaf weight as an index of the internal factor for growth. In general, it may be said that leaf area and weight are suitable indexes of active growing material only during early vegetative growth, but that the leaf protein is suitable for a considerably longer period, provided N is in short supply. Attention is drawn to the errors in net assimilation rates based solely on subaerial parts; such errors are inevitable in analyses of field-grown crops.

**New carriers for plant growth regulators, R. B. WITHROW and F. S. HOWLETT.** (Ind. and Ohio Expt. Stas.). (*Plant Physiol.*, 21 (1946), No. 2, pp. 131-139).—Formulas and methods of preparation for several stable fluid and cream emulsions employing waxes other than lanolin and emulsifying agents other than triethanolamine stearate are presented; mucilage solution formulas are also given. The cream emulsions do not leave sticky residues as does lanolin; they are also non-toxic to plant tissues. Tomato fruit set well when these emulsions were used as carriers for indolebutyric acid. Under high temperatures where lanolin emulsions are toxic, the materials recommended were nontoxic; they are also said to offer advantages where physiologically inert carriers are desired for materials other than growth regulators.

**Geotropic reaction of leaves and content of growth hormone in plants, L. P. ZHDANOVA** (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 49 (1945), No. 1, pp. 62-65, illus. 3).—Based on studies of leaves of hydrangea, perilla, mustard, and Jerusalem-artichoke, it is concluded that the geotropic reaction of leaves severed from the plant does not occur unless they are oriented with their dorsal sides upward; it is lacking under the opposite orientation. This situation is explained by the difference in anatomical structure of the opposite sides of the petiole and a corresponding difference in their reaction to growth hormones. Epinasty and hyponasty of the leaves is believed to depend on the concentration of the growth hormone and on the difference in intensity of the growth processes between the ventral and dorsal sides of the petiole. The degree of geotropic response of the leaves depends on the content of growth hormones synthesized in the apical buds of the stem.

**A growth factor in certain vegetable juices, D. METCALF, G. J. HUCKER, and D. C. CARPENTER.** (N. Y. State Expt. Sta.). (*Jour. Bact.*, 51 (1946), No. 3, pp. 381-384, illus. 1).—It appears that there is present in tomato and certain other vegetable juices an unidentified growth-accessory substance. This "T" factor may act in conjunction with thiamine, but its heat-stable properties indicate it to be distinct from thiamine. The T factor was also found in liver, string beans, carrots, beets, onions, cabbage, peppers, spinach, and orange juice.

**Histological responses of bean plants to phenylacetic acid, A. G. WHITING and M. A. MURRAY** (*Bot. Gaz.*, 107 (1946), No. 3, pp. 312-332, illus. 16).—Young Red Kidney bean plants were decapitated at the second internode and a 2 percent mixture of phenylacetic acid in lanolin was applied to the cut surface. Within 48 hr. the stem tip lightened in color and began to enlarge, about doubling in diameter at 6 days. An apical tumor was evident at 5 days, reaching a maximum at 11 to 15 days, after which growth gradually decreased; many stems were dead at 13 days. Below the cut surface there was marked proliferation on the inner cortical parenchyma, endodermis, and primary phloem parenchyma. The outer cortical parenchyma rays, and pe-

ripheral pith were less active. The derivatives may mature as tracheids or parenchyma, continue as patches of meristematic tissue, or infrequently differentiate as small vascular bundles. After treatment there was increased activity of the cambium; response was slight in the pericycle and secondary phloem, and the epidermis and central pith were inactive. Response at the cut surface resulted in the upward proliferation of a parenchymatous tumor, its central mass being derived from proliferated pith and ray parenchyma, with outer portions from young xylem, cambium, and phloem. Vascularization of the tumor was slight. The small branching strands connected with the vascular bundles of the stem or with bundles differentiated in the pith. Centripetal growth of the tumor filled in the cavity formed by collapse of the central pith. Root primordia were infrequent.

Effect of treating soil and seeds with 2,4-dichlorophenoxyacetic acid on germination and development of seedlings, C. L. HAMNER, J. E. MOULTON, and H. B. TUKEY. (Mich. State Col.). (*Bot. Gaz.*, 107 (1946), No. 3, pp. 352-361, illus. 10).—Many seeds are affected when planted in mineral or muck soil previously treated with this growth substance; concentrations as low as 1 p. p. m. soil were found to affect the germination and growth of many seeds. Although grass seeds can be destroyed, they proved more resistant to the acid than were many others; seeds of six grasses and of white and Red Kidney beans, tomato, cabbage, broccoli, pea, sweetclover, rape, vetch, and alsike clover were used in these experiments.

Movement of 2,4-dichlorophenoxyacetic acid stimulus and its relation to the translocation of organic food materials in plants, J. W. MITCHELL and J. W. BROWN. (U. S. D. A.). (*Bot. Gaz.*, 107 (1946), No. 3, pp. 393-407, illus. 11).—When the above chemical was applied to the outer surface of some species of plants, a stimulus was translocated from the treated region to other parts, where a visible growth response occurred. The effects of light, CO<sub>2</sub>, location of treatment, and stage of development of the plant on the rate of translocation of such a stimulus in snap bean plants was recorded. The stimulus from treatment with this acid was not readily translocated from the leaves when the sugar content was relatively low, as in those exposed to extended darkness or to CO<sub>2</sub>-free air in the light; it was not translocated from young rapidly growing leaves to the stems. When the acid was applied to the leaves, the translocation of the resulting stimulus was closely associated with that of organic food materials. Movement of the acid stimulus from the leaves appeared to occur as a continual flow under conditions favoring carbohydrate translocation and was confined to living cells—probably those of the phloem or parenchyma. When the acid was applied to the root system, however, the resulting stimulus was translocated through nonliving cells of the stem, indicating that it probably traveled in the transpiration stream of the xylem. There are 16 references.

Effect of 2,4-dichlorophenoxyacetic acid on the water relations, the accumulation and distribution of solid matter, and the respiration of bean plants, J. W. BROWN. (U. S. D. A.). (*Bot. Gaz.*, 107 (1946), No. 3, pp. 332-343, illus. 5).—Within an hour after bean seedlings were sprayed with the above acid mixed with Carbowax, those treated with 1,000 p. p. m. showed marked epinastic responses and stem bending, becoming more severe during the next 2 to 3 days; at the end of 5 days the plants were permanently wilted and in 7 days they were dead. The total water absorbed and transpired by sprayed plants during the 5 days immediately after treatment was 34 percent less than for comparable controls. Water uptake was not immediately limited by treatment. Leaf growth and expansion were markedly inhibited in both par-

tially expanded leaves and those in terminal buds, even when sprayed with as low as 25 p. p. m. The solid matter in the above-ground part of the plant decreased with 1,000 p. p. m., but increased accumulation of solid matter was noted in the basal region of the stems of plants sprayed with 25, 50, and 250 p. p. m. The rate of water accumulation in the leaves of sprayed plants was depressed; in the stem tissues it was accelerated. On an over-all basis, however, the treated plants had higher percentages of moisture than the controls. The respiratory rate of seedlings measured at three different temperatures was significantly increased from spraying with an aqueous mixture containing 0.1 percent of the growth substance and 0.6 percent Carbowax 1500; this increase was manifest 24 hr. after treatment. The  $\text{CO}_2$  output of treated plants was about 19 to 80 percent greater than that of controls when sampled during 4 days. Annual wild morning-glory plants sprayed similarly at time of flowering exhibited an 80.6 percent increase in respiration during a 2-hr. period on the fourth day after treatment.

The effect of desiccation on the activity and moisture content of bakers' yeast, J. OYAAS and M. J. JOHNSON. (Wis. Expt. Sta.). (*Jour. Bact.*, 51 (1946), No. 3, pp. 393-395, *illus.* 1).—Commercial bakers' yeast dried at low vapor pressures (0.0016 to 0.1 mm. mercury) retained 0.03 gm. of water per gram of yeast. No additional water was removed by drying over concentrated  $\text{H}_2\text{SO}_4$ . Activity of the yeast as measured by amount of anaerobic  $\text{CO}_2$  production fell about half its original value when the yeast was dried at 10 mm. vapor pressure, but drying at lower vapor pressures caused no further loss of activity.

Viability of yeasts preserved two years by the lyophil process, L. J. WICKERHAM and M. H. FLICKINGER. (U.S.D.A.). (*Brewers Digest*, 21 (1946), No. 4, pp. 55-59, 65, *illus.* 2).—This process is described; by its use 1,161 strains were preserved for an average of 2 yr., 3 mo., 98.1 percent of these yeasts being alive at the end of the period. The approximately 2 percent failing to survive are believed capable of successful preservation by observing their special culture requirements. The advantages of the method are discussed.

Die Blattanalyse: Die wissenschaftlichen und praktischen Grundlagen einer pflanzenphysiologischen Methode der Bestimmung des Düngerbedürfnisses des Bodens [Leaf analysis: The scientific and practical bases of a plant-physiological method of determining the fertilizer needs of the soil], H. LUNDEGARDH (*Jena: Gustav Fischer*, 1945, pp. 164+, *illus.* 29).

The soluble nitrogen fractions of potato tubers; the amides, F. C. STEWARD and H. E. STREET (*Plant Physiol.*, 21 (1946), No. 2, pp. 155-193, *illus.* 6).—In this fifth of a series of papers on the biochemistry of salt absorption by plants, the primary purpose is to establish the identity of the amides of the potato and to suggest such refinements as are now known to be necessary in the methods for their indirect analysis. A survey of the literature (72 references) is presented on the biochemistry of the tissues under conditions conducive to salt absorption and on other pertinent data. The experimental work reported concerns (1) a critical reexamination of the analytical procedures used to estimate the soluble N fractions of the tuber, (2) isolation of the crystalline amides therefrom, and (3) the separation of these amides as pure substances and their final identification. For extracting amides, aqueous extracts were found preferable to 70 percent alcoholic extracts of fresh tissue. A complete account of the alcohol-soluble N and of the N content of purified aqueous extracts can be given in terms of  $\text{NH}_3\text{-N}$ , easily hydrolyzable amide-N, asparagine amide-N, and true amino-N. Methods giving the best results for deter-

mining these fractions are described in detail. The effect of lead acetate precipitation followed by mercuric nitrate precipitation or precipitation by the Neuberg and Krebs reagent (mercuric acetate) on all soluble N fractions was determined, as well as the effect of phosphotungstic acid on the N compounds after liberation from the mercuric precipitates. In the light of these results the procedure for preparing crystalline amides from the tuber was perfected. Crystalline products containing the amides were submitted to repeated crystallizations; by a process described, tyrosine, glutamine, and asparagine were prepared in pure form. Elementary analyses, melting points, and analyses of the amide- and amino-N contents of the crystalline products were all consistent with their identity as the pure substances designated. The yield of glutamine was greater than in any previous report, and the method described should render possible its isolation in high yield even in the presence of greater quantities of asparagine. The identification of the easily hydrolyzable fraction of potato as glutamine, together with its known reactions, reemphasizes the key position already assigned to this amide in protein synthesis. The significance of glutamine seems to be that as the soluble N passes through it the amino groups become particularly susceptible of being "donated" during amino acid formation and the amide group constitutes a particularly labile source of N for synthesis. Further investigation of the amidase and the supposed aminophorase systems of potato are necessary; the nutritional effect of the  $\alpha$ -keto acid supply should also be determined.

Influence of carbohydrate and nitrate-nitrogen nutrition on development of hypocotyledonary buds in flax, V. EGGER (Bot. Gaz., 107 (1946), No. 3, pp. 385-390, illus. 2).—It was apparent from the experimental results reported that the nutritional status of the plant has a decided effect on the time and frequency of bud formation and development in decapitated hypocotyls of flax.

A high carbohydrate supply, found in plants receiving a full amount of sunlight, resulted in earlier development of buds than in those on a low carbohydrate supply from shading. A greater number of these plants produced buds—and with the average number greater—than in the low carbohydrate group. Within the two groups, a variation in the nitrate-N content of the nutrient solution had a direct relation to the number of plants producing buds and to the number developed. In the shaded plants with restricted carbohydrate supply, fewer buds were formed owing to decreased amounts of nitrate N in the nutrient supply than in those with a larger amount of carbohydrate. Under the conditions, the maximum supply of both nutrients resulted in maximum bud production; minimum production was in plants high in carbohydrates but low in nitrate N.

Development of some recent concepts in the physiological chemistry of the tobacco alkaloids, R. F. DAWSON (Plant Physiol., 21 (1946), No. 2, pp. 115-130).—This critical review (49 references) of the physiological functions of tobacco alkaloids and of the mechanisms by which they are synthesized within the plant cell revolves around the distribution of nicotine in the growing plant, the locus of its formation, the extent and nature of its transport, the nature of the nicotine synthetic process, the synthesis of secondary tobacco alkaloids, and the physiological significance of nicotine.

Tannin production from native species of sumac, I. L. BOYD. (Iowa Expt. Sta. and U. S. D. A.). (Iowa Acad. Sci. Proc., 51 (1944), pp. 171-174, illus. 1).—A summary of an investigation over a 5-yr. period of four species of sumac among which the value of *Rhus glabra* is emphasized as in a report previously noted (E. S. R., 93, p. 20).

Further investigation of toxic substances which arise from guayule plants: Relation of toxic substances to the growth of guayule in soil, J. BONNER (*Bot. Gaz.*, 107 (1946), No. 3, pp. 343-351, illus. 1).—Guayule plants have previously been shown to produce inhibitory substances (E. S. R., 92, p. 634), but in the present study it was not possible to detect these inhibitory substances in any of three soils in which guayule had grown in the nursery or field for 2 to 8 yr. It is believed that the toxic materials released from guayule must be destroyed or inactivated in the soil under favorable field conditions. It is conceivable that the infertility of a particular soil toward guayule might be related to accumulation of cinnamic acid or other toxic substances owing to the absence or failure of the system for neutralizing or destroying the toxic substances. All three soils here used were of high potential fertility for guayule.

Ultra-violet irradiation of spores of certain molds collected from bread, D. B. CONKLIN (*Iowa Acad. Sci. Proc.*, 51 (1944), pp. 185-189).—Under irradiation with a 15-w. General Electric mercury vapor lamp at 2,537 a. u. radiation, all forms collected were rendered inactive by 1.5- to 6-min. exposures. The thick-walled heavily pigmented spores of *Aspergillus niger* proved the most resistant, requiring two to four times the exposure of some of the other mold fungi tested. Inability of the spores to send out mycelium was taken as the criterion of inactivation. Mold spores subjected to intermittent radiation were also inactivated when the total exposure equalled in amount the continuous lethal dose. The presence of inhibitory substances in the medium after prolonged irradiation was not demonstrated.

Effects of various agents on the structural viscosity of Elodea protoplasm, H. T. NORTEN. (Univ. Wyo.). (*Plant Physiol.*, 21 (1946), No. 2, pp. 148-154).—Concentrations of 2 percent of ethylene chlorohydrin, 3 thiourea, 4 ether, 6 ethyl alcohol, 3.5 propyl alcohol, and 1.5 percent butyl alcohol, and 0.0001 M cupric chloride and 0.001 M zinc sulfate conditioned decreases in the structural viscosity of the protoplasm at exposures of 2 hr. or less; these decreases were presumed to result from dissociation of protoplasmic proteins. Concentrations one-half those above noted also decreased the viscosity, whereas greater concentrations gave an initial decrease usually followed by an increase. Plasmolysis with 0.6 M sucrose or 0.3 M potassium chloride decreased the viscosity. The viscosity was also lower at 3° than at 21° C. There are 26 references.

Methods for studying the maize ear, R. G. REEVES. (Tex. Expt. Sta.). (*Bot. Gaz.*, 107 (1946), No. 3, p. 425, illus. 1).—For studying the vascular system of the corn ear, the author has developed a retting process involving the use of cellulose-digesting micro-organisms; by this method—here described and illustrated—he reports obtaining excellent material.

## GENETICS

*Saccharum robustum* and other wild relatives of "noble" sugar canes, C. O. GRASSL. (U. S. D. A.) (*Jour. Arnold Arboretum*, 27 (1946), No. 2, pp. 234-252, illus. 8).—On the basis of the morphological and geographical evidence here given, it is suggested that noble sugarcanes are most closely related to *S. robustum* and *Erianthus maximus*. There may have been separate origins of sweet forms in both these groups but it is believed more likely that the main origins were from *S. robustum* and that as these forms were carried eastward beyond the range of wild *Saccharum* they were modified by hybridization with forms of *E. maximus*. Some of the possibilities and prob-

abilities along these lines are discussed. Comparative observations of a large number of original sugarcanes and related wild forms have thus far permitted considerable advance toward elucidation of the origins of sugarcanes. It has become apparent in this study that progress is more certain when all available garden canes and related feral types of an island or region are assembled to compare with similar complete assemblages from other islands or regions. Fortunately some of the regional collections have been on a generous basis; they prove that there are a number of geographic points of origin and satellite regions of modification shown by distinctly different group compositions in different areas. Critical cytological studies of the complex groups involved remain to be made in testing the suggestions here advanced.

**Cytological effects of sulfanilamide on *Allium cepa*, J. J. PETERS (Bot. Gaz., 107 (1946), No. 3, pp. 390-392, illus. 1).**—As in the case of colchicine, sulfanilamide was found to inactivate the spindle mechanism and delay division of the spindle attachment region. Both chemicals induce polyploidy, but colchicine is more effective since it results in a higher percentage of polyploid cells and a greater degree of polyploidy. Sulfanilamide (0.5 percent), unlike colchicine (0.1 percent), inhibits the entrance of cells into mitosis. Colchicine results in multipolar mitosis; sulfanilamide does not.

**Morphology of reproduction in guayule and certain other species of *Parthenium*, K. ESAU (Hilgardia [California Sta.], 17 (1946), No. 2, pp. 61-120, illus. 22).**—Morphologic evidence was found of the occurrence of both sexual and apomictic reproduction in guayule, *P. argentatum*. The sexual form was characteristic of the 36-chromosome plants and the apomictic of guayule plants with higher (polyploid) numbers of chromosomes. Apomixis in *Parthenium* involves mainly generative apospory followed by unreduced pseudogamy. Since some flowers on a given plant show stages of apomictic development and others show those of the sexual reproductive cycle, apomixis in guayule is facultative.

Plants characterized by normal sexual reproduction showed an orderly sequence of events in megasporogenesis and in gametophyte development. The morphologic features of apomictic reproduction contrasted sharply with those of sexual reproduction. Embryo-sac formation showed no orderly sequence of stages. Pollination was, however, highly beneficial or, perhaps, even necessary for endosperm development and for the attainment of normal embryo size.

**Heritability of live animal scores, grades, and certain carcass characteristics in beef cattle, B. KNAPP, JR., and A. W. NORDSKOG. (U. S. D. A. and Mont. Expt. Sta.). (Jour. Anim. Sci., 5 (1946), No. 2, pp. 194-199).**—A study was made of the record of 177 steer calves from 23 sires at the U. S. Range Livestock Experiment Station to estimate the relative effect of heredity on score at weaning, slaughter grade, carcass grade, dressing percentage, and area of cross-section of eye muscle. The animals used were the same as those used for a previous study on weight and gains (E. S. R., 95, p. 42). Heritability was estimated by the use of the paternal half-sib correlation from analysis of variance and in addition from the sire : offspring regression in the case of score at weaning.

Heritabilities obtained by intrasire correlations for the characteristics studied were: Score at weaning 53 percent, slaughter grade 63 percent, carcass grade 84 percent, dressing percentage 1 percent, and area of eye muscle 69 percent. The regression of score at weaning of progeny on sire was negative ( $b = 0.07$ ) and was not significantly different from zero.

It is concluded that though there seems to be less heritability in the meas-

ures of quality of product than in the measures of growth, there is ample opportunity for selection for these characteristics.

Inheritance of skin folds of sheep, J. M. JONES, B. L. WARWICK, R. W. PHILLIPS, D. A. SPENCER, C. B. GODBEY, R. E. PATTERSON, and W. H. DAMERON. (Tex. Expt. Sta. and U. S. D. A.). (*Jour. Anim. Sci.*, 5 (1946), No. 2, pp. 154-169, illus. 4).—Skin folds were recorded and evaluated on 760 rams and 915 ewes of the Rambouillet breed. The records were taken on freshly shorn yearlings. The males had significantly greater skin-fold values than the females. The skin-fold values of all body regions were highly and significantly correlated with each other, with total skin folds, and with total minus the part correlated.

"Regression coefficients for estimating the total skin folds from the record of a part differed by one in each case from those using total minus the part. Either may be used, but that using total skin folds is simpler. The neck regions, top and bottom, may be used either separately or together with a fairly high degree of reliability to replace the record of the entire animal."

Analysis of variance and covariance of parent-offspring groups was made with the progeny of 29 sires. This showed a significant influence of sires. Correlations of other relatives, i. e., dam to daughter, dam to son, half brothers to half brothers, and of half sisters to half sisters were highly significant, and estimates of 45.6 percent and of 51.2 percent heritable portion were found, indicating that definite progress may be expected from selection for or against this character. A few crosses of Rambouillet rams to Corriedale ewes (smooth) were also studied. It is tentatively proposed that lack of skin folds is due to dominant multiple genes, the number not being determined but probably not being extremely large. It is concluded from both phases of the study that skin folds may be easily reduced to a low point by selection alone. "Progeny tests would be necessary only if complete elimination is desired, or if the objective is an intermediate type."

Heritability of face covering and neck folds in range Rambouillet lambs as evaluated by scoring, C. E. TERRILL and L. N. HAZEL. (U. S. D. A.). (*Jour. Anim. Sci.*, 5 (1946), No. 2, pp. 170-179, illus. 3).—Estimates of heritability of face covering and neck folds as evaluated by scoring were calculated from data on 2,183 weanling Rambouillet lambs born in 1941 and 1942 and 892 dam-offspring pairs. Two breeding methods had been followed consisting of inbred lines and top crosses. Estimates based on daughter-dam regressions and half-sib correlations were calculated for each year and breeding method, making eight individual estimates for each trait. Average heritability estimates of  $0.56 \pm 0.05$  for face covering and  $0.39 \pm 0.05$  for neck folds were obtained. No significant differences were found between estimates for years, breeding methods, or methods of estimation. Significant variations between inbred lines were found for each trait. The interpretation of these estimates of heritability in relation to the populations from which they were obtained and their application to breeding programs are discussed.

Nine years of swine breeding bring results, L. M. WINTERS (*Minn. Farm and Home Sci. [Minnesota Sta.]*, 3 (1946), No. 2, pp. 2-3, illus. 3).—This is a review of the Minnesota Swine Breeding Project, initiated in 1936, and deals especially with the development of the Minnesota No. 1 and No. 2 lines.

Cleavage and attachment stages of the pig. W. W. GREEN and L. M. WINTERS. (Minn. Expt. Sta. coop. U. S. D. A.). (*Jour. Morphol.*, 78 (1946), No. 2, pp. 305-316, illus. 10).—This study of the prenatal development of the pig continues the earlier work with the bovine by Winters et al. (E. S. R., 88, p. 181). Segmentation stages of known ages have been recovered from

swine of established lines of breeding, and photomicrographs of fresh, unfixed specimens are presented and discussed.

**Constitution of liver and spleen as a physical basis for genetic resistance to mouse typhoid.** E. F. OAKBERG. (Iowa Expt. Sta.). (*Jour. Infect. Diseases*, 78 (1946), No 2, pp. 79-98, illus. 8).—Observations are reported on six strains of mice, representative of low, intermediate, and high genetic resistance to mouse typhoid, which had been inoculated intraperitoneally with a dose of 200,000 live *Salmonella typhimurium* organisms of a culture with moderate virulence.

**The influence of genetic factors on the transmissibility of fowl sarcomas.** A. W. GREENWOOD and P. R. PEACOCK (*Brit. Jour. Expt. Pathol.*, 26 (1945), No. 5, pp. 357-361).—Two strains of chemically induced sarcoma, one derived from a Barred Plymouth Rock fowl, the other from a Brown Leghorn, have been maintained by serial passage in Brown Leghorn fowls. The results show consistent differences in susceptibility to both tumors by four inbred lines of fowls that had been selectively bred for purposes unrelated to cancer studies. The Brown Leghorn derived sarcoma was more easily grown in the Brown Leghorn stock than the tumor derived from the Barred Plymouth Rock, but the latter tumor could not be maintained in related birds. A definite seasonal variation in transmissibility of both tumors has been noted.

**A histopathological study of depigmented irises from Single Comb White Leghorns.** R. F. BALL. ([N. Y.] Cornell Expt. Sta.). (*Cornell Vet.*, 36 (1946), No. 1, pp. 31-40, illus. 6).—A histopathological study of depigmented and normal reddish bay irises from Single-Comb White Leghorns is presented. As a result of these studies, the reliability of iris color as a criterion in the selection of laying and breeding stock is questioned.

**The wing-spot method for color sexing Rhode Island Reds and New Hampshire chicks.** R. G. JAAP (*Oklahoma Sta. Cir.* 121 (1946), pp. 8, illus. 9).—The wings of red cockerel chicks were shown to carry an identification mark not present on the wings of their sisters. In baby cockerels the mark was a white or yellowish white spot on the top of the wing in the region of the wing web. Baby pullets were a uniform red in color. Sexing of Rhode Island Red chicks was done with an accuracy of 90 to 95 percent, with somewhat less in New Hampshire chicks, which are lighter colored. The size of the spot on different cockerel chicks was very small or relatively large. The accuracy of this method of sexing may be improved by improved breeding of colors of distinct red.

## FIELD CROPS

**Establishment of some true prairie species following reseeding.** D. R. CORNELIUS. (Kans. Expt. Sta.). (*Ecology*, 27 (1946), No. 1, pp. 1-12, illus. 5).—Big bluestem, little bluestem, side-oats grama, switchgrass, Indian grass, and tall dropseed were used in establishment studies, with seedings in 1940, 1941, 1942, and 1943 on eroded upland near Manhattan, Kans.; the field was typical of areas in the true prairie being retired from grain crops to be used for grazing and hay. Reseeding is much quicker and more economical than waiting for secondary succession to occur. It was about 3 yr. after reseeding before grazing or harvesting of hay could be permitted. During the first season of establishment annual weeds dominated; summer grasses and forbs were abundant and perennial grass seedlings usually inconspicuous, only close observation indicating their presence. The annual weedy grasses were suppressed the second year, and these and the forbs

were negligible the third season. Side-oats grama and switchgrass were established more readily than the bluestems in the first season. One or more seasons of competition favored the last, which increased more rapidly in density than the side-oats grama, switchgrass, or tall dropseed. Both density and yield of vegetation were somewhat less in a virgin prairie near the revegetated field than in the third and fourth seasons of the latter. Perennial legumes and other perennial forbs were present in the native prairie instead of the weedy annual forbs of the revegetated areas. Weedy annual grasses of the virgin prairie were winter annuals in contrast to the summer annuals of the revegetated areas. Apparently the native prairie had not completely recovered from the 1934 drought. Densities of big bluestem and side-oats grama were greater in 1943 than those of little bluestem, which probably had been most important before the drought.

Rye nurse crops in range seedling, L. A. STODDART. (Utah Expt. Sta.). (*Ecology*, 27 (1946) No. 1, pp. 61-64).—In dry years and dry climates, according to the findings reported, rye actually draws from the soil moisture that might otherwise be available for perennial grass. On arid lands, this drying action may kill the perennial grass and will certainly reduce its yield. For this reason the use of a small-grain nurse crop cannot generally be recommended in seeding western grasses. Possible exceptions might be irrigated pastures and high mountain ranges where precipitation is relatively high. Seeding rye with range grasses insures forage within a short time after planting because of the rapid growth of the rye. Damage from trampling and some injury from grazing are, however, likely to affect the perennial grass when grazed less than 1.5 to 2 yr. after planting, despite the plentiful forage supplied by the rye. A preferred method is to divide the range and seed part to rye alone and part to grass. Because of its high yield the rye can immediately support all livestock formerly cared for on the entire range; meanwhile, the grass can be protected without livestock reduction. Rye—properly grazed—will continue to supply forage for 2 to 3 yr.; after this the perennial grass portion of the range can bear the burden of grazing. At this time the rye can be killed by heavy spring grazing or late spring mowing, and grass can be drilled into the rye stubble the following fall. This new grass stand, in turn, should be protected from grazing for about 2 yr. It is therefore recommended that perennial grasses and rye be seeded alone for maximum success in range seeding.

Some effects of competition from cheatgrass brome on crested wheatgrass and bluestem wheatgrass, R. S. RUMMELL. (U. S. D. A. and Iowa State Col.). (*Ecology*, 27 (1946), No. 2, pp. 159-167, illus. 1).—Many attempts have been made to reseed perennial grasses on range lands having dense stands of cheatgrass brome, but with little success; in many cases competition from the latter is believed to have been responsible. Analysis of the results of a greenhouse experiment showed that cheatgrass brome actually did deter the establishment of crested wheatgrass and bluestem wheatgrass seedlings. Highly significant reductions in numbers of seedlings and tillers and in weights of tops and roots of both species followed such competition. For the bluestem seedlings, additional highly significant differences in number and total length of rhizomes and number of shoots from rhizomes resulted. Rhizome production by the bluestem seedlings was reduced from 368 in. in the controls to nothing in the plots where cheatgrass was a competitor; the vigor of the bluestem transplants was also materially lowered by this competition. This loss of vigor was evidenced by highly significant differences in the figures for weight of tops and roots, number of tillers, height of tops, and

length of roots found in the competition as compared with the control plots. Crested wheatgrass made more satisfactory growth than the bluestem with the same degree of competition by cheatgrass brome. Seedlings of crested and bluestem wheatgrass were better able to compete with cheatgrass brome under limited moisture conditions than where the water supply was more adequate.

Trials show way to higher yields from permanent pastures, A. C. ARNY (*Minn. Farm and Home Sci. [Minnesota Sta.]*, 3 (1946), No. 2, pp. 4-5, 15, illus. 2).—That carrying capacity of a large proportion of Minnesota's 6 million acres of open permanent pasture could be increased from 35 to 100 percent, or even better, by following thoroughly tried improved practices, was shown by yields on variously treated pastures in southeastern Minnesota. Useful practices include prevention of overgrazing, spreading of droppings and application of manure, use of commercial fertilizers, and renovation by disking, harrowing, and reseeding.

Hay preservatives prove valueless: Tests show that prohibitive quantities would be necessary for effectiveness on stored moist hay, R. B. MUSGRAVE and J. E. DAWSON (*Farm Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 18-19).—In storage tests in which three 1-ton lots of clover-timothy hay at 31 percent moisture were treated with 0, 1, and 5 lb., respectively, of preparations containing sodium bicarbonate, the treatments did not lessen heating, and moreover all three lots of hay molded badly, had a musty odor, and graded "sample." Laboratory tests to measure amounts of CO<sub>2</sub> evolved by molds growing on hay in storage also gave negative results. Preparations containing sodium bicarbonate, drying agents, or mixtures of the two, evidently offer no promise as a practical solution of problems involved in storage of undercured hay.

North Dakota leads in barley production, T. E. STOA (*North Dakota Sta. Bimo. Bul.*, 8 (1946), No. 4, pp. 23-27, illus. 3).—North Dakota ranks first among the States in production of barley. During 1942-45 the production of this crop in the State ranged from about 54 to 67 million bushels, averaging about 60 million, which represents about one-fifth of the United States crop and about one-third of the barley produced in the 12 North Central States. A large acreage and favorable conditions for high yields resulted in a large total production of barley in North Dakota. A short crop in some of the other States, and an increasing industrial demand, has resulted in an increasingly large market for North Dakota barley. Wisconsin 38 is preferred for brewers' malt, L (Kindred), Manchuria, and O. A. C. 21 for distiller's malt, and Tregal and Trebi for feed barley.

Potato varieties grown in North Dakota in 1945, H. MATTSO (*North Dakota Sta. Bimo. Bul.*, 8 (1946), No. 4, pp. 7-8).—Cobbler and Triumph, each producing more than 10,000,000 bu. from about 75,000 acres, were the leading potato varieties in North Dakota in 1945, and were followed by Early Ohio on 7,000 acres and White Rose on about 1,700 acres.

Certified seed potatoes prove their value, F. G. BUTCHER (*North Dakota Sta. Bimo. Bul.*, 8 (1946), No. 4, pp. 9-11).—Certified seed of the Cobbler variety yielded 27 percent more and Triumphs 32 percent more than non-certified potatoes in demonstration plantings at Park River in 1945. These increased yields appeared due to the greater freedom from various diseases in the certified seed lots.

Oil sprays for the control of weeds in carrots and related crops, B. H. GRIGSBY (*Michigan Sta. Quart. Bul.*, 28 (1946), No. 3, pp. 201-207, illus. 4).—Stanisol, Sovasol, oleum spirits, and related oils could be used to give a 95-

percent kill of annual weeds and grasses in carrots. While leaves of perennials, as Canada thistle, nettle, and milkweed, may be killed, these plants recover. Ragweed and beggarticks, although annual plants, are not killed at any growth stage. Although oil sprays will not eradicate all the weeds in a carrot or parsnip planting, on many farms these materials can be used to greatly reduce the amount of hand labor needed for production of these crops. Carrot plants are not usually injured at any stage of growth by these oils. Kerosene and light fuel oils, while less expensive per unit than naphthas, do not give as satisfactory control of weeds and may produce undesirable flavors in carrots. Oil spraying should be done when carrots are in the 2-3 "fern" stage of growth, and a second application if needed may be applied at any time in the following 4-6 weeks. Bunching carrots probably should not receive more than one oil spray, and at least 4 weeks time should elapse between spray application and harvest. From 75 to 100 gal. per acre of sprayed area will give satisfactory control. Recommendations are made for carrot growers whose weeding costs exceed \$25 per acre.

**2,4-D kills weeds,** B. THORNTON (*Colo. Farm Bul. [Colorado Sta.], 8 (1946), No. 1, pp. 3-5, illus. 3*).—Tests in 1945, including trials in 38 counties, favor a concentration of 1,000 p. p. m. (0.1 percent) of 2,4-D applied at the rate of 1½ gal. per square rod (240 gal. per acre), applied when the plant is young, succulent, and actively growing, possibly prebloom stage in most instances, and at temperatures of 70° F. or higher at time of application. Shade slows the killing process but does not necessarily affect the final results. High soil moisture and high fertility are associated with good results, that is, are productive of rapid, succulent growth. Spraying pressure of about 100 lb. is recommended.

As to reaction to treatment with 2,4-D, weeds were grouped as promising—bindweed, silverleaf, and woolly-leaved poverty weeds, perennial sowthistle, burdock, curled dock, fanweed, wild lettuce, lawn weeds, willows, cottonwood sprouts, cattails; doubtful—Canada thistle, white weed, Russian knapweed, leafy spurge; and resistant—grasses (tame and weedy), mouse-ear poverty weed, and many others.

## HORTICULTURE

**Red kidney bean seed presents special problems,** M. T. MUNN. (N. Y. State Expt. Sta.). (*Farm Res. [New York State and Cornell Stas.], 12 (1946), No. 2, p. 6*).—A test planting was made in 1945 of some 60 stocks of red kidney beans, varying in age from 1941 to 1944 production. Among the observations were that age of seed, within reasonable limits, was not important since properly stored seed of 1942 growth gave as even and quick stand as did 1944 seed. Poorly handled 1943 seed, on the other hand, fell away sharply in viability. Depth of planting was not a handicap in the case of strong seed. Mechanical injury, indicated as splits and cracked seed coats, was always reflected in lowered germination. The value of careful germination tests as a measure of value of seed was indicated.

**Bush lima beans show promise,** W. T. TAPLEY. (N. Y. State Expt. Sta.). (*Farm Res. [New York State and Cornell Stas.], 12 (1946), No. 2, pp. 13, 19*).—Four new bush lima beans introduced by the U. S. Department of Agriculture were grown in 1945 in comparison with seven established varieties. Fordhook 242, a potato lima type, outyielded the regular Fordhook by nearly 800 lb. per acre and produced more early beans. The two Henderson types, Nos. 243 and 343, outyielded the regular Henderson by large amounts.

The effect of various fertilizer and manure treatments on the yield, size, stand, and disease resistance of cantaloupes, E. M. RAHN and W. H. PHILLIPS (*Delaware Sta. Bul.* 256 (1945), pp. 42, illus. 1).—Experiments conducted over four seasons on Sassafras loamy sand but located each year at a different location led to the general conclusion that the placement of stable manure or mushroom manure in the furrow appears necessary to produce maximum yields. Poultry manure applied as a side dressing proved almost as effective as the other manures, but commercial fertilizer used alone did not produce maximum yields except under conditions of abundant and well-distributed rainfall. Under these favorable conditions, poultry manure produced maximum yields.

When no animal manure was used, 250 to 330 lb. of plant food of 1-2-2 or 1-2-3 ratios was most effective and should be applied in bands 6 in. from the plant row with two-thirds at seeding and one-third later when the vines start spreading. This amount of plant food may be supplied by 1,100 lb. per acre of 4-8-12, 5-10-10, or 5-10-15 fertilizer.

With stable or mushroom manure, 5 to 10 tons per acre should be placed in the furrow and 700 lb. of 5-10-10 or similar fertilizer should be placed in bands at seeding. If growth is not good, a side dressing such as 400 lb. of 5-10-10, 225 lb. of nitrate of soda, or 2.5 tons of chicken manure should be applied later.

Chicken manure was most effective as a side dressing at the rate of 2.5 tons or more per acre after an initial application in bands at seeding of 700 lb. of 2-8-16.

Under dry conditions, when diseases are not severe, plants were not rendered more susceptible to *Macrosporium* leaf spot by high applications of N or P or of chicken manure. With regard to K, the highest infection observed came at the 110 lb.  $K_2O$  level, with less infection at higher and lower levels.

In dry years, no correlation was noted between marketable yields and disease injury and while spraying decreased disease, yields were not increased.

Carrots weeded with oil sprays, R. D. SWEET. ([N. Y.] Cornell Expt. Sta.). (*Farm Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 9-10, illus. 1).—Information is presented on the use of various light oil sprays for the control of weeds in carrot plantings.

Onion investigation at the Utah Station, L. H. POLLARD (*Farm and Home Sci. [Utah Sta.]*, 7 (1946), No. 1, pp. 8-9, illus. 4).—This is a brief review of investigations conducted by the station in variety testing; development of new varieties by selection and breeding; and methods of harvesting, curing, and storing.

Nitrogen improves quality, increases yields of peas, C. B. SAYRE. (N. Y. State Expt. Sta.). (*Farm Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 8-9).—The liberal use of ammonium sulfate, ammonium nitrate, or sodium nitrate, gave marked increases in the yield of Surprise peas and kept the peas in the fancy grade for a longer period. On July 2, 2 days after the unfertilized peas reached a tenderometer grade of 95, the ammonium nitrate and ammonium sulfate lots were still in the same high quality grade. The increase in yield and quality due to the fertilizer treatments was more than sufficient to pay for the cost of the fertilizers. The two ammonium fertilizers were superior to sodium nitrate, and seed inoculation alone did not meet the N requirements necessary to best yield and quality. Good results were obtained with ammonium sulfate applied to Thomas Laxton peas.

Use of 2,4-dichlorophenoxyacetic acid for the improvement of greenhouse tomato production, M. C. STRONG (*Michigan Sta. Quart. Bul.*, 28 (1946), No. 3, pp. 216-225, illus. 7).—A single application per cluster of 2,4-dichlorophenoxyacetic acid (2,4-D) used as a spray (10 p. p. m.) increased the size of tomato fruits over those produced by hand pollination and decreased the period from bloom to maturity by 1 to 2 weeks. A greater increase in number of fruit set by this spray was obtained in the fall than in the spring crop. The percentage of unmarketable fruits was, however, somewhat greater in the hormone-treated than in the hand-pollinated fruits.

Some of the parthenocarpic fruits were hollow and resembled large peppers, while others showed an internal discoloration when opened. Two applications of the 2,4-D spray to a single cluster failed to increase set or fruit weight over one application and caused injury in some cases. Leaf distortion indicated that 2,4-D is absorbed through the flowers and transported through the plant tissues. Spray treatments were most effective on open flowers.

Vapor treatments with 2,4-D increased the set of fruit, but all plants showed marked deformation of the foliage and inhibition in the development of new flower buds.

Minnesota Fruit Breeding Station to introduce 3 new fruit varieties, W. H. ALDERMAN (*Minn. Farm and Home Sci. [Minnesota Sta.]*, 3 (1946), No. 2, p. 13).—Brief descriptions are presented of an apple, crabapple, and strawberry, known respectively as Minnesota 638, Minnesota 240, and Minnesota 1118, which are planned for distribution in 1946.

The Macoun apple—sets fruits in 1945 under adverse spring weather conditions, W. TOENJES (*Mich. Sta. Quart. Bul.*, 28 (1946), No. 3, pp. 189-190).—A brief discussion is presented of the tree, fruit, and bearing habits of the Macoun apple, a variety which in the adverse 1945 season set and matured a full crop while most adjacent trees of other varieties matured little or no fruit.

Apple varieties for the Western Slope, F. M. GREEN (*Colo. Farm Bul. [Colorado Sta.]*, 8 (1946), No. 1, pp. 6-11, illus. 3).—Over a period of years a considerable number of apple varieties have been under test at the Orchard Substation at Austin. The results are discussed, together with comments as to the need and value of new varieties and some of the outstanding features of varieties tested.

Apple-tree pruning wounds—treatment and healing in sound and winter-injured trees, D. S. WELCH and L. H. MACDANIELS ([*New York*] *Cornell Sta. Bul.* 821 (1945), pp. 23, illus. 7).—The durability and persistence of 24 materials were tested by exposure of freshly painted blocks of green apple wood to weathering for 1 yr. White house paint, bordeaux paint, copper resin, and variations of asphalt water emulsions and asphalt paints proved most durable, while orange shellac, blue wagon paint, coal tar paint, red barn paint, Revere Asphaltum, and water glass had practically disappeared from the wood surfaces and the underlying wood was badly checked at the end of the test.

Tests of the toxic effects of the materials on living apple tissues showed no apparent injury from orange shellac, copper resin, fibrated asphalt paint, and asphalt water emulsion. Paints containing linseed oil caused slight injury, as did also fibrated asphalt to which had been added a small quantity of creosote.

A test of 15 selected materials applied on large pruning wounds in winter-injured trees in five orchards resulted in no instance in preventing bleeding or decay of wood below the pruning wounds. The time between the occur-

rence of winter injury and the pruning varied from a few days to several months and the interval between time of pruning and applications of wound dressings varied even more greatly, thus providing a great variability in conditions.

In general the study failed to show any one material as being entirely suitable for treating pruning wounds on apple trees. From the standpoint of durability and freedom from injury to the cambium, asphalt-water emulsion, white house paint, fibrated asphalt paint, bordeaux paint, and copper resin have considerable promise.

**Influence of the rootstock on the composition of citrus leaves and rootlets.** A. R. C. HAAS. (Calif. Citrus Expt. Sta.). (*Soil Sci.*, 60 (1945), No. 6, pp. 445-461).—Information is presented to show that in addition to boron (E. S. R., 94, p. 338) the rootstock may influence the accumulation of other nutrient elements in the leaves of the scion tops. More Ca and Mg and less K were found in grapefruit and navel and Valencia orange leaves on sour than on sweet orange rootstocks. Valencia leaves of trees on shaddock, trifoliate orange, rough lemon, and Cleopatra mandarin were relatively high in Mg, whereas leaves of trees on grapefruit were relatively low.

The highest total N in Valencia orange leaves occurred in trees on Koethen sweet orange roots. Sulfur was higher in Valencia leaves on rough lemon, grapefruit, citrange, and most sweet orange rootstocks than in leaves from trees on sour or trifoliate orange and Cleopatra mandarin stocks. Total P was found relatively high in Valencia leaves from trees on sweet or trifoliate orange and generally low in leaves from Valencia trees on sour orange, rough lemon, and lemon shaddock roots. Leaves of large seedling sour orange trees contained more Ca and Mg, less total P, and about one-half as much K as did leaves of large seedling sweet orange trees.

The rootlets of sour orange budded with Valencia orange were high in Ca and low in K, total N, S, and P as compared with those of Koethen sweet orange.

It is concluded that for orange trees the relative order or type of absorption of nutrient elements which seedling trees impose on their own leaves resembles in certain respect the order that these seedlings, as rootstocks, impress on the leaves of the scion variety.

**Citrus industry of Florida.** A. F. CAMP ET AL. (*Tallahassee: Fla. [State] Dept. Agr.*, [n. d.], pp. 199, illus. 86).—This comprehensive discussion covers the various phases of citrus production, including propagation, culture, harvesting, packing house operations, marketing, and processing. Two of the principal articles *Citrus Growing in Florida*, (pp. 5-140) and *Packinghouse Operation* (pp. 141-167), were prepared by A. F. Camp of the Citrus Experiment Station at Lake Alfred.

**Tung culture in southern Mississippi.** S. R. GREER, T. E. ASHLEY, G. F. POTTER, and E. ANGELO. (Coop. U. S. D. A.). (*Mississippi Sta. Bul.* 409 (1944), pp. 26, illus. 12).—The status of tung oil production and importation in the United States is reviewed briefly and general information is presented on selection of sites, preparation of soil, selection of planting stock, planting, fertilizing, pruning, general cultural care, harvesting, etc. Records taken on the yield of a number of young budded varieties showed a great variation ranging in 1944 from 19.0 to 1.5 lb. per tree. Phosphorus plus nitrogen alone or P plus N in any combination with potassium, calcium, and magnesium increased production consistently. K used alone tended to decrease yield. In most of the soils of southern Mississippi the cover crop makes but little growth unless fertilized liberally with P. Basic slag proved to be a good fer-

tilizer for the cover crop and was not harmful to the seed or to the inoculation on the seed. Many Mississippi growers apply the P and K to the cover crop and the N directly to the trees in early spring. Ammonium nitrate at the rate of 1 to 2 lb. per 6- to 8-year-old trees gave an outstanding response. Fruit from plots that received K contained 1.25 more percentage units of oil than that from plots where no K was applied. Nitrogen, although reducing slightly the percentage of oil, increased the size of nuts to such an extent that oil was actually increased. Tung nuts must be stored to permit them to become air-dry before milling.

The quality of flower and vegetable seeds on sale in New York in 1945, M. T. MUNN (*New York State Sta. Bul. 717 (1946), pp. 69*).—The results are presented of germination tests on a total of 2,400 samples of flower and vegetable seeds collected by the State Department of Agriculture and Markets. The flower seeds averaged rather low in quality, with 38 percent of the 426 samples too low in germination and another 11 percent practically worthless. The vegetables averaged better in quality, with over 90 percent labeled correctly as to germination and only 13.2 percent showing a specific label discrepancy or deficiency of some sort.

## FORESTRY

Water and our forests, B. FRANK and C. A. BETTS (*U. S. Dept. Agr., Misc. Pub. 600 (1946), pp. 29+*, *illus. 24*).—This pamphlet discusses the vital role that water plays in the welfare of people; the damage resulting from excessive rains, melting snows, and drought; how soils, forests, and water are related; how forest covers help retain moisture, regulate stream flow, and reduce erosion; the need of protecting watersheds; and related topics.

Water and light in relation to pine reproduction, H. J. OOSTING and P. J. KRAMER (*Ecology, 27 (1946), No. 1, pp. 47-53, illus. 2*).—The more successful establishment of shortleaf pine at the margin of a forest than in the interior is attributed to better light conditions rather than to more favorable soil moisture. Measurements of soil moisture showed no more water available at the margins of the forest than within the stands. No environmental factor other than light was significantly more favorable at the forest margin than within the stand. The pines growing at the margin are in a favorable position with respect to photosynthesis, and can probably manufacture more food with which to develop extensive root systems which in turn can withstand drought better than trees within the forest.

Preliminary observations on northern white cedar in Maine, J. D. CURTIS. (Univ. Maine). (*Ecology, 27 (1946), No. 1, pp. 23-36, illus. 5*).—Northern white cedar occurs in both mixed and pure stands in soils ranging from a pH of 4.5 on uplands to a pH of 7.25 in swamps. The species reproduces by seed and vegetatively depending on the environment. Vegetative reproduction is common in the swamp and seed reproduction on upland soils. Seeding reproduction appears to be limited in the swamp sites due to fluctuations in the water table and to smothering by sphagnum moss. Evidence was obtained that white cedar is not as tolerant to limited light as believed commonly. This was indicated by a scarcity of advance reproduction, especially seedlings over 1 ft. in height, in all stands containing cedar. Among other factors limiting development of white cedar are snow, ice, deer, and porcupines.

Bibliography on cork oak, R. C. WATROUS and H. V. BARNES (*U. S. Dept. Agr., Bibliog. Bul. 7 (1946), pp. 66+*).—This bibliography includes refer-

ences to the literature on the cork oak and its culture; the stripping, treatment, and properties of cork; and the cork industry and trade of various countries. The cork of commerce is the outer bark stripped from the cork oak tree, *Quercus suber*, or its subspecies, *Q. suber occidentalis*. The cork oaks are native to the western Mediterranean region and probable successful culture elsewhere depends on the degree to which the climatic and other environmental requirements are met.

Ecuador's forests and the war, K. H. WYLIE (*U. S. Dept. Agr., Foreign Agr.*, 10 (1946), No. 5, pp. 75-80, illus. 2).—This is a description of the principal forest products in Ecuador (balsa, rubber, cinchona, tagua, kapok, tanning materials, and panama hats), especially as affected by the war and post-war conditions.

## DISEASES OF PLANTS

[Abstracts of papers accepted for presentation at the thirty-seventh annual meeting of the American Phytopathological Society, St. Louis, Mo., March 27 to 30, 1946] (*Phytopathology*, 36 (1946), No. 5, pp. 394-413).—Abstracts of papers on the following subjects—many of them by State experiment station and U. S. Department of Agriculture workers—are included:

*Cereal and forage crop diseases:* Corn—pericarp injuries and seedling diseases, genetic variation in *Gibberella zeae* in relation to adaptation, inheritance of susceptibility to *Helminthosporium carbonum* race 1, prevalence of *H. turcicum*, *Angiospora zeae*, and *Phyllacora graminis* on corn in Guatemala, *Puccinia sorghi* on corn in Mexico, *Sclerospora* in dwarfing and witches' broom, differences in diploid lines of *Ustilago zeae*, adaptation of *U. zeae* lines to arsenic, and new inoculation method for *U. zeae*; teosinte—diseases in Mexico; barley—helminthosporium foot rot; milo—laboratory and greenhouse studies of "milo disease;" oats—new helminthosporium disease, varietal reactions to *Helminthosporium* n. sp., and a new race of *U. avenae*; rice—new race of *Cercospora oryzae*; wheat—bunt effect on seedling blight and foot rot, fusarium head blight effect on bunt, leaf and stripe rusts in Mexico, and stem rust changes in Mexico; *Fusarium* spp. from cereal seeds in Canada; crop sequence effects on root rot in cereals and grasses; copper spot control on fine turf grasses, crown rust reactions of *Festuca elatior* and its variety *arundinacea*, and cytology of *U. striaeformis* from *Poa pratensis*; distribution and control of *Tilletia* spp. in Mexico; and viability of stored seeds of forage crops treated with different fungicides.

*Truck crop diseases:* Asparagus species and varieties—*Fusarium oxysporum* f. *asparagi* causing wilt and foot rot; bean—virosis in Montana; cabbage—varietal reactions to mosaic viruses and improvement of ascorbic acid content of yellows-resistant varieties; cucumber—anthracnose control with Fer-mate; spinach—virus inhibitors in extract; tomato—cuticle cracking in green fruits, cuttings wilted by toxic substance from *Phytomonas tumefaciens*, and Dithane control of fusarium wilt; and watermelon—D-D mixture against nematodes permitting two crops per year for breeding work in Florida.

*Potato and root crop diseases:* Potato—spraying and dusting, organic and inorganic fungicides compared against late blight, pigment-pathogenicity correlation in *Actinomyces* of scab, polymodal dosage-response curve between Ca-K ratio and scab, soil nutrient effects on leaf roll symptom expression in the Green Mountain variety in greenhouse, and serological relationship of potato latent and virulent ring spot viruses; sweetpotato—fungicides compared as dips for "seed" roots.

*Fruit crop and forest tree diseases:* Apple—Mn toxicity in measles, *Glomerella cingulata* as affected by growth substances, chromogenic line of *G. cingulata*, inheritance of pathogenicity and sex reaction in *Venturia inaequalis*, and C and N nutrition and vitamins vs. growth of pathogenic and nonpathogenic lines of *V. inaequalis*; banana—soil actinomycetes in relation to Panama disease; citrus—fruit rot control and actinomycete wood necrosis and gummosis; stone fruits—ring spot virus contaminating virus cultures, sour cherry yellows vs. yields, temperature effects on symptom expression in sour cherry yellows and necrotic ring spot, virus wilt and decline of sour and sweet cherries, rusty mottlelike virus of sweet cherry, and interaction of peach mosaic virus forms; Pierce's disease—vector feeding method and tissues involved in transmitting virus in grape and alfalfa; black raspberry—mild streak disease; and forest tree diseases—cankers and rots of deciduous forests in Quebec; burn blight of jack and red pines following spittle insect injury; spread and control of chalara wilt of oaks; and tubercularia canker and dieback of *Ulmus pumila*.

*Miscellaneous field crop diseases:* Cotton—varietal reactions to bacterial blight, bacterial blight as affected by leaf development and inoculation method, and field tests with Dow 9 on cottonseed; soybean—pathogenicity of *Rhizoctonia solani* isolates, fungus brown stem rot, bacterial pustule controlled by dusting, and seed treatment, stand, and yield tests; sugar beet—seedling infection by fungi in Montana; tobacco—breeding for mosaic resistance, hybrids and varieties in relation to root rots, and mosaic transmission via dodder as influenced by shading.

*General and miscellaneous:* Outstanding diseases of agricultural crops and uses of fungicides in the United States, plant pathology in the U. S. Navy in wartime, water congestion and infection experiments on various plant species, some phenols as agricultural fungicides, Cu availability in dusts as influenced by diluents, physiology and pathogenicity of *Corticium solani* strains, *Phoma lingam* variability, nutrient needs of the antibiotic fungus *Streptomyces griseus*, and virus complex in *Eryngium aquaticum*.

The Plant Disease Reporter [April 15 and May 15, 1946] (*U. S. Dept. Agr., Plant Disease Rptr.*, 30 (1946), Nos. 4, pp. 93–128, illus. 5; 5, pp. 129–173, illus. 7).—The above issues contain the following:

No. 4.—Host-parasite check list revision—*Pisum* (*Leguminosae*), by F. Weiss; bean diseases in some of the Intermountain States in 1945, by W. J. Zaumeyer; winter injury of fall seeded wheat in Idaho, by E. C. Blodgett; fungi isolated from dormant grasses at Mandan, N. D., in January, by R. Sprague; cooperative flax seed treatment tests in 1945, by F. J. Greaney; diseases of vegetable crops during February in Palm Beach and Broward Counties, Florida, by G. R. Townsend, R. C. Cassell, E. L. Felix, and R. Desrosiers (Fla. Everglades Expt. Sta.); tobacco blue mold in Georgia, by J. G. Gaines; and some unusual disease occurrences, including *Phytophthora* isolated from Russian olive, by J. C. Carter, and *Phyllosticta hederæ* on English ivy, by D. Gottlieb (both Ill. Nat. Hist. Survey) and a leaf blight of jack-bean in Cuba, by J. A. Stevenson.

No. 5.—Host-parasite check list revision—*Psoralea-Thermopsis* (*Leguminosae*), by F. Weiss; the sclerotinia rot disease of beans in Idaho (and experimental study with 11 literature references), by E. C. Blodgett (coop. Idaho Expt. Sta.); observations on some botrytis diseases in California, by K. F. Baker (Univ. Calif.); known distribution of phloem necrosis of the American elm, by T. W. Bretz and R. U. Swingle; report of the regional peanut seed treatment tests conducted in 1945, by S. B. Fenne (coop. Va. A. and M. Col.);

control of cucumber anthracnose with organic fungicides—a correction, by J. W. Heuberger (Del. Sta.); experimental forecast of wheat leaf rust in Oklahoma for 1946, by K. S. Chester and D. A. Preston (Okla. Sta.); wheat leaf rust in Texas, by I. M. Atkins (Tex. Sta.); diseases of vegetable crops during March in Palm Beach, Broward, and Martin Counties, Florida, by G. R. Townsend, R. C. Cassell, E. L. Felix, and R. Desrosiers (Fla. Everglades Sta.); and plant disease report Homestead area, Dade County, Florida, fall and winter season 1945–46, by H. I. Borders (Fla. Subtropical Sta.).

**Index to Supplements 145–150, 1944** (*U. S. Dept. Agr., Plant Disease Rptr., 1946, Sup. 151, pp. 483–530+*).

**An ascomycetous parasite of Cephaleuros**, M. J. THIRUMALACHAR (*Indian Acad. Sci. Proc., 22 (1945), No. 6, Sect. B, pp. 374–377, illus. 4*).—*Cephaleuros* spp. are well-known algal parasites on the leaves and tender shoots of many economic plants. *C. mycoidea* is regarded as a very superficial parasite, but *C. parasiticus* may become serious, since the filaments penetrate and spread within the mesophyll tissues. Both species have been collected on a large number of hosts in Mysore—the former, particularly, causing blemishes on guava fruits. In most of the author's collections of *C. parasiticus* the algal patches appeared to have been killed by an ascomycete; the entire patches were studded with fructifications of the fungus, which is identified as a species of *Strigula* and considered a true parasite of the alga. The relationships between the two and the possible use of the fungus for controlling this and similar parasites—such as the red rust of tea—are briefly discussed.

**Differential isolation of Chaetomium spp. from mixed populations by hypochlorite solution**, D. O. NORRIS (*Jour. Council Sci. and Indus. Res. [Australia], 18 (1945), No. 4, pp. 310–313, illus. 3*).—Spores of this fungus genus are highly resistant to calcium hypochlorite solution, which is very effective against other organisms. Large numbers of spores of *C. globosum* survived immersion for 15 min., and an occasional spore may survive for up to 2 hr., in a solution containing approximately 2 percent chlorine. This differential sensitivity enables *Chaetomium* spp. to be isolated at will from mixed populations.

**An undescribed species of Elsinoë from Mysore**, M. T. THIRUMALACHAR (*Mycologia, 38 (1946), No. 2, pp. 220–225, illus. 7*).—*E. bitancourtiana* n. sp.—causing infection spots on living leaves of *Scutia myrtina*—is described and illustrated.

**New and old fungicides for plant diseases**, W. A. KREUTZER and R. E. ATKINSON (*Colo. Farm Bul. [Colorado Sta.], 8 (1946), No. 3, pp. 9–11, illus. 1*).—Some of the newer chemicals are being tested by the station for seed and soil disinfection and as plant protectants; a brief outline of this work and its results is presented.

**Reaction of dodders to stems of other dodders and to their own stems**, C. F. LACKEY. (U. S. D. A.). (*Phytopathology, 36 (1946), No. 5, pp. 386–393, illus. 1*).—The two dodders, *Cuscuta subinclusa* and *C. californica*, commonly used in studying curly top and other virus diseases, were found able to grow parasitically on each and on their own stems as well as on other species of dodder. Their haustorial hyphae contact the vascular tissues of the dodder hosts without apparent harm to the tissues invaded.

**Blights affect barley production**, W. E. BRENTZEL (*North Dakota Sta. Bimo. Bul., 8 (1946), No. 4, pp. 27–29*).—This brief report largely concerns blights originating from the seed, but also to some extent those coming from the soil. Data from 2 years' trials appear to indicate that the increased yields from Ceresan-treated seed were both from improved stands and from

prevention of root rots appearing after the seedling stage. The majority of the trials seem to support the practice of selecting heavy seed for sowing, and the application of a good seed disinfectant gave significant increases in yields for all trials during both years.

**Powdery mildew of broad bean** caused by *Erysiphe polygoni* DC. in Yunnan, China, T. F. YU (*Phytopathology*, 36 (1946), No. 5, pp. 370-378).—The author states in this first report of powdery mildew of broadbean in China that, although not of great economic importance, the disease attacks leaves, petioles, stems, and pods. In the northern bean-growing regions it appears late in the season on volunteer beans; in southern Yunnan it attacks the commercial crop. The occurrence of the disease has been correlated with air temperature, 20°-24° C. being optimum for development. The fungus overwinters as conidia or perithecia on beans, peas, or wild species of *Vicia*. Cross-inoculation tests with conidia from garden pea and 14 species of *Vicia* demonstrated that the fungus attacking both broadbean and pea in Yunnan is a distinct physiologic race, here designated *E. polygoni viciae pisi* n. f. This view is substantiated by the consistency of spore size and shape in conidia collected from the various hosts. Powdery mildew on *Lathyrus quinquenervius* is distinct from the powdery mildew of broadbean.

**Clover rot**, W. A. R. DILLON WESTON, A. R. LOVELESS, and R. E. TAYLOR (*Jour. Agr. Sci. [England]*, 36 (1946), No. 1, pp. 18-28+, illus. 5).—In addition to its wide distribution in America and western Europe, the clover sickness caused by *Sclerotinia trifoliorum* is reported to be of considerable importance in Britain. Most of the common legumes are subject to infection but vary in susceptibility; infected peas have not been observed in the field but succumb on artificial inoculation. On the basis of pathogenicity there appears no valid reason for according varietal rank to the bean strain of the fungus. Ascospores of either strain infect both clover and beans and react identically on each host; it is proposed, however, that the name *S. trifoliorum fabae* be retained until measurements have been made of the ascospores from widely separated localities. It is shown that apothecia may be produced from the sclerotia buried in the soil at depths down to 2 in., and that spore discharge from them may continue for 4 weeks. Ascospore infection, contamination of seed with sclerotia, and the distribution of sclerotia in stable manure or on soil adhering to implements are ways in which the disease may be spread. In an examination of 1,000 infected bean stems, sclerotia were found to a height of 15 in., but were most frequent between 2 and 7 in. It is estimated that if a 5-in. stubble is left, 93,000 sclerotia may be harvested with the haulms from a 10-acre crop having 1 percent infection; these may find their way into the manure if diseased haulms are used for litter. Sclerotia buried in manure in stockyards proved viable up to 3 mo., although they quickly lost viability when placed under wet conditions. Sclerotia in manure retained their viability longest when near the surface and least when buried more deeply. Losses may be reduced by avoiding too frequent cropping with susceptible hosts, by use of clean seed, and sometimes by allowing sheep to feed on over-luxuriant crops. To prevent spread of the sclerotia, it is suggested that where bean haulms or clover from an infected crop are employed for litter or feeding, they should be used first to insure incorporation into the lower layers of the manure in yards.

**Relation of molds to the deterioration of corn in storage—a review**, G. SEMENIUK and J. C. GILMAN. (Iowa Expt. Sta. coop. U. S. D. A.). (*Iowa Acad. Sci. Proc.*, 51 (1944), pp. 265-280).—"The present review [3 pages of references] attempts to assemble the published information on corn

in storage, with special reference to the role that micro-organisms, particularly the fungi, may assume in its deterioration." Observations and experimental data have shown that the water relations of corn—both the moisture content of the grain and the relative humidity of the air in which it is stored—are the principal factors in the problem of safe storage. The hygroscopicity of the corn contributes to the importance of the relative humidity and is in turn affected by the type of kernel. Temperatures are also involved—the higher increasing the speed of deterioration and the possibilities of spoilage and the lower favoring safe storage. The conditions under which deterioration occurs and the changes following its initiation indicate it to be primarily a biological decomposition. Examination of affected bins disclosed the presence of many fungi, among which *Penicillium*, *Aspergillus*, and *Rhizopus* predominated. The moisture requirements of these fungi are lower than for those ordinarily attacking corn in the field; although the latter group might be expected to be carried into storage, their moisture relations make them of minor significance in the corn storage problem. From the standpoint of practice, drying shelled corn to a point below that required for the growth of fungi—to an approximate 12-percent moisture content—and storing under conditions preventive of moisture condensation and its subsequent absorption are said to be the essential requisites of successful storage.

Seed treatment cheap insurance—pays off when germination is low, M. B. MOORE (*Minn. Farm and Home Sci. [Minnesota Sta.]*, 3 (1946), No. 2, p. 14, illus. 1).—Seed treatment tests on corn during the past 9 yr., using more than 60 different seed lots of standard hybrids, indicated an average increase of 3.7 bu. per acre; similar tests with other farm crops revealed smaller but still very attractive gains from treatment. By rather extensive laboratory tests it is possible to gain a fairly accurate idea as to whether a particular seed lot will be benefited by treatment. The percentage of fungus infection is many times a good indication of how badly a seed lot needs treatment, but since this is a laborious test the safest procedure is usually to treat all small grains and corn every year.

A contribution to the study of the physiology of galloping wilt in cotton, P. V. SABUROVA (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 49 (1945), No. 1, pp. 69–72).—In the experiments reported, the amount of sap excreted by diseased plants was less than that from the healthy ones; the transpiration intensity between the diseased and healthy leaves was to the disadvantage of the former; no noticeable water deficiency was observed in the diseased plants. The physiology of the fungi causing galloping wilt or sclerotium root rot (*Sclerotium bataticola*) and "chronic wilt" or tracheomycosis (*Verticillium dahliae*) was studied. The parasitism of the former consisted in destruction of the living cortical tissues; the latter fungus lived in the xylem elements. In tests with aqueous extracts prepared from each of the fungi, a violent withering occurred in cotton branches placed therein. It is concluded that both diseases are associated with physiological disturbances in the plant and with the toxic effects of substances produced by the fungi.

Mosaics of winter oats induced by soil-borne viruses, H. H. MCKINNEY. (U S. D. A.). (*Phytopathology*, 36 (1946), No. 5, pp. 359–369, illus. 4).—Mosaic diseases of winter oats occur in limited areas of the Carolinas, Georgia, and Alabama. Transmission to healthy seedlings was accomplished by wiping the leaves (carborundum powder method) with juices from the leaves and sheaths of mosaicked plants; manual transmission proved difficult. The viruses are carried over by some means in the soil; the optimum constant temperature for infection from this source is 65° F. Symptom expression is fa-

vored by 65°, which is satisfactory for manual transmission. Seed from diseased plants gave good germination and produced mosaic-free plants. The virus isolates studied are regarded as a new species. One isolate inducing spindle-shaped chlorotic markings (eye spots) is believed to be a variety of the predominating field type that causes broken or continuous chlorotic streaks—chiefly toward the apical region in younger leaves of the Letoria variety.

Leafspot of peanut associated with magnesium deficiency, R. W. BLEDSOE, H. C. HARRIS, and W. B. TISDALE. (Fla. Expt. Sta.). (*Plant Physiol.*, 21 (1946), No. 2, pp. 237-240, illus. 2).—Peanuts are susceptible to leafspot infection which becomes economically important during the last half of the growth period, when the crop is planted in spring; the severity and rapid spread in the field may not be due to the mere presence of the ubiquitous pathogen, but to the susceptibility of plants suffering from improper nutrition at certain growth stages. In the experiments reported, the plants were grown in sand cultures; in those with Mg deficiency, leaf spots were observed on those leaves which first showed symptoms of the nutritional disturbance and *Mycosphaerella arachidicola* was isolated from them. The progress of the disease followed the same order of development as that of the deficiency symptoms. Chemical analyses showed a decrease in Mg concentration from the basal to the terminal leaves, and spectrographic analyses substantiated these results. The prevalence of leafspot on plants grown under a deficiency of elements other than Mg was no greater than that of controls. In this study it thus appears that the low level of Mg was either directly or indirectly responsible for the susceptibility to leafspot.

Occurrence of *Bacillus polymyxa* (Praz.) Mig. in Alberta soils with special reference to its pathogenicity on potato tubers, A. W. JACKSON and A. W. HENRY (*Canad. Jour. Res.*, 24 (1946), No. 2, Sect. C, pp. 39-46, illus. 3).—This spore former was found widely distributed in Alberta soils. All isolates from the soil, together with several from other sources, proved capable of rotting potato tubers under high moisture and temperature conditions, when introduced through wounds. In these studies, pure cultures of *B. polymyxa* rotted potato slices at 20° to 45° C. and whole tubers at 30° to 45°, but caused no damage below the above minimum. Though it is probable that potato tubers and other vegetables developing in the soil often come into contact with this bacterium, they are unlikely to be rotted by it except when temperature and other factors are favorable. Field soil temperatures in Alberta are, in general, not conducive to decay of potatoes by this organism, but those near the soil surface may on occasion become favorable to its development. The fact that *B. polymyxa* can be isolated frequently from potatoes rotted in storage indicates that it is of some importance as a cause of decay in harvested tubers; if, however, recommended temperatures are maintained no damage from this organism should occur in storage.

Potato "bolters": An explanation based on photoperiodism, J. G. HAWKES (*Nature [London]*, 157 (1946), No. 3986, pp. 375-376).—The preliminary experiments reported, though insufficient for statistical analysis, "nevertheless give a very definite indication that the bolter condition is due to a genetical alteration of some nature, converting the plant from a long-day to a short-day type. Under short days the 'bolter' grows normally, but shows various 'wild' characteristics under long days, as with the short day, adapted *S[olanum]* andigenum when grown under the long summer days of temperate latitudes."

The relation of stomatal behavior at the time of inoculation to the severity of infection of soybeans by *Xanthomonas phaseoli* var. *sojense* (Hedges) (Starr) Burk., W. B. ALLINGTON and C. V. FEASTER. (U. S. D. A. and Mo. Expt.

Sta.). (*Phytopathology*, 36 (1946), No. 5, pp. 385-386, *illus.* 1).—Soybeans were inoculated with a suspension of *X. phaseoli sojense*—cause of the bacterial pustule of soybean. Inoculum was applied with a power sprayer maintaining about 150 lb. pressure and with the nozzle adjusted to deliver an unbroken stream of water until within a few inches of the leaves, where it broke up into large droplets similar to beating rain. Inoculations were made at 2-hr. intervals from 3 a. m. until 9 p. m., and each time the average width of the stomatal openings was determined. The amount of infection was found directly correlated with the width of the stomatal openings; both were greatest around midday. These findings should prove of considerable value in developing an improved technic for inducing artificial field epidemics of bacterial leaf spots for disease-resistance studies.

The separation and properties of tobacco mosaic virus in different states of aggregation, F. C. BAWDEN and N. W. PRIE (*Brit. Jour. Expt. Pathol.*, 26 (1945), No. 5, pp. 294-312).—This study revealed that tobacco mosaic virus forms aggregates when exposed to the constituents of sap and to many other agents; a method is described for extracting the virus from infected leaves which greatly minimizes this aggregation. The virus in such extracts is inhomogeneous and can be separated by differential ultracentrifugation into fractions widely differing in properties. The most slowly sedimenting fractions contained much material other than virus nucleoprotein; the virus in these fractions exhibited no anisotropy of flow, behaved serologically like somatic antigens, and had only slight infectivity. The most rapidly sedimenting fractions, on the other hand, contained little except virus nucleoprotein, showed anisotropy of flow, and exhibited a serological behavior characteristic of flagellar antigens. In most fractions this change was accompanied by destruction of material other than virus nucleoprotein. The authors suggest that the primary virus particle is small and not greatly elongated, and that it occurs in the plant combined with extraneous materials, the removal of which sets free groups capable of combining with one another. Reasons for variations in the infectivity of different fractions are discussed, without definite conclusions. There are 31 references.

The ultracentrifugal examination of fractions of tobacco mosaic virus, J. P. JOHNSTON and A. G. OGSTON (*Brit. Jour. Expt. Pathol.*, 26 (1945), No. 5, pp. 313-315, *illus.* 1).—Using the "diagonal-schlieren" method of J. S. Philpot,<sup>2</sup> the authors examined 11 samples of preparations of tobacco mosaic virus in a Svedberg oil-turbine centrifuge, and the results are tabulated and discussed. The findings, in general, agreed with the rest of the evidence at hand on the nature of the virus fractions. None of the more slowly sedimenting components could be identified as containing the postulated primary virus; this is not considered surprising because of the possibility that the primary virus may be combined with nonspecific protein and in view of the amount of polydisperse material present in those fractions. It is notable that the fastest fraction appeared to be by far the most nearly monodisperse. The form of its boundary could not be used as a measure of the degree of polydispersity because of the distortion in the record, the lack of knowledge of the diffusion constant and of the variation in sedimentation constant with size for highly anisotropic particles, and because of the effect of variation in sedimentation constant with concentration. It is believed likely, however, that the range of particle sizes is not very great, and that if this fraction is formed by aggregation some factor limits the final degree or range of this aggregation fairly sharply.

<sup>2</sup>Nature [London], 141 (1938), No. 3563, p. 283.

**Transmission of the mosaic virus of tobacco through larvae of *Plusia gamma* L.**, K. S. SUKHOV and A. M. VOVK (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser., 49 (1945), No. 2, pp. 146-147*).—In the tests reported the larvae of *P. gamma* proved able to transmit the infection in a considerable number of cases.

**Further studies on the purification and properties of a virus causing tobacco necrosis**, F. C. BAWDEN and N. W. PIRIE (*Brit. Jour. Expt. Pathol., 26 (1945), No. 5, pp. 277-285, illus. 4*).—A nucleoprotein not present in healthy leaves was isolated from bean and tobacco leaves infected with the Rothamsted culture of tobacco necrosis virus. This has not crystallized when precipitated with salt, but it crystallized slowly from concentrated salt-free solutions or during sedimentation by ultracentrifugation; it had a sedimentation constant of 498—smaller than that of other plant virus preparations thus far studied. This strain readily loses its infectivity, and the relationship between the crystallizable protein and the virus remains uncertain. It is believed most likely that much of the protein is a noninfective derivative of the virus, having many physical, chemical, and serological properties in common with it.

**Ultracentrifugal examination of a virus causing tobacco necrosis**, A. G. OGSTON (*Brit. Jour. Expt. Pathol., 26 (1945), No. 5, pp. 286-287, illus. 1*).—A brief note on the findings from examination of three samples of tobacco necrosis virus in a Svedberg oil-turbine ultracentrifuge; the samples were the whole (preparative) ultracentrifuge pellet redissolved, the more rapidly dissolving fraction of a pellet, and the corresponding more slowly dissolving residue. Each preparation contained only a single visible component—apparently homogeneous—and the sedimentation constants failed to differ significantly. The ultracentrifuge revealed no difference between the fractions of the pellets exhibiting different rates of solution.

**The etiology of take-all disease of wheat**, I, II, N. H. WHITE (*Jour. Council Sci. and Indus. Res. [Austral.], 18 (1945), No. 4, pp. 318-335, illus. 5*).

I. *A survey of a take-all affected field at Canberra*, A. C. T. (pp. 318-323).—As part of a detailed survey of a take-all affected field, some preliminary observations are recorded beginning the first year of cropping to wheat after conversion from a savannah-woodland natural pasture and extending over 4 yr. Take-all plants occurred singly or in small groups throughout the field, but conspicuously in large irregular-shaped and well-defined areas. Soil from these and adjacent healthy areas failed to show significant differences in physical condition, organic C and N content, or reaction. Among random-sampled plants from both areas, 64 percent from the take-all areas and 7 percent from the healthy areas developed perithecia of *Ophiobolus graminis* on the culm bases; plantings from both lots yielded other fungi. From both lots the fungus species and the frequency of their occurrence were the same, including *Helminthosporium sativum* and *Fusarium culmorum*. During the first two seasons of cropping to wheat, the take-all patches were in the well-defined areas; in the succeeding years the diseased plants were widely distributed over the whole field. It was found that the location of these take-all areas shifted from season to season, although there was a tendency for them to be associated in succeeding years. Seedling blight symptoms in the field were associated with the presence of *O. graminis*. The distribution of plants exhibiting these symptoms was of a fundamental type of clustering, suggesting the operation of a locality factor; it is considered that this factor consists of foci of *O. graminis* inoculum. The evidence presented indicates that local

differences in soil condition other than those investigated and the location of the foci of inoculum may have been the factors determining the position of take-all patches in the field.

II. *Progressive necrosis and microfloral succession in root and crown tissue of wheat* (pp. 329–335).—During the development of a wheat crop spontaneously affected by take-all, there was an increase in the amount of diseased tissue, first in the seminal roots, then in the crown roots, and finally in the crowns of the wheat plants. There was also an increase in the number of plants with lesions as the crop developed, and at the ripe stage all plants had root lesions. The distinction between the condition of the roots of white-eared and normal-eared plants in this field was one of degree only. The lesions were caused by a primary invading organism—*O. graminis*. In the tissue lesions of the roots and crowns, there was a microfloral succession which resulted in the disappearance of *O. graminis*. Organisms isolated from the basal tissues of wheat plants with take-all symptoms may not have a true causal relation to the disease, but instead represent the dominants of a climax fungus community found in senescent root tissues. There are 24 references to the two parts.

Yellow berry and stem rust of wheat, G. MINZ (*Phytopathology*, 36 (1946), No. 5, pp. 381–383).—According to studies in Palestine, Florence wheat rust when controlled by sulfur dusts revealed an average reduction from 24 to 0.2 percent yellow spots in the kernels. An etiological connection between yellow berry and stem rust of wheat may be assumed; thus control of the rust is simultaneously effective against yellow berry.

The effect of DDT on the stem rust reaction of Khapli wheat, T. JOHNSON (*Canad. Jour. Res.*, 24 (1946), No. 2, Sect. C, pp. 23–25, illus. 1).—Seedling leaves of this wheat—a variety highly resistant to the physiologic races of *Puccinia graminis tritici* prevalent in North America—became susceptible a few days after spraying with DDT (1 oz. to 5 gal. water). This response proved highly specific, since only one other of the resistant wheats tested (Arnautka) exhibited any indication of susceptibility consequent on such spraying. Specificity of response was also indicated by the development of marked chlorosis on leaves of some varieties, whereas others remained unaffected.

Effect of storage on treated seed wheat, W. CROSIER. (N. Y. State Expt. Sta.). (*Farm Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 4, 10).—New Improved Ceresan at only 0.5 oz. per bushel of wheat seed is reported to eliminate smut and to control seedling blights; even smaller dosages controlled smut when the treated seed was stored for about a week. The effectiveness of this material depends on its volatility; thus if stored for prolonged periods the seed should be held in sacks in an open granary so that the excess gas may escape without injury to the seed. Treated seed planted within a week usually produced 2 to 3 bu. more than the untreated, even with smut absent; when bunt spores are present, the treatment often increases the yield by 10 to 15 bu. per acre.

Physiologic races of *Puccinia graminis tritici* in Canada, 1919 to 1944, M. NEWTON and T. JOHNSON (*Canad. Jour. Res.*, 24 (1946), No. 2, Sect. C, pp. 26–38, illus. 1).—During 1919–44, 65 races were identified from a total of 4,543 isolates derived from uredial collections; 49 races were obtained from the Prairie Provinces (3,475 isolates), 40 in eastern Canada (1,013 isolates), and 12 in British Columbia (55 isolates). During this period the predominant races exhibited notable fluctuations in prevalence. Races 36, 17, and 21 were the most common until shortly after 1930 and were largely

responsible for the severest rust losses in Marquis and other common wheats during the preceding decade. Races 34 and 49 were frequently collected from 1927 to about 1935. All these races diminished in prevalence during 1930-36, whereas race 56—first collected in Canada in 1931—has become the predominant race since 1934; it was this race which played a major role in the epidemic of 1935. Another recent change was a recrudescence in 1940 of race 17, which for several years had been of minor importance; in 1941 this race challenged the preeminent position of race 56 but receded again in the following years to a minor position.

The distribution of races is somewhat similar but not identical in different parts of Canada. Races 36 and 21 have been relatively more common in the Prairie Provinces than in eastern Canada; the contrary is true of race 38. Only about 12 of the 65 races have thus far assumed much economic importance; a few others may be considered of minor significance, but at least two-thirds of the races have been found only occasionally and have—for reasons not fully understood—failed to gain even limited distribution. Comparison of the number of physiologic races collected in eastern Canada vs. the Prairie Provinces has indicated a somewhat greater variety in the former area, a condition possibly explainable by the presence of the common barberry in many localities of eastern Canada. There are 22 references.

**Infection studies with *Actinomyces scabies*, W. J. HOOKER and G. C. KENT.** (Iowa Expt. Sta.). (*Phytopathology*, 36 (1946), No. 5, pp. 388-389).—This brief account of work in progress reports stunting, root necrosis, and premature death of seedlings of radish and other vegetables grown in sterilized peat soil artificially infested with cultures of the potato scab organism, *A. scabies*. Spore suspensions applied to wounded potato foliage induced localized necrosis.

**Fungicidal control of cantaloupe powdery mildew, J. T. MIDDLETON and C. E. YARWOOD** (*California Sta. Bul.* 697 (1946), pp. 8, illus. 4).—As based on experimental control of *Erysiphe cichoracearum*, a first spray should be applied when one to five mildew spots per leaf are found on the lower surfaces of the crown leaves. For early-planted cantaloupes a second application should follow when mildew again increases to the same degree of severity; usually, however, only one treatment is necessary for the medium and late crops. With temperatures below 95° F., 38 oz. liquid lime-sulfur (0.3 gal.) plus 6 oz. B-1956 per 100 gal. water is said to be the most economical mixture and one of the most effective sprays used; above 95° it is injurious, and 1.5-2-100 burgundy or 1.5-100 Cuprocid plus spreader may be recommended. The highest yield increase in the experimental work was secured on early cantaloupes receiving an early spray of liquid lime-sulfur, followed 2 weeks later by Cuprocid.

**Relative susceptibility of carrot varieties to nematode damage, yellows, and defoliation by blights, J. D. WILSON** (*Ohio Sta. Bimo. Bul.* 239 (1946), pp. 35-39, illus. 2).—Nematodes, yellows, and leaf blights are said to make it increasingly difficult to grow carrots on the muck lands of Ohio; 35 varieties were compared at McGuffey (1945) for resistance to damage by these diseases. Little resistance to nematode infestation and damage was encountered, though some varieties were more severely affected than others. Both long- and short-root types were deformed, but there was some indication that the short-rooted forcing types are least able to develop marketable roots following nematode injury to the growing point of the root. All varieties were susceptible to yellows, though some exhibited a considerably higher percentage than others. Streamliner, Amsterdam Forcing, St. Vallery, Short Top

Shipper, and Improved Short White were all over 10 percent diseased; others, like Luc and Coreless Chantenay, were below 3 percent. There was a wide variation in susceptibility to defoliation by leaf blights. Some of this may have been due to the fact that the disease failed to become serious until late in the season, when the tops of many of the early-maturing varieties had already started to die from natural causes. Varieties such as Chantenay, Redheart, Hutchinson, French Market, and the Belgian stock carrots were least attacked; those most susceptible included French Forcing, Nantes Half Long, Touchon, and Table Queen, among others.

**Diplodia rot of onions,** G. B. RAMSEY, B. C. HEIBERG, and J. S. WIAINT. (U. S. D. A.). (*Phytopathology*, 36 (1946), No. 4, pp. 245-251, illus. 3).—A market disease of Texas-grown Crystal Wax onions caused by *Diplodia natalensis* is here described for the first time; colored-skin varieties from Texas were not affected. Only the dead outer scales and the dying parts of the outer fleshy scales were invaded. A chemical (probably protocatechuic acid) associated with the pigments in aqueous extracts of the dry outer scales of colored varieties proved toxic to the spores of this fungus, but the dry scales of white onions do not carry this toxic agent in sufficient amounts to interfere with spore germination. Determination of the pH of both the dry outer and the fleshy scales of white and colored varieties revealed that the acidity of these tissues is not the primary factor in limiting the pathogenicity of the *Diplodia* to white varieties. Although the fungus is not strongly pathogenic to onions, it may cause a great reduction in market value by producing slight decay and by blemishing the southern white onion crop.

**Dust fungicides versus formaldehyde in the control of onion smut,** R. NELSON (*Michigan Sta. Quart. Bul.*, 28 (1946), No. 3, pp. 226-247, illus. 4).—Smut (*Urocystis cepulae*) is one of the major diseases of the seeded onion crop in Michigan, occurring in most of the important onion districts and with constantly increasing range. The standard method of prevention consists in applying a dilute formaldehyde solution in the row with the seed; though very effective, it is objectionable because of the time and labor involved. In three season trials of dust fungicides, they were either mixed in the drill with the seed or stuck to it with special binding materials; those containing tetramethyl thiuramdisulfide (Arasan, Thiosan) were tested at ratios of 1-1, 1-4, 1-8, and 1-25. The evidence, while inconclusive, indicates that dusts are neither equal nor superior in effectiveness to the standard method under moderate to heavy soil infestation with the smut fungus. In some commercial plantings where soil infestation was light they gave adequate control. In small-scale trials Arasan (1 lb. to 4 lb. seed) gave satisfactory control in the heavy seedings for set production. Until additional tests are completed Michigan farmers are urged to try the dust treatment only experimentally and to use formaldehyde for the main plantings.

**Late blight of tomatoes in east Texas at transplanting time,** P. A. YOUNG. (Tex. Expt. Sta.). (*Phytopathology*, 36 (1946), No. 5, pp. 389-391, illus. 1).—Tomato plants 6 to 12 in. tall brought from the Lower Rio Grande Valley of Texas in March 1945 were set out in fields near Jacksonville, where most of them died of late blight (*Phytophthora infestans*).—This parasite spread into nearby hot beds and cold frames, killing the tomato seedlings in them. The imported plants developed light brown stem cankers—the stems becoming constricted, twisted, and broken at such points. Nearly all of the leaves and most of the stems were killed in the cold frame. Some infected plants survived until warm weather and developed new tops. This is apparently the first time that late blight has been reported in east Texas and indicates that it was introduced in the diseased plants.

Certain aspects of the epiphytology and control of tomato fruit rot caused by *Phytophthora capsici* Leonian, W. A. KREUTZER and L. R. BRYANT. (Colo. Expt. Sta.). (*Phytopathology*, 36 (1946), No. 5, pp. 329-339, illus. 1).—*P. capsici* isolates from rotting tomatoes developed sporangia abundantly within 48 hr. at 25° C. when 20- to 60-day-old giant cultures were ground and mixed with well-moistened nonsteamed field soil. Sporangia developed readily at 20° to 30°, but none was produced at 18° or below or at 35°. Though abundant moisture is essential, the prime requisite for an epidemic is a soil temperature between 18.3° and 29.4°. When water was added to soil inoculum that had been held at 25° for 48 hr., swarm spore production reached its peak in 2 to 3 hr. at 25°. Earliest infection of noninjured green or ripe tomato fruits occurred after a 60-min. exposure to drops of inoculum containing swarm spores at 25° and 30°. Infection reached its peak after a 180-min. exposure at 25° and 30°. Exposure of fruits to swarm spores at 10° for 5 hr. resulted in infection. Studies of swarm spore activity showed that the time required to produce infection is correlated with the time required for swarm spore germination. Tests on culture practices for control of fruit rot revealed that mulching with straw or staking results in more healthy fruit than the corresponding controls (1 percent level of significance). Ridging produced significantly more healthy fruit than the controls (5 percent level of significance). In trials with fungicidal dusts on fruits in contact with the ground, 5 and 10 percent cuprous oxide and 10 percent copper oxychloride gave highly significant control; bordeaux spray (4-4-50) also effectively controlled the disease. Preliminary studies on the addition of  $\text{CuSO}_4$  to irrigation water at the time of soil inoculation indicated a highly significant degree of control. Of 120 commercial varieties, lines, and types of tomatoes tested in the field, a few lines have shown some slight promise of resistance.

"Flue dust" as an agent in the production of sun scald on tomato seedlings, R. MCKAY ([Ireland] *Eire Dept. Agr. Jour.*, 42 (1945), No. 2, pp. 233-235, illus. 4).—For a number of years some growers had been mixing the flue dust from cement factories with the dark compost used for raising tomato seedlings. The "sunscald" injury experienced was suspected of having a relation to this material. Later, the injury was experimentally reproduced several times in September 1941, and again in March 1945, by mixing the flue dust with the compost or by adding a layer to the surface in the seed boxes, followed by exposure to direct sunlight. Control plants raised in the same compost without the flue dust and kept under the same conditions were unaffected, as also were seedlings raised in compost plus flue dust but kept in the shade or continually moist. The worst sunscald occurred when the surface layer in the boxes to which flue dust had been added was allowed to dry out and form a crust. It is well known that dark soils readily absorb the sun's rays, and when a crust forms it acts as a better conductor of heat to the plants.

Temperature effects on the expression of the yellows virus in sour cherries, W. D. MILLS. (Cornell Univ.). (*Phytopathology*, 36 (1946), No. 5, pp. 353-358).—Statistical examination of data on the severity of the virus yellows of Montmorency cherries during the past 25 yr. revealed that the chief factor in determining yellows expression in the orchard for any one year is the prevailing temperature for 30 days after petal fall. The symptoms are more severe in seasons of early bloom because of the lower temperatures normally following it. Factors not influencing the degree of orchard symptoms in any one season are the prevailing temperatures after the symptoms

first appear, the incidence of cherry leaf spot, and the amount of precipitation. Since prevailing temperatures following bloom cause a high variation in the apparent amount of yellows present from year to year, no information as yet in hand can either prove or disprove any spread of the virus after the trees are set in the orchard.

Physiologic races of yellow rust of raspberries in western Washington, F. JOHNSON. (Wash. and West. Wash. Expt. Stas.). (*Phytopathology*, 36 (1946), No. 5, pp. 382-384, illus. 1).—Inoculations indicated that there are two physiologic races of yellow rust (*Phragmidium rubi-idaei*) infecting red raspberries in western Washington. The one from Whatcom County—adjacent to Canada—infected both Cuthbert and Washington varieties equally well. On the other hand, the latter variety proved resistant to infection by the race collected from Cuthbert and Marlboro raspberries grown in the Puyallup Valley. No rust has been found in Whatcom County on the Lloyd George or Newburgh varieties grown in close proximity to infected Washington plants; the Tahoma variety was apparently immune to both races.

Mineral nutrient deficiencies in California citrus trees and their causes.—II, Relation of each element to citrus, P. W. ROHRBAUGH (*Calif. Citrog.*, 31 (1946), No. 7, pp. 250, 258-260).—In this part (E. S. R., 95, p. 217) the relations to citrus of Ca, Mg, K, P, N, B, Fe, Mn, Zn, and Cu are taken up. It is said to be evident from field observations that at least occasional deficiencies in N, Fe, Zn, Mn, and Cu are not uncommon on citrus in southern California, and it is believed possible that there are some deficiencies in K and P. It is also believed quite evident that the deficiency problem—aside from N—is largely one of unavailability rather than of absence from the soil; the factors behind such conditions are briefly discussed.

Gray mold studies, L. J. KLOTZ, E. C. CALAVAN, and G. A. ZENTMYER (*Citrus Leaves*, 26 (1946), No. 5, pp. 6-7, 14, illus. 4).—Because of its alleged role in decreasing the set of young lemons and thus reducing the yields the gray mold fungus, *Botrytis cinerea*, has demanded renewed attention and study. This is a brief discussion of present knowledge on injuries caused by it and experiments under way for its control.

A progress report on quick decline studies. (Calif. Citrus Expt. Sta.). (*Calif. Citrog.*, 31 (1946), No. 6, pp. 198-199, 207, 210-215, illus. 1).—The purpose of this report is to show the status of investigations on quick decline of orange trees according to the facts—both positive and negative—accumulated by the workers whose discussions appear under the following headings: Starch Relationships, by H. S. Fawcett; Histological Studies, by H. Schneider; The Effect of "Quick Decline" on the Respiration Rate, by P. W. Rohrbach, L. J. Klotz, and G. A. Zentmyer; Experiments on the Possible Fungal, Bacterial, and Other Biological Relationships of Quick Decline, by L. J. Klotz and G. A. Zentmyer; Root Decay of Trees Affected With Quick Decline, by J. M. Wallace and G. A. Zentmyer; and Transmission Experiments With Diseased Tissues, by H. S. Fawcett and J. M. Wallace.

Quick decline studies. (Calif. Citrus Expt. Sta.). (*Citrus Leaves*, 26 (1946), No. 4, pp. 6-9, 16, 22, 28, 38-40, illus. 3).—See preceding entry.

The rootstock factor in quick decline, K. M. SMOYER and F. F. HALMA. (Univ. Calif. et al.). (*Calif. Citrog.*, 31 (1946), No. 7, pp. 249, 282, illus. 2).—In a 2-yr. survey, only navel and Valencia oranges on sour stock were found affected with quick decline. It is believed that sweet orange, probably grapefruit, and possibly trifoliata and rough lemon are either highly resistant or immune. Definite symptoms were encountered only on trees 3 or more years old. No regular pattern of spread was observed, and the rate within

and between orchards was not consistent. Some evidence was found that Eureka lemon is not susceptible. No Marsh grapefruit orchards were located in the affected area under study.

Quick decline studies, F. F. HALMA and K. M. SMOYER (*Citrus Leaves*, 26 (1946), No. 5, pp. 8-9, 38, illus. 2).—See preceding entry.

Notas sobre la podredumbre de las raicillas o "tristeza" de los naranjos [Notes on root rot or "tristeza" of orange trees], G. L. FAWCETT (*Rev. Indus. y Agr. Tucumán*, 35 (1945), No. 1-3, pp. 33-35).

Botrytis mold in lemons in Ventura County, C. C. DELPHEY (*Citrus Leaves*, 26 (1946), No. 5, p. 7).—A brief note on a field test in which Bordeaux (3-3-100) gave promising results.

The effect of botrytis rot on lemons, L. J. KLOTZ, E. C. CALAVAN, and G. A. ZENTMYER. (Calif. Citrus Expt. Sta.). (*Calif. Citrog.*, 31 (1946), No. 7, pp. 247, 262, illus. 5).—A summary of an address reporting the effect of botrytis rot on lemons in orchard and packing house.

Camellia flower blight, H. EARL THOMAS and H. N. HANSEN. (Univ. Calif.). (*Phytopathology*, 36 (1946), No. 5, pp. 380-381).—Sclerotia of the causal fungus *Sclerotinia camelliae*, which had been placed in soil under lath in 1943, produced apothecia in 1944, 1945, and 1946.

The eradicant action of a fungicide on *Colletotrichum lilii* in lily bulbs, F. J. LEBEAU. (La. Expt. Sta.). (*Phytopathology*, 36 (1946), No. 5, pp. 391-393, illus. 1).—Puratized N5X and its improved form Puratized N5E (10 percent phenyl mercuri triethanol ammonium lactate) were effective in eradicating *C. lilii*—cause of black scale of Easter lily—when the bulbs were immersed in aqueous solutions of these materials. The effective concentration ranged from 1-250 to 1-4,000; 24-hr. treatments proved sufficient for all but the highest dilution, for which 48 hr. appeared necessary. Control was poor with treatment times of less than 24 hr., regardless of concentration; no injury occurred except at 1-500 or higher concentrations.

Perithecia of powdery mildew on zinnia seed, K. F. BAKER and W. F. LOCKE. (Univ. Calif.). (*Phytopathology*, 36 (1946), No. 5, pp. 379-380).—Perithecia of *Erysiphe cichoracearum* developed on zinnia seed in the field, following vegetative development of the fungus in the flower heads. Although perithecia were still present on 2.31 percent of the seed after threshing and cleaning and on some seed coats after they had pushed through the soil in germination, there were no infections of the seedlings. Sulfur dusts should be applied prior to the time of flower infections for mildew control in seed fields.

Modifications de la morphologie et de l'économie hydrique des feuilles de *Fagus silvatica* par l'action d'une période de gel au cours de la feuillaison [Modifications in the morphology and water economy of the leaves of European beech caused by a period of frost during foliation], G. LEMÉE, (*Compt. Rend. Acad. Sci. [Paris]*, 222 (1946), No. 8, pp. 451-453).

Alcoholic fermentation of carbohydrates and dehydrogenation of alcohols by certain wood-destroying fungi, F. F. NORD, L. J. SCIARINI, J. C. VITUCCI, and E. S. PALLARES (*Nature [London]*, 157 (1946), No. 3985, pp. 335-336).—The results recorded in this preliminary report further substantiate the presence of a dehydrogenating enzyme system in the four wood-destroying fungi (*Merulius* spp. and *Fomes annosus*) used.

New species of *Poria*, L. O. OVERHOLTS and J. L. LOWE. (Pa. Expt. Sta. et al.). (*Mycologia*, 38 (1946), No. 2, pp. 202-212, illus. 2).—In the course of independent studies of miscellaneous collections of fungi of this genus of the Polyporaceae and the timber rots caused by them, the authors found seven apparently undescribed species which are here described as new.

Host-parasite relationships of the root-knot nematode *Heterodera marioni*.—II, Some effects of the host on the parasite, J. R. CHRISTIE. (U. S. D. A.). (*Phytopathology*, 36 (1946), No. 5, pp. 340-352, illus. 3).—In continuation of this series (E. S. R., 92, p. 230) it was found that some plants are highly suitable hosts for *H. marioni* and others are highly unsuitable; most plants, however, lie between these extremes, representing various intermediate degrees of suitability. Unsuitability as a host is manifested through retarded development of the parasite. A series of controlled experiments demonstrated that the rate of parasite development may differ (1) when different plants serve as hosts for the same race of parasite or (2) when the same plant serves as host for different races of the parasite. When the plant is a slightly unsuitable host and parasite development is but slightly retarded, the effect may be little more than to reduce the number of generations in a given period. When the plant is a moderately unsuitable host and parasite development is more strongly retarded, many of the ♀ nematodes never reach maturity and there may be a reduction in the egg output of those that do. When the plant is a highly unsuitable host, parasite development is almost completely suppressed and eggs are not produced. Unsuitability of the plant to serve as host is not necessarily accompanied by a corresponding reduction in the severity of gall formation.

## ECONOMIC ZOOLOGY—ENTOMOLOGY

Notes on recent opinions of the International Commission on Zoological Nomenclature, C. W. SABROSKY (*Ent. News*, 57 (1946), No. 1, pp. 14-16).

Studies on deciduous forest animal populations during a two-year period with differences in rainfall, L. A. RICE (*Amer. Midland Nat.*, 35 (1946), No. 1, pp. 153-171, illus. 5).—The purpose of this paper is to report on several aspects of forest animal populations in the William Trelease Woods of the University of Illinois—a 50-acre woodland tract near Urbana. Sweeping a definite area revealed that 50 strokes would give an average sample of inhabitants of that area but would not take all individuals on the area. The population of resident species inhabiting the herbs and shrubs was larger in 1934 than in 1935; the overwintering population of these species was much larger in the spring of 1934 than in that of 1935. The population of certain herb-inhabiting species declined during the summer of 1934, in which rainfall was below normal in May; the population increased toward the end of the summer of 1935, in which rainfall was much above normal in May and slightly so in June-July. The winter and migrant populations of birds ranged from 400 to 600 and were over 70 percent insectivorous. In 1935 robins took five-sixths of the hibernating invertebrates in an area of 25 acres. The largest number of migrating birds came through when the insect population was moving in and out of the woods for hibernation. Though the population of invertebrates available to birds is probably 20 times that consumed by them—including their young—the pressure falls on the Lepidoptera, Diptera, Hymenoptera (sawflies, etc.), and large palatable Hemiptera, while the small leafhoppers and flea beetles are utilized to a small extent. The species with large individuals are rarely abundant in the woods.

Vertebrate inhabitants of the piñon association in the Death Valley region, A. H. MILLER. (Univ. Calif.). (*Ecology*, 27 (1946), No. 1, pp. 54-60).—“In the Grapevine Mountains, immediately east of Death Valley, the piñon belt extends from 6,000 to 8,700 ft. In addition to normal piñon woodland, there has developed locally a forest of piñons, an unusual climax stand, which

has provided 'life-forms' for one group of vertebrates that otherwise would be absent in the breeding season. In the upper levels of the mountains there is a temperature zone comparable to that of the Transition Life Zone elsewhere into which the piñons have spread from the Upper Sonoran Zone. The moderately cool summer temperatures of the higher levels make possible the establishment of another group of species not customarily associated with the piñons. In analyzing these departures from the normal composition of the piñon-juniper community, one inevitably reverts to stressing requirements of individual species, particularly when it is seen how variously the species respond to the factors which have been conceived of as circumscribing the concepts of life zone and biome." Lists of summer resident and transient and vagrant birds and of mammals are included.

Study of the Alaska tundra with reference to its reactions to reindeer and other grazing, L. J. PALMER and C. H. ROUSE (*U. S. Dept. Int., Fish and Wildlife Serv., Res. Rpt. 10 (1945), pp. 48+, illus. 20*).—The Alaska tundra varies in width from a few miles to 200 miles along the Bering Sea and from 100 to 150 miles along the Arctic coast. Plant composition consists largely of lichens, grasses, sedges, alpiners, and shrubs, 16 distinct vegetative types of which are described in this report. Studies were begun in 1920 to work out the principal range and range requirements of the reindeer. Subsequent disturbance by grazing and fire—accompanied by climatic changes—has resulted in general confusion in plant mixture and occupation. Recovery of the lichen range—injured by grazing or fire—may require 20 to 40 yr. for restoration of the original density and height. Reestablishment of vascular plants is rapid. Moderate grazing by open herding and rotational use should permit sustained utilization of undamaged tundra.

The pocket gopher in relation to soil erosion on mountain range, L. ELLISON. (*U. S. D. A.*). (*Ecology, 37 (1946), No. 2, pp. 101-114, illus. 6*).—In what is considered a representative part of the subalpine zone of the Wasatch Plateau in Utah, annual displacement of soil to the surface by pocket gophers was found in 1941 to be at least 5 tons per acre and to cover 3.5 percent of the surface; their base population is estimated to be around 4 to 16 individuals per acre. The gopher diggings tend to be cast out on bare spaces between masses of vegetation where, as a result of grazing, the loose soil is most exposed; the diggings also tend to be concentrated in gullies where the soil is readily swept away. Both these effects are pronounced in proportion as the range is depleted. The tendency for the pocket gopher to displace soil consistently downhill is one factor in normal erosion creep; its magnitude is abnormally increased in proportion as protective vegetation is absent. No evidence was found in this area that their tunnels concentrate overland flow in a degree to create gullies unless, possibly, abnormal superficial runoff is induced by other causes. Delayed infiltration—cause of gully-cutting runoff—cannot be attributed to gopher activities; on the contrary, loosening of the soil and formation of minor irregularities on the surface by pocket gophers are believed to increase the rapidity of infiltration. No evidence was found on the area that gophers destroy vegetation sufficiently to cause accelerated erosion; their diggings provide a surface for establishing vegetation that is less favorable than an undisturbed soil surface with a plant cover, but apparently more so than a severely eroded surface. The gophers seem to be instrumental in the revegetation of some erosion-pavement areas. It is concluded that the pocket gopher is an agent in both geologic-normal and accelerated erosion; it is not, however, the primary cause of accelerated erosion on the Wasatch Plateau; there, the primary cause is over-

grazing. The amount of accelerated soil resulting from the gopher activity is related to the degree in which the soil mantle is dissected and the soil surface bared by man's abuse of land.

**A supplementary note on the winter food habits of cottontail rabbits, H. L. SWEETMAN.** (Mass. State Col.). (*Ecology*, 27 (1946), No. 2, pp. 185-188).—Additional information (E. S. R., 92 p. 676) is presented on the selectivity of woody plants as food for the cottontail rabbit on a site having 101 species, which are tabulated and discussed.

**Mammals and plague distribution in the United States, W. H. LAHNUM** (*U. S. Naval Med. Bul.*, 46 (1946), No. 5, pp. 782-785).—Native rodents, as hosts of bubonic plague, are said to possess a place of prime importance in spreading this disease in the United States. The distribution of human and rodent plague as here presented is a compilation from many sources intended as an aid to personnel engaged in rodent control work.

**Comparative assays of rodenticides on wild Norway rats.—I, Toxicity, S. H. DIEKE and C. P. RICHTER** (*Pub. Health Rpts. [U. S.]*, 61 (1946), No. 19, pp. 672-679, illus. 2).—Using 406 recently trapped adult wild Norway rats, the authors bioassayed 8 rodenticides. The various poisons suspended or dissolved in 10 percent acacia solution were administered to unanesthetized rats through a metal stomach tube. No significant seasonal variation was observed, nor was there any difference in results between the sexes except with red squill. The median lethal doses and their standard errors were found to be as follows in milligrams per kilogram body weight: 1080 (sodium fluoroacetate),  $0.22 \pm 0.01$ ; strychnine sulfate,  $4.8 \pm 0.4$ ; ANTU (alpha-naphthyl thiourea),  $6.9 \pm 0.5$ ; thallium sulfate,  $15.8 \pm 0.9$ ; zinc phosphide,  $40.5 \pm 2.9$ ; arsenic trioxide,  $138 \pm 13$ , fortified red squill—♀♀  $133 \pm 10$ , ♂♂  $276 \pm 29$ ; and barium carbonate,  $1,480 \pm 340$ .

**Instructions for using ANTU as a poison for the common Norway rat, C. P. RICHTER and J. T. EMLEN, JR.** (*Pub. Health Rpts. [U. S.]*, 61 (1946), No. 17, pp. 602-607).—This paper considers rat control as a community problem, and presents instructions on how, where, and when to use this specific poison (alpha-naphthylthiourea), how to prepare it for use, how to check results, precautions to be observed, and how to treat accidental poisoning.

**Du Pont "Antu" Rodenticide (alphanaphthylthiourea), E. H. RIEMAN** (*Pests*, 14 (1946), No. 3, pp. 28, 30).—A general statement on this rodenticide, including directions for use.

**Nesting heights of birds building in shrubs, F. W. PRESTON** (*Ecology*, 27, (1946), No. 1, pp. 87-91, illus. 6).—The vertical distribution of nests of the Brewer blackbird—as reported by La Rivers (E. S. R., 93, p. 54)—and of the catbird and American robin—as observed at Butler, Pa.—approximates to a simple Gaussian distribution if height is plotted logarithmically. This, the author states, is to be expected if the bird has a "favorite" nesting height above ground level, is "conscious" of the ground as a controlling factor in choosing the site, but has only a very confused notion of the "art" of measuring the height.

**Calculation of fish condition from scale dimensions in the bluegill (*Lepomis macrochirus*), H. B. CHASE.** (Ill. Nat. Hist. Survey and Univ. Ill.). (*Ecology*, 27 (1946), No. 2, pp. 182-184).—A method of estimating weight and thereby condition at previous times by means of the scale record was devised for the bluegill, and formulas based on the findings from the study are presented.

**Variations in abundance of certain invertebrates in William Trelease Woods, 1933-1938, S. E. JONES** (*Amer. Midland Nat.*, 35 (1946), No. 1, pp.

172-192, *illus.* 4).—In this University of Illinois woodland during 1933-38 the abundance of various invertebrates has varied sharply. Not all the species in one locality respond in the same way to weather conditions; one set of conditions affects the various species differently. Following the severe winter of 1935-36 some species increased and some decreased in abundance. During hot dry seasons the majority of invertebrates in an elm-maple forest were less abundant than in moderately warm humid seasons. In the warm damp spring of 1938 most invertebrates emerged from hibernation earlier than in the cold spring of 1937. The time at which animals begin or end hibernation can be determined only by frequent collections made during the period of migration into or out of hibernation. The causes of many common phenomena in invertebrate populations will be better understood if a community study is continued over a period much longer than 5 yr. Weather conditions cannot explain all the variations in invertebrate populations; other factors must exert at least a slight effect.

On some centipedes from Georgia, R. V. CHAMBERLIN (*Canad. Ent.*, 77 (1945), No. 11, pp. 215-216).—Among the chilopods listed are descriptions of one new species each of *Neolithobius* (with key) and *Eulithobius*.

A poison-squirting spider, E. R. TINKHAM ([U. S.] *Off. Surg. Gen., U. S. Army Med. Dept. Bul.*, 5 (1946), No. 3, pp. 361-362).—Note on a spider identified as *Peuceetia viridans*.

Season of attachment and growth of sedentary marine organisms at Lamoine, Maine, J. L. FULLER. (Univ. Maine). (*Ecology*, 27 (1946), No. 2, pp. 150-158).—Initiation of this study was stimulated by the problem of fouling of ships, buoys, and other immersed objects; aside from such practical applications, these animal and plant communities are of great ecological interest. Data are presented on the seasonal occurrence of the species found, their relative abundance, and their rate of growth. Fouling occurs through June-September but is most rapid during July-August. Preliminary observations on the influence of depth, method of panel suspension, location, and other ecological factors are reported in detail.

A new parasitic dinoflagellate from fresh-water fish, D. L. JACOBS. (Univ. Minn.) (*Amer. Micros. Soc. Trans.*, 65 (1946), No. 1, pp. 1-17, *illus.* 15).—*Oodinium linneticum* n. sp. is described as parasitizing nine species of exotic fresh-water fish kept in an aquarium; its life history and pathological, taxonomic, and certain ecological relationships are discussed.

[Abstracts of papers presented before the American Society of Parasitologists, March 28-30, 1946] (*Jour. Parasitol.*, 31 (1945), *Sup.*, pp. 15-16, 16-17, 18, 19-20, 23-24, 25).—The following are included: Tumor Formation as a Reaction to *Litomosoides carinii*, a Filariid of the Cotton Rat, by J. A. Scott and J. B. Cross (pp. 15-16); Anatomical Studies on the Fourth Stage Larvae and Adults of *Litomosoides carinii*, a Filariid of the Cotton Rat, by J. B. Cross and J. A. Scott (pp. 16-17); Infection Experiments With a Hookworm of the Cotton Rat, by L. J. Thomas (p. 18) (Univ. Ill.); Cercarial Production in Snails and Metacercarial Infections in Fish From Carrol Lake, Wisconsin, by L. O. Nolf (pp. 19-20) (Univ. Wis. et al.); Studies on Parasites of Bassalian Fishes, by R. F. Nigrelli (p. 23); the Nematode Parasites of the Bufoninae (Amphibia: Salientia: Procoela; Bufonidae), I-III, by A. C. Walton (pp. 23-24); and Chemotherapy of Filariasis (*Litomosoides carinii*) in the Cotton Rat by the Administration of Stibanose (= Solustibosan), by J. T. Culbertson and E. Pearce (p. 25).

Insects and the spectrum, H. B. WEISS (*Jour. N. Y. Ent. Soc.*, 54 (1946), No. 1, pp. 17-30).—In a previous paper the results of various workers were

summarized with respect to insect responses to colors (E. S. R., 92, p. 238). The present article was written to gather from the literature (94 references) any additional evidence that might have a bearing on insect responses to color stimuli.

**Waterproofing mechanism of an insect egg, J. W. L. BEAMENT** (*Nature* [London], 157 (1946), No. 3986, p. 370).—Water proofing of the eggshell of *Rhodnius prolixus* (Hemiptera) is reported in this preliminary account to consist of a wax layer about  $0.25\mu$  thick covering the inner surface of the shell.

**Connecticut State entomologist, forty-fourth report, 1944, R. B. FRIEND ET AL.** (Partly coop. U. S. D. A. et al.). (*Connecticut* [New Haven] *Sta. Bul.* 488 (1945), pp. 297–425+, illus. 18).—The following reports are included: Work of the Department, by R. B. Friend (pp. 301–308); Inspection of Nurseries, 1944 (pp. 308–311), Inspection of Apiaries (pp. 313–317), and Dutch Elm Disease (pp. 322–323), all by M. P. Zappe; Quarantine Enforcement and Miscellaneous Inspections, 1944, by M. P. Zappe and L. A. DeVaux (pp. 311–313); Gypsy Moth Control, by D. LaBelle and R. B. Friend (pp. 319–321); Mosquito Control in 1944, by R. C. Botsford (pp. 323–329); Rodent Control, by F. B. Schuler (p. 329); Report on Parasites (p. 330) and High Mean Temperatures as Affecting Plum Curculio Damage on Apples During the Past Seven Years (pp. 339–341), both by P. Garman; Status of the Natural Enemies of the Japanese Beetle in Connecticut (pp. 331–339) and Egg Parasitism of the Fall Cankerworm (*Alsophila pometaria* (Harris)) (pp. 416–418), both by J. C. Schread; The European Apple Sawfly, by P. Garman and J. F. Townsend (pp. 341–344); Wireworm Investigations, by D. E. Greenwood (pp. 344–347); DDT Dusts in Dosage Tests on Vegetable Pests (pp. 348–353). Use of Disodium Ethylene Bis Dithiocarbamate (Dithane) on the Soil to Control Insect Pests of Plants (pp. 353–356), and Effect of an Alkaline Diluent on Cryolite Dust (pp. 357–358), all by N. Turner; Certain Effects of Defoliation of Deciduous Trees (pp. 358–373) and Biology and Control of the Dogwood Borer *Synanthedon scitula* Harris (pp. 373–395), both by P. P. Wallace; The Corpora Allata of Mosquitoes, by D. Bodenstein (pp. 396–405); and Notes on the Effect of Aluminum Sulfate and Kolofog in Lime Sprays Applied to Soybeans as Repellents for the Japanese Beetle (pp. 405–406), *Aphonus castaneus* Melsh. (pp. 407–411), and The Incinerator Beetle *Dermestes cadaverinus* Fabr. (pp. 411–415), all by J. P. Johnson. Miscellaneous insect notes are also included.

**A review of twenty-five years of economic entomology in the Island of Mauritius, L. A. MOUTIA and R. MAMET** (*Bul. Ent. Res.*, 36 (1946), No. 4, pp. 439–472, illus. 15).—The authors discuss the practical results achieved in the past 25 years' work on the major insect problems of Mauritius. There are 78 references.

The general ecological characteristics of the outbreak areas and outbreak years of the Australian plague locust (*Chortoicetes terminifera* Walk.), K. H. L. KEY (*Austral. Council Sci. and Indus. Res., Bul.* 186 (1945), pp. 127+, illus. 32).—This detailed report describes the general ecology of the outbreak areas and years with special reference to those features which are important in relation to swarm formation. The main part of the text is taken up with the general climatic and topographical characteristics—with the interaction between these two factors, delimitation and description of the individual outbreak areas in Australia, and regions in which outbreak areas could develop on clearing.

**The identification of nyrphs of the genus *Melanoplus* of Manitoba and adjacent areas, R. H. HANDFORD** (*Sci. Agr.*, 26 (1946), No. 4, pp. 147–180,

*illus. 93*).—The author describes and compares 21 species of this genus of spur-throated locusts—18 of them from Manitoba. A tentative key to 19 species of adult ♀♀ is included.

**Differential feeding in relation to local distribution of grasshoppers**, F. B. ISELY (*Ecology*, 27 (1946), No. 2, pp. 128-138, *illus. 2*).—Photographic records of the feeding behavior of five midsummer species confirmed the basic fact of differential feeding by grasshoppers. Graminivorous species—in nature thriving best in mesophytic habitats—selected succulent grasses for their food when caged. Species more tolerant of xeric environments refused succulent grasses and fed on the more mature native grasses typically found in drier situations. Critical field observations over a 3-yr. period of a backyard area with seven distinct types of vegetation definitely correlated grasshopper distribution under natural conditions with differential feeding behavior under insectary environments. A far-reaching program on the ecology of the Acrididae is urged as promising valuable contributions to an understanding of terrestrial communities and control of pest grasshoppers.

**Comparative morphology and taxonomy of the Capniidae (Plecoptera)**, J. F. HANSON (*Amer. Midland Nat.*, 35 (1946), No. 1, pp. 193-249, *illus. 66*).—Detailed comparative studies of insects, particularly within the genera and species, are said to have been few; not until such studies are made can it be expected that the phylogenetic and taxonomic relationships of the insects concerned will be understood. It is the author's hope that this paper on one family of the stone flies "partially fulfills a need for such work in one small niche of taxonomic entomology." There are two pages of references.

**Two new Paraclius (Diptera: Dolichopodidae)**, F. C. HARMSTON and G. F. KNOWLTON. (*Utah State Agr. Col.*). (*Jour. Kans. Ent. Soc.*, 19 (1946), No. 1, pp. 23-25).—Collections taken during recent years have made possible this treatment of three interesting species of *Paraclius*; two are here described as new and a key is given to aid in their separation.

**Types of genera and subgenera of Pipunculidae**, W. F. RAPP, JR. (*Univ. Ill.*). (*Canad. Ent.*, 77 (1945), No. 11, p. 209).—This annotated list of genera and subgenera has been compiled to aid workers in the family Pipunculidae the big-eyed flies.

**The Erythroneura of the vulnerata group (Homoptera: Cicadellidae)**, R. H. BEAMER (*Jour. Kans. Ent. Soc.*, 19 (1946), No. 1, pp. 15-22, *illus. 1*).—Includes keys to the groups and species of this genus and one new species.

**The genus Stenocranus in America north of Mexico (Homoptera: Fulgoroidea: Delphacinae)**, R. H. BEAMER (*Jour. Kans. Ent. Soc.*, 19 (1946), No. 1, pp. 1-11, *illus. 2*).—Includes new taxonomy.

**Two new characters in the Geometridae**, W. T. M. FORBES. (*Cornell Univ.*). (*Jour. N. Y. Ent. Soc.*, 54 (1946), No. 1, pp. 39-46).—This insect family—with over a thousand genera and far more than 10,000 species—is said to have suffered in its classification from lack of good characters that could be seen without dissection. In an attempt to define the genera of the eastern United States better, the author discusses two structures—the chaetosema and the gena—that are easy to see. The first shows good grouping characters, while the second appears erratically—often differing between closely related genera and in a few cases within an obviously sound genus—but is easily seen and rarely shows intermediate states.

**Notes on some skippers, with new records for the United States (Lepidoptera: HesperIIDae)**, H. A. FREEMAN (*Canad. Ent.*, 77 (1945), No. 11, p. 201).

Flights of *Nymphalis californica* Bdv. in British Columbia and Alberta in 1945, H. B. LEECH (*Canad. Ent.*, 77 (1945), No. 11, p. 203).—The spiny caterpillars of this butterfly are known as defoliators of *Ceanothus* spp. The flight records given are considered of particular interest in that no reports of damage by the caterpillars were received during 1945.

The occurrence in North America of the European staphylinid *Deleaster dichrous* Grav., C. G. MACNAY (*Canad. Ent.*, 77 (1945), No. 11, p. 213).—Believed to be the second record of this beetle in North America.

A new Phyllophaga from Alabama and Georgia (Scarabaeidae: Coleoptera), O. L. CARTWRIGHT. (S. C. Expt. Sta.). (*Ent. News*, 57 (1946), No. 1, pp. 10-12, illus. 1).—*P. hubbelli* n. sp. is described.

Studies on the milky disease of Japanese beetle larvae, R. L. BEARD (*Connecticut [New Haven] Sta. Bul.* 491 (1945), pp. 501-583, illus. 27).—The type-A milky disease of the Japanese beetle is caused by *Bacillus popilliae*; the available published material on it is reviewed (52 references) as a background for the present studies. The normal invasion route is via the alimentary canal; both vegetative and spore forms seem to be infective, but the spores apparently germinate before reaching the hemolymph. Though not fully proved, the evidence indicates the malpighian tubules to be the most probable site of penetration from the gut into the blood. The course of the disease in this study is divided into four phases, viz, invasion, incubation, sporulation, and completion; the time required for the disease to develop was found largely a function of temperature. Infected grubs may live and feed for a longer or shorter time; when diseased the young grubs die sooner than the older ones. Molting and metamorphosis of the host is inhibited even when prompt death does not ensue. There is no apparent disturbance of body tissues or organs other than the blood; changes in the inorganic chemical constituents, number of blood cells, osmotic pressure, and pH of the blood, or its manner and time of coagulation are considered too slight to account for the over-all effect of the disease. At least one enzyme system is, however, commonly disturbed, and it is believed that the pathologic effects may be due to the destruction of one or more enzyme systems. The probability of a grub becoming infected increases with the spore dose. The three larval instars appear equally susceptible.

As tested, grubs fed prior to inoculation exhibited susceptibilities not differing significantly from those removed from cold storage at inoculation time. Grubs incubated at 75° and 85° F. appeared equally susceptible to inoculation. Spores kept as dried blood films showed no loss of potency with time; exposure in soil to weather caused no loss in potency. A single test indicated that fresh spores were six times as potent as those in dust form; exposure to ultra-violet light (sun lamp) caused very marked reductions in potency. Although low pH appears to affect spores adversely, the pH of soils usually encountered in Connecticut did not significantly affect their potency; marked loss of potency followed them at temperatures above 194°. The effect on potency of successive passages of the bacteria through a series of hosts was not well defined; some loss of potency was observed when the spores were kept refrigerated in water suspension. The average number of spores produced per grub approximated 2 billion; the number produced was not correlated with body weight of host, temperature of incubation within favorable limits, or size of inoculum. Healthy grubs may acquire the disease by biting diseased individuals; more commonly, it is acquired by ingesting spores along with food. Disintegration of diseased grubs serves to liberate spores to the soil, where dissemination is much more prompt than from intact individuals.

As measured by bioassay methods, the spores tend to remain more concentrated in the top 2 in. of soil, but there is some vertical spread of spores applied to the surface.

Several experiments demonstrated the importance of heavy grub populations for rapid spread of the disease; a high inoculum potential also favors it. The spread of infection was observed over periods of time among third instar grubs and among developing populations reared under different conditions. In several instances, an increasing inoculum failed to result in a progressive increase in incidence; instead, a period of increasing morbidity was followed by a decline. The reason for this result was that the infection rate at first exceeds the mortality rate; later the mortality rate exceeds the infection rate. The slower infection rate may be due, in part, to an accumulation of more resistant grubs. The role of *B. popilliae* as a parasite is discussed, and comparisons are made between infection trends of milky disease and characteristic epidemic curves.

Wheel-bug vs. Japanese beetle, S. W. BROMLEY (*Ent. News*, 57 (1946), No. 1, p. 21).—A brief note reporting the killing of large numbers of Japanese beetles by the wheel bug.

Daily fluctuations in aboveground activity of three species of ants, M. TALBOT (*Ecology*, 27 (1946), No. 1, pp. 65-70, *illus.* 2).—The daily fluctuations in above-ground activity in the three species of ants—*Formica pallidefulva schaufussi incerta* Emery, *Lasius niger neoniger* Emery, and *Myrmica sabuleti americana* Weber—were studied on a sand ridge in Michigan during July-August 1944. The heights of activity came at different times of day for the three species, these daily fluctuations in activity apparently being correlated primarily with temperature changes; reactions to humidity and to light also differed among the three species. Detailed findings are reported.

A new house-invading ant from Massachusetts, J. ENZMANN (*Jour. N. Y. Ent. Soc.*, 54 (1946), No. 1, pp. 47-49, *illus.* 2).—*Myrmica (Myrmica) brevinodis transversinodis* n. var. is described from Massachusetts.

On Euphiloides, an oriental subgenus of Crossocerus (Hymenoptera: Sphecidae: Pemphilidini), V. S. L. PATE. (U. S. D. A.). (*Ent. Soc. Wash. Proc.*, 48 (1946), No. 3, pp. 53-60, *illus.* 3).—The new subgenus, the three species (two new), and one new subspecies are described. A key to the forms is provided.

North American species of the genus *Lestiphorus* (Hymenoptera: Sphecidae: Gorytini), V. S. L. PATE (*Canad. Ent.*, 77 (1945), No. 11, pp. 210-213).—A taxonomic study of this small genus of relatively rare wasps distributed throughout the Holarctic region, including a key to the Nearctic species and a copious annotation of the three species included.

Microphotography as an aid to the identification of trombiculine larvae, D. A. GILL and E. PARRISH (*Jour. Council Sci. and Indus. Res. [Austral.]*, 18 (1945), No. 4, pp. 298-300, *illus.* 12).—The difficulty in identifying somewhat similar species of trombiculine mites from descriptions, drawings, and measurements is discussed; use of photomicrography of the whole mite and of its dorsal scutum is recommended as an additional aid. The technic used to obtain the accompanying illustrations is detailed; a complete series of such photographs covering all known species would, it is believed, be of great assistance.

The place of new sprays and dusts in the control of insects and diseases: A panel discussion led by E. N. CORY (*Peninsula Hort. Soc. [Del.] Trans.*, 59 (1945), pp. 18-41).—The following brief papers are included: Recent

Experimental Results with DDT on Control of the Codling Moth, by W. S. Hough (pp. 19-25) (Va. Expt. Sta.); Results With DDT for Codling Moth Control, Delaware, 1945, by P. L. Rice and L. A. Stearns (pp. 26-31), and New Developments in Fungicides, by J. W. Heuberger (pp. 36-41) (both Del. Sta.); and 800 Acres With DDT—West Virginia Grower Reports on Experience of Three Seasons, by H. W. Miller, Jr., (pp. 32-35).

New fumigant controls most important greenhouse pest, W. E. BLAUVELT. ([N. Y.] Cornell Expt. Sta.). (*Farm Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 12-13).—Studies have shown that azobenzene, when used as a fumigant in vapor form, appears to offer for the first time a satisfactory chemical control for red spider mite on roses, as well as an improved control for other florist crops. Although first made available commercially in November 1945, over 30,000 pounds of azobenzene powder have been purchased by growers, and four companies are marketing the recommended formulation, which contains 70 percent of azobenzene.

Low temperature fumigation, H. A. U. MONRO (*Canad. Ent.*, 77 (1945), No. 10, pp. 192-196).—The author briefly reviews the problem of conducting fumigations below 60° F. for controlling insect pests, including a discussion of the literature (10 references). Experiments with the European corn borer revealed that methyl bromide can penetrate cold bales of broomcorn at temperatures as low as 26°—and probably lower—in toxic amounts by employing increased dosages as the temperature is lowered. No fan was used to circulate the fumigant, but problems of distribution under practical space-fumigation conditions could not be properly duplicated since the test vault used could hold only one bale and the fumigant was discharged directly above it.

Factors influencing the interaction of insecticidal mists and flying insects.—I, The design of a spray testing chamber and some of its properties, W. A. L. DAVID (*Bul. Ent. Res.*, 36 (1946), No. 4, pp. 373-393, illus. 4).—The considerations influencing designs of spray-testing chambers are discussed, and a description is given of equipment specifically intended for use with most mosquitoes as test insects. In its essentials, the apparatus consists of a metal chamber surrounded by a "Masonite" cabinet, with an air space between the two. In this space, air at constant temperature is circulated around the outer face of the inner metal chamber for temperature control. The cabinet is fitted with lights, wet and dry bulb thermometers to check the humidity—controlled by blowing in steam—a fan to circulate air, a spray gun, four ports through which the insect exposure cages are introduced, a shelf to carry the cages, and an exhaust and intake port to allow the mist to be removed at the end of a test. In practice the apparatus gave satisfactory results, permitting accurate comparisons between different strengths of a given insecticidal solution; care must be taken, however, to insure that the nonvolatile contents of sprays being compared are essentially similar. Examples of application of the method to pyrethrum, DDT, and activated sprays are given. The results of the various experiments are fully described in the text. It is concluded that temperature influences considerably the level of kill recorded, but humidity seemed to have little or no effect within the range 40 to 80 percent relative humidity. Increasing the interval at which the insects were inserted after spraying for 0 to 10 min. influenced the level of kill without affecting the comparative efficiency of the insecticides examined. Caging the insects, on the other hand, had a pronounced effect on the comparative efficiency of pyrethrin sprays used with and without added non-volatile material.

Investigation of insecticidal sprays, A. B. P. PAGE, A. STRINGER, and R. E. BLACKITH (*Nature* [London], 157 (1946), No. 3977, pp. 80-81, illus. 2).—To this brief review on the methods of bioassaying insecticides the author adds his results obtained with pyrethrins as activating agents against the yellow-fever mosquito, leading him to the conception of a pair of average threshold values of the amount picked up by the insect which control its responses. The lower value governs the transition from normal to stimulated flight activity; the second, or "knock-down" threshold, shows itself biologically by a sudden rapid increase in the rate of knock-down action with increase of pyrethrin concentration in the spray, but is more evident as a sharp peak in the spray pick-up-pyrethrin concentration curve which varies with the spray dosage in such a way that the corresponding pyrethrin pick-up remains constant, just as the "activation" threshold is independent of the spray dosage. Preliminary investigation of the housefly, northern house mosquito, *Coccinella septempunctata* L., *Vespula vulgans* L., *V. germanica* F.—queens and workers, and *Rhagozycha fulva* Scop. confirmed the existence of both threshold values for these insects also. The method described is believed to open up a new line of attack on the form of the dosage-mortality curve.

Some physical properties of DDT and certain derivatives, H. L. ANDREWS, W. C. WHITE, L. R. GAMOW, and D. C. PETERSON (*Pub. Health Rpts.* [U. S.], 61 (1946), No. 13, pp. 450-456, illus. 3).—Certain derivatives of DDT have proved of particular interest in studies of the mode of action and fate of ingested DDT. This paper extends the ultraviolet absorption<sup>3</sup> to four derivatives and includes the infrared absorption spectra and X-ray diffraction patterns of the five compounds; a crystallographic analysis of DDT is also presented. The X-ray diffraction pattern of DDT was of sufficient intensity to permit its identification in a dust sample when present in a concentration of 10 percent or more; the actual amount of DDT detectable by diffraction pattern was about 1 mg. The other compounds were detected in somewhat smaller concentrations.

The use of D.D.T. as an agricultural insecticide—results of trials, 1944-45, G. A. H. HELSON and T. GREAVES (*Jour. Council Sci. and Indus. Res.* [Austral.], 18 (1945), No. 4, pp. 301-309).—The trials reported showed that DDT gave effective control of a number of pests, e. g., the southern green stinkbug, black peach aphid, green peach aphid, codling moth, potato tuber worm, cabbage webworm, corn ear worm, diamondback moth, imported cabbageworm, *Doralis fabae* Scop., *Macrosiphum gei* Koch, *Cydia molesta* Busck., *Crocicidolomia hirtulalis* Zell., *Prodenia litura* F., *Caliroa limacina* de Geer, and certain ants. This list contains various species which could not be controlled adequately by previously used insecticides. On the other hand, a few pests proved resistant to DDT in the preparations used, notably the cabbage aphid, woolly apple aphid, and the red spider *Tetranychus urticae* Koch.

Some uses of D. D. T. in agriculture, H. SHAW (*Nature* [London], 157 (1946), No. 3984, pp. 285-287).—A summary of recent experimental results presented by various workers at a 1945 meeting of the Association of Applied Biologists.

Effects of DDT on cabbage maggot of radish and on aster yellows and the leaf hopper on head lettuce: A progress report, P. H. BOWSER (*Mich. Sta. Quart. Bul.*, 28 (1946), No. 3, pp. 194-200).—The tests presented in this progress report indicate that spraying or dusting against the cabbage margot must

begin with emergence of the seedling, and that DDT in certain concentrations applied as a dust gave better control than any treatment previously used at the station. Neither the seed nor the spray treatments were satisfactory, but the 25 and 5 percent dusts applied three times after emergence proved effective and show promise of providing relief from the maggot problem. A 5 percent bait prepared from 100 percent chemical DDT with corn meal was not as satisfactory as the prepared dusts. It is possible that a 10 percent DDT dust may be an intermediate concentration more effective than the 5 and less expensive than the 25 percent mixture. At present a 5 percent mix dust handled properly and applied at proper times is recommended.

It was shown that as the summer season progresses the damage from the six-spotted leafhopper increases up to the September harvest. The largest yields in each crop were obtained where a 25 percent DDT dust was applied; reasonably good control, however, was obtained with a 5 percent dust. Higher concentrations are correspondingly more expensive and likely to give objectionably high residues. The time, number, and method of application need further study. Observations from this progress report indicate that earlier dusting may increase the leafhopper control; it seems also that frequency rather than concentration is most important. It may pay to dust all grass areas and fence rows surrounding lettuce fields to prepare a trap area for migrating hoppers. Since a very low tolerance for DDT has been set up for edible products, it would be hazardous on lettuce, except very early in the season.

Quick-breaking fuel-oil emulsions containing DDT, P. M. EIDE, C. C. DEONIER, and E. NOTTINGHAM. (U. S. D. A.). (*Mosquito News*, 6 (1946), No. 1, pp. 17-19).—Use of 2-percent of an emulsifier containing 5 percent of DDT in No. 2 fuel oil permitted addition of water from mosquito breeding places, thus making it possible to obtain the quantity of spray necessary for thorough distribution of the low dosages of DDT with available equipment. Any emulsifier may be used which will form good emulsions with fuel oil; the emulsion concentrates may be used to form quick-breaking emulsions by diluting 1 part concentrate to 4 parts fuel oil.

The use of DDT and 1080 in Murine typhus control in the Southwest. R. G. UPTON (*Pests*, 14 (1946), No. 3, pp. 24, 26).

More research needed on DDT insecticides, C. E. PALM. ([N. Y.] Cornell Expt. Sta.). (*Farm Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 5-6, illus. 1).—This article points out the need for further experimental tests, especially studies which will make possible the development of better dosages and formulations.

Toxic effects of copper on attachment and growth of *Bugula neritina*, M. A. MILLER. (Univ. Calif.). (*Biol. Bul.*, 90 (1946), No. 2, pp. 132-140, illus. 8).—This paper describes physiological experiments dealing with the effect of copper on the attachment and development of *B. neritina*, a widely distributed marine fouling organism; the studies were designed to evolve a clearer understanding of the specific role of copper in the prevention of fouling and the mechanism by which copper surfaces act. Such paint surfaces were found to prevent the establishment of *B. neritina* by repelling or killing the larvae and inhibiting the growth and metamorphosis of attached larvae. A gradient of toxicity extending outward a few millimeters from a copper paint surface was demonstrated. Detailed findings are presented. There are 18 references.

"*Tephrosia noctiflora*" como planta insecticida, A. MUTINELLI (*Rev. Argentina Agron.*, 12 (1945), No. 4, pp. 291-314, illus. 4; *Eng. abs.*, p. 313).—The author reports 4-yr. experiments with this plant at Misiones, Argentina, finding the roots and seeds to possess high potency as a fish poison and as a contact insecticide. Unlike the plant group producing rotenone, he also found it ecologically adapted to the region and believes it may prove of considerable economic importance to the country.

The ability of the beet leafhopper to regain lost vitality when transferred from unfavorable to favorable host plants, W. C. COOK. (U. S. D. A.). (*Ecology*, 27 (1946), No. 1, pp. 37-46, illus. 1).—Experiments at Modesto, Calif., revealed that ♀ beet leafhoppers fed on desert sage—an unfavorable hold-over host—until they have lost much of their vitality can regain some or all of it by feeding on more favorable plants, such as sugar beets, quail brush, or *Lepidospartum*. Vitality was measured by a standard starvation test and by determining the amount of crude fat present by extraction with ethyl ether or chloroform. The rate at which vitality is regained depends on temperature, being very slow at 45° to 50° F. and more rapid above 55°. Unless it is later demonstrated that feeding on an unfavorable host affects reproduction adversely, the most important result of such feeding is a high mortality. In fall spraying operations against leafhopper, these findings make it possible to center attention first against the favorable host plants, allowing natural mortality to have its effects on unfavorable hosts before spraying is done there. This practice will often reduce the size of the area that must be sprayed.

Contribution à l' étude des Silphes de la betterave en Suisse [Contribution to a study of the carrion beetles (Silphidae) of the beet in Switzerland], H. MARTIN (*Landw. Jahrb. Schweiz*, 59 (1945), No. 9, pp. 757-819, illus. 19; *Ger. abs.*, pp. 817-818).—Part 1 of this monograph deals with the two species of carrion beetles—*Blitophaga opaca* L. and *B. undata* Müll.—injurious to beets, considering their history, taxonomy, geographical distribution, morphology and anatomy, biology, ecology, and the nature and importance of the damage which they cause. Part 2 deals more briefly with other insects injurious to beets. There are 32 references.

Influence of aphides upon carbohydrate exchange in cotton, Z. L. NEVSKAYA (*Compt. Rend. (Dok.) Acad. Sci. U. R. S. S., n. ser.*, 48 (1945), No. 5, pp. 369-373).—In leaves of cotton infested with aphids which—in feeding—introduced into the tissues enzymes from their salivary glands, the amylase and invertase activity averaged an increase of 100 percent. Owing to the intense hydrolysis, disaccharides and polysaccharides passed into the only form in which they could be directly assimilated by aphids, viz, monosaccharides; these sugars were ingested so vigorously by the aphids that the concentration of soluble carbohydrates in the sap of the leaf petioles—the first to convey the downward flow of sap—was reduced by an average of 40 percent, and the amount of reserve carbohydrates in the axial organs of the plant was reduced by about 50 percent. The carbohydrate starvation of the vegetative organs led to a lowered supply of nutritive material to the reproductive organs; this resulted in shedding at the critical periods of growth and also influenced the quality of the raw cotton in the bolls that escaped.

Les adultes de doryphore peuvent s'attaquer à leurs propres oeufs [Adults of the Colorado potato beetle attacking their own eggs], M. DURCHON (*Compt. Rend. Acad. Sci. [Paris]*, 222 (1946), No. 6, pp. 340-342).

**Recommendations for control of borer by dusting with cryolite.** (La. Expt. Sta. and U. S. D. A.). (*Sugar Bul.*, 24 (1946), No. 15, pp. 116, 118).—These recommendations for controlling the sugarcane borer in 1946 were prepared jointly by the Louisiana Station and the U. S. Bureau of Entomology and Plant Quarantine.

**Additional host and distribution records of the sweetpotato leaf beetle *Typophorus viridicyaneus* (Crotch) (Coleoptera: Chrysomelidae),** R. L. PARKER. (Kans. Expt. Sta.). (*Jour. Kans. Ent. Soc.*, 19 (1946), No. 1, pp. 11-12).—Further information (E. S. R., 94, p. 503) is presented on this beetle, which has been reported to cause considerable damage to sweetpotatoes in Kansas.

**Hessian fly in the spring wheat of southwestern North Dakota,** R. W. SMITH. (Coop. U. S. D. A.). (*North Dakota Sta. Bimo. Bul.*, 8 (1946), No. 4, pp. 3-6).—In 1944, after a succession of cool seasons with good rainfall, reports came in of unusual insect injury—later shown to be from the hessian fly. Varietal plots of spring wheat at the station began to show the injurious effects of these pests early in June, and records were made of the relative numbers of the flies on the different varieties. With few changes in varieties, 29 spring wheats were again seeded in the field in 1945; with some exceptions, those with but few flies in 1944 had few again in 1945. Results for the 2 yr. are not conclusive, but observations of farmers in the area agreed with the station results as showing that Mida wheat was definitely more resistant than other commonly grown standard varieties of spring wheat. There was also a definite tendency for the yields to drop as the insect infestation increased. Though Mida is not immune, it may have enough resistance to render losses negligible where it is grown; this variety is being employed in breeding work.

**The effect of Say stinkbug feeding on wheat,** L. A. JACOBSON (*Canad. Ent.*, 77 (1945), No. 11, p. 200).—The Say stinkbug is reported to be a comparatively new pest of wheat and other seed crops in western Canada, doing severe damage to wheat in many localized areas. Damage to ripening grain is caused by the feeding of adults as well as occasional nymphs, both of which are usually very abundant in early spring around weeds, along roadways, ditches, and field margins and in abandoned fields. The results of a survey of a severe outbreak at Turin, Alberta (1941), are briefly presented.

**Aphids on Canada wild rice,** J. B. ADAMS. (*Canad. Ent.*, 77 (1945), No. 10, p. 176).—Note on heavy infestation by the apple grain aphid.

**The European chafer in lawns,** F. L. GAMBRELL. (N. Y. State Expt. Sta.). (*Farm Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 19-20, illus. 2).—Grubs of the European chafer are reported to be troublesome in lawns of restricted areas in western New York. Experimental evidence has shown that lead arsenate as spray or dust applied at a minimum dosage of 500 lb. per acre (1 lb. to each 100 sq. ft. of lawn) will afford considerable protection against the next brood of grubs. It is highly desirable to "wash in" the arsenical to avoid danger to children or animals; early spring application takes advantage of alternate freezing and thawing and frequent heavy rains. Preliminary results with DDT are said to give promise.

**One year's results from dusting snap beans to control anthracnose and leaf hoppers,** E. H. BJORNSETH (*Michigan Sta. Quart. Bul.*, 28 (1946), No. 3, pp. 191-196).—On the basis of 1945 tests it is apparent that leafhoppers cause considerable losses in the early snap bean crop and that DDT properly applied will control them. Tolerance for the amount of DDT residue permitted on vegetables has been determined by the Federal Food and Drug Adminis-

tration; it is probable, in view of the rapid growth of bean pods, that the amount of residue would be below this tolerance if 3 percent DDT dust were applied so that the third treatment came a week before the first picking and the fourth just after it. The cost of four applications was about \$15 per acre; the yield was increased 66.65 bu. Early snap beans usually sell at the highest price; the practice should thus be economical and profitable for the early crop. The 1945 conditions were unfavorable for anthracnose, so the value of Fermate could not be determined. Late in summer, however, conditions are usually favorable to its spread, and it is believed possible that use of such a fungicide would be justified.

The hop-vine borer and its control in New York hop yards, R. O. MAGIE and F. G. MUNDINGER. (N. Y. State Expt. Sta.). (*Farm. Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 11-12, illus. 3).—The life history and control measures for the hopvine borer (*Hydroecia immanis* Guenee) are discussed. Among the possible control measures are elimination of grasses on which eggs are laid within and near hopyards, destruction of eggs during the dormant season by burning or spraying, killing larvae within hopyards, and destruction of migrating, newly hatched larvae. Of these the first is deemed the most positive and in the long run the least expensive.

DDT for the control of onion thrips, J. P. SLEESMAN (*Ohio Sta. Rimo. Bul.* 239 (1946), pp. 39-40).—In the test reported, DDT gave the most outstanding performance of any material used on onions during the past 15 yr. Each application reduced to and maintained a very low level in the thrips population for at least 7 days. Three formulations were compared: DDT as a wettable powder, solubilized in an oil emulsion, and a 3 percent dust mixture; equally good control and yields were obtainable with all three. DDT thus appears to be a practical and effective control for the onion thrips; additional information on dosage, residual efficiency, spray intervals, and other factors must be obtained, however, before this insecticide can be used most effectively and efficiently.

Influence of population number on egg production in the four-spotted pea beetle, *Bruchus quadrimaculatus* Fabr., A. BRAUER. (Univ. Ky.). (*Ky. Acad. Sci. Trans.*, 11 (1943-44), pp. 56-62, illus. 1).—It is experimentally shown that maximum egg production is realized when single pairs are confined in relatively small volumes of peas; as the number of pairs increased there was a steady decline for each additional pair. Sexual contact appeared definitely to be the chief biotic factor responsible for the drop in egg production of the more crowded cultures. The normal laying behavior insures a distribution of eggs over numerous peas—a condition favorable to larval feeding. Crowded cultures prevent the freedom required by the ♀♀ for this behavior in that they are continually aggravated by moving beetles or by soliciting ♂♂. When peas become overinfested with eggs, the feeding larvae later crowd one another from their excavations before feeding is completed and maturity reached; these fail to pupate and mature. A priori reasoning would lead to the conclusion that for a given volume of peas there must be an optimum population number which is large enough to insure sufficient sexual contacts between beetles for maximum egg production yet not great enough to overstock the peas with eggs and larvae.

Japanese beetle abundance and injury on sweet corn, L. A. CARRUTH, L. M. BARTLETT, and J. A. ADAMS (*New York State Sta. Bul.* 715 (1946), pp. 16, illus. 3).—Since 1943 beetle populations on western Long Island have declined steadily because of drought during 1943 and 1944 and the increased activity

of natural enemies, particularly *Tiphia* parasites and the bacterium causing milky disease. The heaviest infestations of beetle abundance during the summer period were on the silks, and the heaviest infestations on the silks were found to occur approximately 1 week after the first appearance of the silks. Beetle populations occurring a week after silking apparently had little effect on ear pollination, although later beetle feeding is probably more important for the direct injury produced and for secondary injuries from birds, corn smut, and other causes. It was observed that within the same cornfield beetle populations were lighter in the center than at the edges, particularly when the latter adjoined hedgerows and grassy areas. Studies on the factors influencing beetle abundance and spread suggest that no severe general damage may again be expected in Nassau County, but cornfields near Suffolk, Rockland, Westchester, and Putnam counties may be menaced for several years. Plantings of corn in the vicinity of the larger cities along the Hudson River in Orange, Ulster, Dutchess, and southern Columbia counties may be affected. In the southern two-thirds of the State the authors believe that infestations with the Japanese beetle are likely, but hope that serious damage may be minimized through distribution of parasites and spores causing milky disease.

Progress report of pest control, W. J. O'NEILL. (Wash. Expt. Sta.). (*Wash. State Hort. Assoc. Proc.*, 41 (1945), pp. 27-33).—Research with DDT for controlling fruit insect pests has been intensive during the past 2 yr.; the author briefly summarizes the findings in Washington State and elsewhere, with discussion.

Experiences with DDT for codling moth in western New York, S. W. HARMAN. (N. Y. State Expt. Sta.). (*Farm Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 1-3).—A discussion of DDT for codling moth control under western New York conditions with observations on the residue question and possible disadvantages of this material. Studies indicate that DDT is probably the most effective insecticide used against codling moth, although some failures have resulted because of poor timing and inefficient spraying. The author also considers that, because of the limited knowledge of DDT and the possibility of secondary problems resulting from its use, the application of DDT is still in the experimental stage. Nevertheless, for fruit growers who have failed to handle their codling moth problem with lead arsenate there appear to be legitimate reasons for using DDT.

Valeur insecticide des huiles végétales dans la lutte contre le pou de San José (*Quadraspidiotus perniciosus* Comst.). [The insecticidal value of vegetable oils for control of San Jose scale], G. VIEL (*Compt. Rend. Acad. Sci. [Paris]*, 221 (1945), No. 20, pp. 589-590).—Peanut oil proved more active than any of the other plant oils tested, viz, bigseed falseflax, rape (cameline, navette), cottonseed, linseed, and grape seed. It was inferior to refined white petroleum oil, but its effectiveness in a 2.8 percent emulsion was above that of a 1.6 percent mineral oil emulsion. Because of the extraordinary fecundity of the San Jose scale, a satisfactory insecticide must have an effectiveness of over 97 percent kill; peanut oil is said to give emulsions which at 3.5 to 4 percent of oil satisfy this condition. The other oils—even at high enough concentrations to injure the plant—possessed insufficient insecticidal properties.

Further data on the value of hand control of the tent caterpillar *Malacosoma americana* Fabr. (Lepidoptera: Lasiocampidae), H. L. SWEETMAN. (Mass. State Col.). (*Canad. Ent.*, 77 (1945), No. 11, pp. 202-203).—Destruction of this pest just as the colonies are becoming established in tents was found to be accomplished with minimum effort by the mechanical method

described; little feeding has occurred at this stage. The present 10-yr. findings fully corroborate those reported earlier.<sup>4</sup> Application of an insecticide before the eggs hatch or on the newly formed tents would cost more in time and money than the crushing method used; this procedure—with the limitations noted in the earlier paper—is strongly recommended.

The cherry fruitfly problem in eastern Washington, P. M. EIDE. (Wash. Expt. Sta.). (*Wash. State Hort. Assoc. Proc.*, 41 (1945), pp. 55-61).—The life history and description of the cherry fruitfly are briefly presented. The pest is reported to have been common in lower Yakima Valley commercial orchards during 1945. In experimental tests, DDT had practically no effect on it and cryolite gave very poor control; rotenone gave a definite reduction in wormy fruits but without satisfactory control; xanthone gave results about like lead arsenate; phenothiazine was believed to act as a repellent, and how it might perform on an entire orchard is problematical. Clean picking of the fruit is advised, and a spray program based on current findings is presented.

Pear psylla control in 1945, L. G. DAVIS. (U. S. D. A.). (*Wash. State Hort. Assoc. Proc.*, 41 (1945), pp. 143-149).—A survey of pear psylla control in commercial orchards of the Pacific Northwest in 1945, with a brief outline of the control program.

Some possible uses for DDT on soft fruits, E. J. NEWCOMER. (U. S. D. A.). (*Wash. State Hort. Assoc. Proc.*, 41 (1945), pp. 51-53).—A brief review of possible uses of DDT against the insect pests of soft fruits; no recommendations for this purpose can as yet be made.

Characters, distribution, and food plants of phlepsid leafhopper vectors of California aster-yellows virus, D. M. DELONG and H. H. P. SEVERIN (*Hilgardia* [California Sta.], 17 (1945), No. 1, pp. 1-20, illus. 6).—This paper deals with the characters, distribution, habitat, and food plants of six species of phlepsid leafhopper vectors. The general distribution, habitat, and food plants, and a key for identification of the six species are given, followed by information on *Phlepsius apertinus* Osborn and Lathrop, *Texananus lathropi* Baker, *T. pergradus* DeLong, *T. spatulatus* Van Duzee, *T. oregonus* Ball, and *T. latipex* DeLong. Plates showing details of the six species are given, as well as a list of the more important references.

Evidence of nonspecific transmission of California aster-yellows virus by leafhoppers, H. H. P. SEVERIN (*Hilgardia* [California Sta.], 17 (1945), No. 1, pp. 21-59, illus. 3).—These studies showed that six new vectors carry the California aster yellows virus, which proves that the virus is not transmitted by a specific leafhopper. Infections produced by 150 males and 150 females of *Texananus lathropi* Baker, each kept singly on a healthy celery plant, were 18.7 and 16.0 percent, respectively, and by 100 males and 100 females of *T. latipex* DeLong were 18.0 and 32 percent, respectively. It was observed that lower percentages of infections occurred with asters than with celery, and with one exception lower percentages of asters were infected in daily than in weekly transfers. A higher percentage of infection in celery with lots of 5, 10, and 20 adults indicated that the number of leafhoppers plays a role in virus transmission. With *T. lathropi* the minimum latent period of the virus in the males and females was 7 and 8 days, respectively, whereas with *T. latipex* with one lot of 80 males it was 8 days. The maximum latent period in *T. lathropi* was 33 days compared with 37 days in *T. latipex*. Life history observations were made covering the egg periods, egg-laying capacity, and duration of the nymphal instars.

<sup>4</sup> Canad. Ent., 72 (1910), No. 12, pp. 245-250.

The aster yellows virus was not transmitted by the first nymphal instar of *Tetananus spatulatus* Van Duzee, but all other nymphal instars transmitted the virus. Thirty-four percent of the celery was infected by single males and 29 percent by single females, whereas lots of 5 males transmitted the virus to 88 percent and lots of 5 females to 72 percent of the first set of celery and to 40 and 50 percent of the second set, respectively. With this species the latent period of the virus in the adults was 6 to 42 days. One male retained the virus for 84 days, and one female 99 days. In most instances adults caused one infection and then apparently lost the infective dose.

Attempts to transmit curly-top virus by means of *T. spatulatus* failed, as did attempts to transmit Pierce's disease of grapevines and alfalfa dwarf to healthy grapevine seedlings and alfalfa. Males and females of *T. oregonus* Ball tested singly on healthy celery infected 5 of 14 plants and 11 of 22 plants, respectively. With *T. pergradus* DeLong there was no infection when 100 males and females were kept singly on healthy celery, but 1 aster was infected by 1 of 50 males. Twelve lots of 10, 25 lots of 20, and 5 lots of 40 males produced 1, 5, and 1 infection. In the case of *Phlepsius apertinus* Osborn and Lathrop, 13 males and 12 females infected 7 of 13 and 8 of 14 celery plants, respectively. Lots of 2 to 30 adults produced 14 infections.

The lily weevil, a potentially serious pest in the Pacific Northwest, C. F. DOUCETTE and R. LATTA (*U. S. Dept. Agr. Cir. 746 (1946), pp. 24, illus. 18*).—The lily weevil is considered a potential pest of Easter lilies in the Pacific Northwest, since adults feed on the leaves of lilies of many species and larvae feed in the stems and bulbs. The weevil occurs along the Pacific coast from Vancouver Island, British Columbia, to the northern part of California. Females deposit eggs by inserting them in the epidermis of the lower leaves of the host plant during May. Hatching occurs 15-20 days later. Larvae attack the underground portions of the plants, stems, or bulbs, and become mature in September. At this time they leave the stems or bulbs and form cells 10-15 in. below the surface of the soil. The larvae remain more or less inactive in these soils until transforming to pupae the following summer and changing to adults late in the summer but the adults remain in the soils until the following spring; thus a life cycle covers 2 yr. Plantings of lilies which are close to brushy areas where native host plants of this weevil are present are likely to suffer serious injury. During the period of time between adult appearance and the beginning of egg deposition the adults feed on the lily foliage. This permits efficient use of stomach poisons for control, and lead arsenate (2 lb. to 50 gal. of water plus sticker) has been found effective.

Report on the survey of the insects and pests attacking the Bermuda cedar, R. L. PARKER. (Kans. State Col.). ([Hamilton]: *Bermuda Bd. Agr.*, (1945), pp. 5+).

New descriptions of larvae of forest insects: *Nyctobia*, *Eufidonia* (Lepidoptera: Geometridae), W. C. MCGUFFIN (*Canad. Ent.*, 77 (1945), No. 11, pp. 197-199, illus. 2).—Among the several species of green loopers found on Canadian conifers in July are two which to the naked eye appear somewhat similar. Larvae of these two—*N. limitaria* Wlk. and *E. notataria* Wlk.—are described along with that of the other Nearctic species, *E. discospilata* Wlk., which is a health-plant feeder.

Entomology in western pine silviculture, F. P. KEEN. (U. S. D. A.) (*Pan-Pacific Ent.*, 22 (1946), No. 1, pp. 1-8).—The presidential address read before the Pacific Coast Entomological Society, January 12, 1946.

**A revision of the family Acaridae (Tyroglyphidae), order Acari, based on comparative morphological studies.**—I, Historical, morphological, and general taxonomic studies, H. H. J. NESBITT (*Canad. Jour. Res.*, 23 (1945), No. 6, Sect. D, pp. 139–188, illus. 55).—The author's purpose is to lay the basis for some serious work on comparative acarology; for this purpose the restricted group Acaridae was selected, and the results of a detailed morphological study based on about 40 species representative of the various genera are presented. The classifications of other workers are briefly reviewed and evaluated in the light of the author's findings, a discussion of the composition and interrelationships of the various genera and higher groups is given, and a synopsis of the tribes and genera of the family—based on characters believed to be of phylogenetic significance—is included. The extent of damage caused by these mites to grain and farinaceous products in storage has warranted a thorough investigation of the habits and systematic position of these economic pests.

**Life history and habits of the flat grain beetle (*Laemophloeus minutus* Oliv.),** N. M. PAYNE (*Jour. N. Y. Ent. Soc.*, 54 (1946), No. 1, pp. 9–12).—This beetle was reared on whole-wheat flour or shorts as well as on siftings from weevil cultures; it may live as a scavenger but can also live on sound material. At 78° F. and humidity near saturation, the duration of the immature stages was 46 to 57 days; adults lived for 6 mo. to 1 yr.

**A new species of nitidulid beetle,** L. G. GILLOGLY (*Pan-Pacific Ent.*, 22 (1946), No. 1, pp. 22–24, illus. 1).—Dried fruit beetles are said to be of considerable importance in the processing and storing of certain California agricultural products; those most often found in drying or rotting fruit are those of the genera *Carpophilus* and *Haptoncus*. Until recently only one species of the latter (*H. luteolus* (Erich.)) was known to the State fauna. *H. californicus* n. sp. is here described and illustrated.

**The influence of certain biological factors on the resistance of bed-bugs (*Cimex lectularius* L.) to DDT,** S. BARNES (*Bul. Ent. Res.*, 36 (1946), No. 4, pp. 419–422).—Adult bedbugs proved more resistant to DDT than nymphs; among nymphs, resistance increased with each successive instar. No difference in resistance was revealed among recently fed young ♂♂ and ♀♀; that of adult ♂♂ after 10 to 20 days' starvation was greater than for ♀♀—either gravid or virgin—starved for a similar period, but during the first 7 days' starvation virgin ♀♀ were more resistant than the gravid ones. The resistance of ♂♂ and gravid and virgin ♀♀ was lower at 24 hr. after feeding than after starvation for 5 and 3 days, respectively. Individuals kept at 30° C. were less resistant than those kept at 23° and 25°. DDT was not ovicidal, but the percentage of nymphs surviving from the sprayed eggs was small.

**Methyl bromide as a delousing agent,** R. LATTA, H. H. RICHARDSON, and J. B. KINDLER (*S. S. Dept. Agr. Cir.* 745 (1946), pp. 40, illus. 26).—The three methods of application of methyl bromide developed for control of body louse eggs were vault fumigation, individual bag fumigation, and pit fumigation. A demountable vault was devised and tests with this unit suggested a dosage of 9 lb. of methyl bromide per 1,000 cu. ft. of space at temperatures lower than 60°. Individual gastight fumigation bags about 25 in. wide and 50 in. long with self-contained closures were developed. Methyl bromide ampoules were broken inside the sealed bag, and the standard dosage suggested was 20 cc. per bag. Pit fumigation tests showed dosages comparable to those used in other methods to be effective, and best results were obtained with pits having small openings and covers made of gastight materials. Methyl bromide could be rapidly removed from clothing by aeration. This material

has been utilized by the armed forces in the field, at permanent delousing stations, and at ports of debarkation.

**Fly and insect control with DDT,** H. H. SCHWARDT. (Cornell Univ.). (*Milk Dealer*, 35 (1946), No. 7, pp. 114, 116-117).—A brief summary of tests in New York State dairy barns, using wettable sulfurs, kerosene solution, xylene emulsion, and DDT, along with "helpful hints" based on recent information with respect to DDT—its properties and toxicity—and a note on sprays in milk plants.

**Concentrated sprays tested for utility in control of flies and mosquitoes,** H. O. SCHROEDER, A. H. MADDEN, A. W. LINDQUIST, and H. A. JONES. (U. S. D. A.). (*Soap and Sanit. Chem.*, 22 (1946), No. 4, pp. 145, 147, 153).—The authors report on experiments in a 340,000-cu. ft. room, using finely atomized concentrated DDT sprays and an aerosol against the common malaria mosquito and the housefly; exposures were made in stationary and swinging screen cages at heights of 8 to 35 ft. and at the center, sides, and corners of the room. Dosages of 285 to 310 cc. of concentrated sprays containing 10 percent of DDT proved at least as good as 280 gm. of an aerosol containing the same DDT concentration. Best results followed application of 310 cc. of 10 percent DDT plus 20 percent of *o*-dichlorobenzene discharged over an electric fan. The findings show that use of a concentrated spray offers promise as a means of controlling mosquitoes in factories. Suggestions for practical application are presented.

[Papers on mosquitoes and their control] (*Mosquito News*, 6 (1946), No. 1, pp. 1-6, 12-16, 25-33, 38, illus. 2).—The following are included: Facts and Fallacies About DDT (pp. 1-6), Mosquitoes and Other Insects Killed by Aerial Spraying With DDT in Panama (pp. 12-13), and The Use of DDT Residual Sprays in Native Mexican Homes for Controlling *Anopheles pseudopunctipennis* Mosquitoes (p. 38), all by H. H. Stage, and DDT Applied With Hand Equipment for the Control of Salt-Marsh Mosquito Larvae, by C. B. Wisecup (pp. 14-16) (all U. S. D. A.); Effectiveness of DDT as a Residual Treatment of Bed Nets, by B. V. Travis (pp. 25-26); Bigger and Better Spraying Units, by L. E. Yettaw (pp. 27-29); Composition of DDT Products, by J. M. Ginsburg (pp. 29-31) (N. J. Expt. Stas.); and The Occurrence of *Anopheles quadrimaculatus*, *Anopheles occidentalis*, and *Anopheles walkeri* in Vermont, by R. C. Barnes (pp. 32-33).

**Aedes tortilis** (Theobald), a mosquito new to the United States, A. E. STAEBLER and W. F. BUREN (*Pub. Health Rpts.* [U. S.], 61 (1946), No. 19, p. 685).—This mosquito—taken at Key West, Fla.—occurs in the Bahamas, Virgin Islands, and the Greater Antilles; it is believed possible that it may have been recently introduced by aircraft.

The larva and pupa of *Uranotaenia bimaculata* Leicester on Okinawa Shima, Ryukyu Retto (Diptera: Culicidae), L. ROTH. (Ohio State Univ.). (*Ent. Soc. Wash. Proc.*, 48 (1946), No. 3, pp. 67-75, illus. 2).—A descriptive and taxonomic study of this species of mosquito.

Guide to the insects of Connecticut.—VI, The Diptera or true flies of Connecticut—second fascicle: Family Culicidae, the mosquitoes, R. MATHE-SON. (Cornell Univ.). (*Conn. State Geol. and Nat. Hist. Survey Bul.* 68 (1945), pp. 48+, illus. 28). This second fascicle on the Diptera of Connecticut (E. S. R., 90, p. 217) considers the mosquitoes of the State, including mosquito-borne diseases and the war, bibliographical references, the structure of mosquitoes, a key to the subfamilies, tribes, and genera, and detailed treatment of the genera and species under the subfamilies Chaoborinae and Culicinae (tribes Anophelini and Culicini). An index to the species is provided.

Keys to the larval and adult mosquitoes of *Espiritu Santo* (New Hebrides) with notes on their bionomics, W. J. PERRY (*Pan-Pacific Ent.*, 22 (1946), No. 1, pp. 9-18).

The mosquitoes of the Kaimosi Forest, Kenya Colony, with special reference to yellow fever, P. C. C. GARNHAM, J. O. HARPER, and R. B. HIGHTON (*Bul. Ent. Res.*, 36 (1946), No. 4, pp. 473-496, illus. 9).—The danger of establishing yellow fever in certain forests of this region is pointed out; two recognized cases have been reported in recent years. The Kaimosi Forest was selected as a suitable area for study, and its general environal conditions are described. A mosquito survey was carried out over a 2-yr. period, particular attention being paid to the preference of certain species for life in the treetops. Five species were found to breed in high tree holes; four were found biting in the treetops, two of these being rare in ground catches. Detailed points of interest are presented with respect to individual species. Probably at least two trees per acre had rot holes with larvae, and about 14 percent of the *Dracaena* plants were found infested; holes in shaded granite boulders were another common source of sylvan mosquitoes. Surveys of adjacent forest areas at different altitudes revealed striking changes in the mosquito fauna. A study of lists of mammals, trees, and mosquitoes indicated that the relict forest of Kaimosi contains numerous "western" species which are not elsewhere found so far to the east. Though yellow fever is absent from this forest area, it was found suitable from every standpoint for the establishment of jungle fever, and possible measures of control are briefly suggested. Brief reference is made to other infections. Short descriptions of new species, etc., of mosquitoes are given in an appendix. There are 21 references.

Moonlight and house-haunting habits of female anophelines in West Africa, C. R. RIBBANDS (*Bul. Ent. Res.*, 36 (1946), No. 4, pp. 395-417, illus. 3).—In the huts in which they had been fed, 97 percent of the ♀♀ of *Anopheles gambiae*, *A. funestus*, and *A. melas* remained until after dawn; the last species seldom left suitable huts in the daytime. There was a high positive correlation between the time at which ♀ *A. funestus* entered huts and the time of moonlight. During moonless periods, the fighting of the ♀♀ was partially inhibited; when the moon came out the waiting mosquitoes entered the huts in greatest numbers. On moonless nights many mosquitoes waited until twilight of the following evening before entering the huts; consequently the average proportion caught in the period ending at 8 p. m. was six times greater on moonless nights than on the nights after full moon. The records for *A. melas* were less complete, and the correlation coefficient for the relation between time of entry and time of moonlight was barely significant; in view of the high significant correlations found for *A. funestus*, however, it is believed unlikely that this one is fortuitous. The essential difference between the behavior of ♀ *A. funestus* and that of *A. gambiae* is that the former flight earlier than the latter. Of the anophelines caught at 8 p. m., 58 percent were unfed, indicating that early entrants usually rest before feeding, and that average times of biting are later than average times of entry. Gravid or half-gravid mosquitoes and those containing partly digested blood failed to enter the huts. There was evidence that anophelines usually become fully gorged at one feeding; of those caught in the huts after dawn, 95 percent were fully fed.

Japanese B encephalitis virus in the blood of experimentally inoculated chickens, W. M. HAMMON, W. C. REEVES, and R. BURROUGHS. (Univ. Calif.). (*Soc. Expt. Biol. and Med. Proc.*, 61 (1946), No. 3, pp. 304-308).—

As a result of inoculating Japanese B encephalitis virus into chickens, the virus was frequently detected in the serum 24 hr. to 7 days later; it was also demonstrated that following the bite of four infected mosquitoes infection occurred in the one chicken used. Though these experiments do not conclusively prove that chickens may be a source of Japanese B virus infection for mosquitoes, they do indicate such a possibility. It is believed that chickens and other birds should be considered as potential sources of mosquito infection and that they deserve further study with recently isolated strains of the virus.

Chlorine as a possible ovicide for *Aedes aegypti* eggs, S. P. HATCHETT (*Pub. Health Rpts. [U. S.], 61 (1946), No. 19, pp. 683-685*).—From the data presented, it appears that newly prepared solutions of calcium hypochlorite containing 50 to 100 p. p. m. of available Cl are effective ovicides for both continuously wet and previously dried eggs of the yellow fever mosquito. Although water thus treated would be unsuitable for drinking, this procedure might have useful application for fire-protection containers, water stored in barrels to prevent shrinkage, and similar cases where water is stored for purposes other than drinking. It might also be used before dumping and replacing potable water in barrels breeding mosquitoes, to induce the eggs on the sides of the containers to hatch and then be destroyed.

Outdoor control of adult mosquitoes with DDT or pyrethrum applied with ground equipment, A. H. MADDEN, A. W. LINDQUIST, B. V. TRAVIS, and E. F. KNIPLING. (U. S. D. A.). (*Mosquito News, 6 (1946), No. 1, pp. 7-11*).—Dusts applied at rates of 0.035 to 4 lb. of DDT per acre gave good control of the adult salt marsh mosquitoes *Aedes taeniorhynchus* (Wied.) and *A. sollicitans* (Walk.), but for practical use are considered less satisfactory than sprays. Sprays applied at 0.025 lb. per acre gave nearly complete reduction of mosquitoes when atomized properly and applied in 20-ft. swaths. Similar results were obtained with sprays containing 0.75 percent pyrethrins applied at the rate of 0.004 lb. per acre. Heavy power equipment did not appear sufficiently better to warrant its use in jungle areas. The contents of a standard 1-lb. aerosol container held 8 in. from the ground and applied in the same way as dusts and sprays proved able to give 91 to 100 percent control over an acre of jungle; the aerosol was also effective against *Mansonia* spp. and *Anopheles albimanus* Wied. in Panama. DDT and pyrethrum aerosols were about equally effective. Large amounts of aerosol discharged at one point and drifted downward gave conflicting results in open areas.

Tests on the airplane application of DDT for the control of adult mosquitoes in open, unwooded areas, C. B. WISECUP, W. C. BROTHERS, and P. M. EIDE. (U. S. D. A.). (*Mosquito News, 6 (1946), No. 1, pp. 20-24*).—Large-scale tests of the effectiveness of DDT in controlling adult *Anopheles* and *Psorophora* mosquitoes were conducted during May 5–September 4, 1944, in the rice fields and pasture lands in Arkansas; 14 tests, involving over 450 acres, and using liaison-type airplanes, indicated that the abundance of *Psorophora* adults was reduced by at least 90 percent when rice fields were sprayed with 0.1 lb. or more of high-grade commercial DDT in aqueous emulsion per acre. Six-area control tests on pastures and waste lands in large open non-breeding areas indicated that technics for determining adult mosquito populations should be improved; treatments with either fuel oil or aqueous emulsion containing DDT at dosages of 0.2 to 1.0 lb. per acre are of doubtful effectiveness against adults of the malaria mosquito; light-trap collection of adult *Psorophora* spp. showed no marked differences between treated and untreated areas; landing-rate counts of *Psorophora* spp. showed marked reduction of daytime

annoyance from these mosquitoes in the treated areas; and apparently there is an extensive nighttime activity of adult mosquitoes of both *Psorophora* spp. and the malaria mosquito under conditions of open, unwooded terrain, with a heavy breeding pressure from surrounding rice fields. Under such conditions light traps and catching stations are unsuitable for evaluating differences in populations unless very large areas are to be treated.

Notes on the gapeworms (Nematoda: Syngamidae) of galliform and passeriform birds in New York State, F. C. GOBLE and H. L. KUTZ (*Jour. Parasitol.*, 31 (1945), No. 6, pp. 394-400).—The authors record and discuss in the light of the literature (30 references) their observations on gapeworm (*Syngamus trachea*) infestations in ruffed grouse, ring-necked pheasant, eastern crow, eastern robin, eastern meadowlark, and bronzed grackle.

Six new mites of the superfamily Parasitoidea, H. L. KEEGAN (*Amer. Micros. Soc. Trans.*, 65 (1946), No. 1, pp. 69-77, illus. 21).—The mites here described are *Liponyssus geomydis* n. sp. from the pocket gopher (*Geomys bursarius*); *Haemolaelaps scalopi* n. sp. from the mole (*Scalopus aquaticus*); *Euhaemogamasus sciuropteri* n. sp. from a squirrel (*Sciurus* sp.); *Entonyssus fragilis* n. sp. from the king snake (*Lampropeltis g. getulus*); *Pachyseius insculpta* n. sp. from the tipulid *Symplecta cana* (Walk.); and *Pachylaelaps ornata* n. sp., host unknown.

A new mite, *Laelaps aplodontiae*, from Aplodontia, W. L. JELLISON (*Jour. Parasitol.*, 31 (1945), No. 6, pp. 373-374, illus. 1).—Several collections of mites from the mountain beaver (*Aplodontia rufa*) were found to represent the new species here described.

New use for DDT, E. T. KREBS, JR. (*Science*, 103 (1946), No. 2676, pp. 459-460).—"Scab mites" (*Psoroptes cuniculi*) on laboratory rabbits were effectively controlled by applying a 5-percent solution of DDT by an ordinary nebulizer to the inner surface of the ear.

Population studies on *Cochliomyia americana* in Arizona, C. C. DEONIER (U. S. D. A.). (*Jour. Kans. Ent. Soc.*, 19 (1946), No. 1, pp. 26-29).—Adults of the screwworm were found uniformly distributed over relatively small areas only under uniform ecological conditions. Extremely high temperatures were not a limiting factor in the development of these insects under favorable moisture relations. The presence of a larger fly population in the immediate surroundings of the host material was indicated. During hot dry weather the flies in the range sections were restricted to the vicinity of streams and mesquite draws, where moisture and shade were available. Some shifting of populations to favorable areas was observed.

The life of the queen bee, L. SUTHERLAND (*New York; Beechhurst Press*, 1946, pp. 126, illus. 24).—This volume considers in popular language the birth of the queen bee, the young queen, the worker bee, the drones, the nuptial flight, the bee and the flower, a worker bee afield, the reigning queen, working together in the hive, the queen in swarming, the massacre of the drones, the closing days of the queen, swarming—and the death of the queen, other ways of queens, beekeeping as a hobby, and the ancients and bees and includes a chapter entitled "odds and oddities."

Sur la sécrétion cérière de l'abeille [The secretion of wax by bees], R. MOREAUX (*Compt. Rend. Acad. Sci. [Paris]*, 221 (1945), No. 20, pp. 590-592).

Feeding bees for comb production, W. WHITCOMB, JR. (U. S. D. A. coop. La. State Univ.). (*Gleanings Bee Cult.*, 74 (1946), No. 4, pp. 198-202, 247, illus. 3).—A method was devised by which colonies were fed honey continuously and frames with full sheets of foundation given at regular intervals.

In this way it was found that excellent combs partially drawn and firmly fixed to the wooden frame could be produced for 19 ct. each. During the test period—July 14–September 22, 1943—488 combs were drawn from foundation by feeding 772.5 lb. of low-grade honey or 1.58 lb. of honey for each comb produced. The average amount of wax added to each foundation was 0.188 lb.; for the four colonies the cumulative ratio of wax produced to honey consumed was 1 : 8.4. The quality of these combs was superior to those drawn by colonies during a normal flow. Although no reason for it was apparent, the efficiency of colonies in wax production increased as the test continued. In areas where it is difficult to produce good-quality combs during slow honey flows—as in many sections of the South—this method should merit attention.

On directing the flight of bees, R. G. SCHMIEDER (*Ent. News*, 57 (1946), No. 1, pp. 16–19).—A note and brief review on methods for directing the flight of bees to the flowers of particular plant species.

Some bee plants of Utah, G. H. VANSELL. (Coop. U. S. D. A.). (*Farm and Home Sci. [Utah Sta.]*, 7 (1946), No. 1, pp. 6–7, illus. 4).—Lists are presented of the 12 plants considered as major sources of honey in the Western States and of 23 species serving as minor sources of honey or pollen. Alfalfa, the leading honey plant of Utah, is grown extensively for hay and for seed production; comments are made on several other honey sources.

A dry feeder for supplying a pollen substitute to bees, W. E. DUNHAM (*Ohio Sta. Bimo. Bul.* 239 (1946), pp. 41–43, illus. 3).—Considerable interest has been shown in the dry-feeding method for supplying a pollen substitute to bees. This brief paper discusses the advantages and disadvantages of the method, factors to consider in using it, and the preparation of the pollen substitute.

Honeybees as pollinators in the production of hybrid cucumber seed, S. W. EDGECOMB (*Amer. Bee Jour.*, 86 (1946), No. 4, p. 147).—Promising results are reported for two experiments (Iowa and Pennsylvania, 1945). Yet to be clarified are the largest number of “♀” rows that may be used to one “♂” row, the optimum time to deflorate the “♀” parent, and provision for a sufficient number of ♂ flowers on the “♂” variety to insure adequate pollen for the ♀ flowers on the “♀” variety.

A simple field test for American foulbrood, E. C. HOLST. (U. S. D. A.). (*Amer. Bee Jour.*, 86 (1946), No. 1, pp. 14, 34; also in *Bee World*, 27 (1946), No. 2, pp. 13–14).—The test is based on an enzyme produced by *Bacillus larvae* which causes the liquefaction of milk casein or curd from either re-constituted or skim milk.

## ANIMAL PRODUCTION

The loss of nutrients in hay and meadow crop silage during storage, C. F. MONROE, J. H. HILTON, R. E. HODGSON, W. A. KING, and W. E. KRAUSS. (Ohio Expt. Sta., N. C. State Col., Purdue Univ., and U. S. D. A.). (*Jour. Dairy Sci.*, 29 (1946), No. 4, pp. 239–256).—From findings gathered from nearly 100 publications concerning the preservation of meadow crops as hay and as silage, the authors conclude that “well-cured” long hay, defined as that containing less than 30 percent of moisture, undergoes a storage loss of dry-matter content of from 3.5 to 9 percent; more than this in some instances. Loss of the nitrogen-free extract components was found greatest, but a loss of the ether-extract components was also indicated. From hay browned or blackened by heating due to storage at a moisture content exceeding 30 percent, losses were found to range as high as from 15 to 40 percent. Such

heating lowered the digestibility of hays, especially that of their protein content, and increased carotene losses. Some browned hays were found palatable, but the heated hays had usually lost palatability. Heating due to a given moisture content was greater in chopped than in long hay. It is held that chopped hay should contain less than 25 percent of moisture, as should hay for field baling. Salting was found not to prevent excessive heating of undercured forage. Artificially dried hay was found to suffer in storage practically negligible losses of dry matter and nutrients other than carotene. Forced ventilation mow-drying, either with or without artificial heat, usually produced hay of good quality and high feeding value. It is considered, however, that more work on the nutrient value palatability of mow-cured hay is needed. Well-cured long hay may have only one-fourth of the original carotene value after 300 days in the mow, and the carotene value may be entirely lost from heated hay.

From silage the percentage lost by top spoilage, estimated generally as from 3 to 6 percent, may be a greater proportion of the original material because of the loss of organic matter through decay and the drying out of the material. Dry-matter losses by seepage from the silo, though varying with silo size and original moisture content, are considered to be usually less than 1 percent from forage containing initially 70 percent or less of moisture. Fermentation losses per se are stated as from 5 to 10 percent. Feed analyses were found similar to those of the forage ensiled, and digestibility also similar except when lowered by heating. Some of the work cited showed a carotene retention of from 60 to 90 percent of that of the forage ensiled, but other investigations gave lower figures. Mineral acid treatment generally gave a high percentage of carotene preservation, the lowest percentages resulting from no treatment or wilting. A high silage carotene content gave high milk carotene content. The "grass-juice factor" promoting growth was found in grass silage, especially in that preserved with soured whey or with phosphoric acid. It is noted that proper moisture evaluation and control are needed for minimizing the losses in storing forages as hay and silages.

Production and utilization of silage in Mississippi, H. W. BENNETT, R. H. MEANS, W. C. COWSERT, O. A. LEONARD, and M. GIEGER. (*Mississippi Sta. Bul.* 425 (1945), pp. 23).—An extensive discussion of silage production problems with emphasis on the sorghums, Johnson grass, sweetpotatoes and sweetpotato vines, and various legumes. Data are presented on the influence of additions of molasses, phosphoric acid, and urea to ensiled material on composition and nutritive value. Methods of utilizing various silages and their relative worth for wintering beef cows and finishing steers for market and for the dairy herd also are discussed.

The nutritive value of the protein in tobacco-seed oilmeal, K. E. RAPP, J. T. SKINNER, and J. S. MCHARGUE. (Ky. Expt. Sta.). (*Jour. Nutr.*, 31 (1946), No. 3, pp. 261-271, illus. 3).—When a cold-pressed tobacco-seed oil meal containing about 30 percent crude protein and 21 percent oil was fed to rats at levels of 15 to 18 percent protein, only slow growth followed. The oil meal was proved to be deficient in lysine, but when supplemented with casein, lactalbumin, skim milk powder, or lysine, good growth was obtained. Rolled oats, corn meal, and gelatin were less satisfactory supplements to the oil meal protein. Addition of wheat gluten was no more effective than increasing the proportion of tobacco-seed oil meal so as to equalize the protein content of the two rations.

The biological values of the protein of tobacco-seed oil meal and skim milk powder when fed at a level of 10 percent were 51.4 and 78.5, respectively.

Values for true digestibility of the two in the order named were 78.0 and 96.6. The biological value of the oil meal protein when supplemented with lysine was approximately that of milk proteins. "Because of its relatively high net protein value, tobacco seed oil meal deserves consideration as a source of dietary protein."

The nutritive value of tobacco-seed oil, K. E. RAPP, J. T. SKINNER, and J. S. MCHARGUE. (Ky. Expt. Sta.). (*Jour. Nutr.*, 31 (1946), No. 3, pp. 273-282, illus. 2).—Tobacco-seed oil from *Nicotiana tabacum* was analyzed and found to be free from nicotine and nornicotine. Both temperature and surface area affected its rate of oxidation. No particular care was necessary in storing the isolated oil, but when incorporated in a ration and stored for some time refrigeration was essential.

When tobacco-seed oil was fed to rats at levels of 5, 15, and 30 percent of the respective rations, it gave an average coefficient of digestibility of 97.9 as compared with 99.1 and 98.2 for cottonseed oil and butterfat, respectively. With paired feeding of refrigerated rations containing 30 percent of tobacco-seed oil and butterfat, respectively, growth rates of rats did not differ significantly. When fed ad libitum, the difference in consumption of the two rations produced a greater rate of growth in rats fed butterfat. Of six rats fed a refrigerated ration and four animals fed a nonrefrigerated ration containing 30 percent tobacco-seed oil during the 5-week period when growth is usually maximum, all proved to be fertile upon reaching maturity.

La pulpa de cafe como alimento del ganado [Coffee pulp as a feed for livestock], F. CHOussy (*San Salvador: Inst. Tecnol. de El Salvador, 1945*, pp. 16, illus. 1).—Based on observations that coffee pulp is relatively rich in protein and that cows in a farm herd receiving rations high in dry coffee pulp showed no ill effects from the presence of caffeine or tannins, the Technological Institute of El Salvador conducted preliminary tests on the preparation of silage from coffee pulp and the value of such silage for milking cows. A palatable, so-called sweet type of silage resulted from adding 1 to 1½ m. of the wet pulp to the silo at a time, with 24- to 36-hr. intervals between successive additions and by providing an outlet for drainage of excess water from the mass. Such silage was palatable to milking cows and definitely improved the nutritive value of the imperfectly balanced basal ration. It is concluded that coffee pulp silage may prove to be a desirable feed which will aid in solving the difficult problem of supplying high quality animal feed in the area.

The physiology of digestion in the ruminant, A. T. PHILLIPSON (*Vet. Rec.*, 58 (1946), No. 3, pp. 81-87).—This address and accompanying discussion reviews recent literature on the subject.

The relation of the route of administration of thyroxine, thyroprotein, and intermediate products upon their utilization by ruminants, C. W. TURNER and E. P. REINEKE (*Missouri Sta. Res. Bul. 397 (1946)*, pp. 20, illus. 1).—Measuring the effect of the route of administration of thyroxine, thyroprotein, and intermediate products upon their utilization by sheep by determining the decline in body weight of the assay animals during a 2-week period, it was found that the subcutaneous administration of a sample of thyroprotein was 20 times as effective as the same sample when fed. Similarly, *d,l*-thyroxine administered orally was only about one-eighth as effective as that administered subcutaneously. The administration of thyroprotein orally in dry form in a capsule was about twice as effective as when the same preparation was suspended in a slightly alkaline or in a phosphate buffer solution and given as a drench. Coating the thyroprotein particles by stearic acid, paraffin, bees-

wax, rosin, clarite, vinylite, and linseed oil in every case reduced the biological effect. Other tests indicated that the low oral biological value of thyroprotein was not due to destruction in the rumen. Acid hydrolysates of thyroprotein given as a drench gave increased biological responses when administered by mouth or directly into the abomasum. However, hydrolysis did not increase the biological value above that of the same preparation administered in a capsule. About 90 percent of the thyroxine value of thyroprotein was recovered as an acid-insoluble precipitate, but when administered orally this acid-insoluble fraction was only about 6 percent as effective as that administered by subcutaneous injection. Fairly good agreement between the biological assays and the chemical determination of the thyroxine content of thyroprotein was obtained.

**A new type of glass cage for metabolism studies**, K. E. RAPP, J. T. SKINNER, and J. S. MCHARGUE. (Ky. Expt. Sta.). (*Jour. Lab. and Clin. Med.*, 31 (1946), No. 5, pp. 598-599, illus. 1).—A cage constructed from a 1-gal. glass jug which permits the separation of urine and feces is described.

**Range land of America and some research on its management**, L. A. STODDART (Logan, Utah: Utah State Agr. Col., 1945, pp. 32, illus. 4).—A brief history of the range and a review of range research at the Utah Agricultural Experiment Station, with a bibliography of 19 references.

**A proposed method of measuring pasture yields with grazing cattle**, R. W. KIDDER. (Fla. Expt. Sta.). (*Jour. Anim. Sci.*, 5 (1946), No. 2, pp. 187-193).—A proposed adaptation of the indirect method of measuring pasture yields with grazing cattle is described. This is based on the assumption that the average total digestible nutrient requirement for maintenance of a 1,000-lb. cow is 7.93 lb. of total digestible nutrients per day and that the average daily maintenance requirement for animals of other weights is proportional to the 0.73 power of the live weight. From this proportion the average requirement for daily maintenance of animals of any weight is calculated by the formula 
$$\frac{W^{0.73}}{19.53} = T. D. N.$$

Applications of this method to several steer-feeding experiments are presented. Yields of grass obtained through these calculations of animal performance were found to be within the range of annual yields of grass reported by Neller and Daane (*E. S. R.*, 83, p. 49).

**Progress reports: Feeding tests with sheep, swine, and beef cattle, 1945-46** (*Oklahoma Sta. Bul.* 296 (1946), pp. 46, illus. 4).—Preliminary results are presented from experiments on the following subjects: Feeding Dried Sweet Potatoes to Fattening Hogs, by C. P. Thompson (p. 3); The Utilization of Bluestem Grass in Maintaining the Commercial Cow Herd, by A. E. Darlow, V. G. Heller, W. D. Campbell, and J. C. Hillier (pp. 5-8); Protein and Mineral Supplements for Wintering Two-Year-Old Steers on Grass, by A. E. Darlow, V. G. Heller, W. D. Campbell, J. C. Hillier, and J. A. Hofer (pp. 8-11); Vitamin A (Carotene) in Rations for Sheep and Cattle, by J. A. Hofer, W. D. Gallup, and J. C. Hillier (pp. 12-15); Linebreeding [Farm Animals], by J. A. Whatley, Jr. (pp. 15-21); Yield and Feeding Value of Prairie Hay Cut at Different Stages of Maturity, by H. M. Briggs, W. D. Gallup, A. E. Darlow, and C. Kinney (pp. 22-24); Urea as a Partial Protein (Nitrogen) Supplement for Beef Cattle, by H. M. Briggs, W. D. Gallup, A. E. Darlow, J. C. Hillier, C. Kinney, E. Harris, D. F. Stephens, J. A. Hofer, and W. D. Campbell (pp. 24-28); Supplements for Fattening Two-Year-Old Steers on Grass, by A. E. Darlow, V. G. Heller, J. C. Hillier, D.

Campbell, B. R. Taylor, D. Stephens, H. M. Briggs, and J. A. Hoefler (pp. 28-34); Summer Gains of Yearling Steers Wintered at Different Levels, by A. E. Darlow, V. G. Heller, D. Campbell, H. M. Briggs, J. C. Hillier, J. A. Hoefler, and D. Stephens (pp. 34-39); A Comparison of Dried Sweet Potatoes, Wheat, and Corn for Fattening Steer Calves, by A. E. Darlow, W. D. Campbell, F. B. Cross, V. G. Heller, and H. M. Briggs (pp. 39-42); and How Well Should Calves be Wintered, by A. E. Darlow, W. D. Campbell, V. G. Heller, and H. M. Briggs (pp. 43-46).

Vitamin A requirements in calves, J. M. LEWIS and L. T. WILSON (*Jour. Nutr.*, 30 (1945), No. 6, pp. 467-475, illus. 2).—Calves 2 to 9 days old were placed on a vitamin A-low diet to deplete their stores of this vitamin. When weight gains had ceased, they were divided into six groups of four calves each and fed levels of vitamin A ranging from 32 to 1,024 U. S. P. units per kilogram of body weight per day.

Results were similar to those previously observed with rats (E. S. R., 88, p. 707) and infants (E. S. R., 83, p. 849).

The minimum requirement for calves was about 32 units per kilogram. At this level, growth was fair, and practically no signs of night blindness were noted; however, blood levels of vitamin A were low, and there was little or no liver storage. Maximum growth occurred when the level was raised to 64 units, but maximum concentration of vitamin A in the blood did not appear until 512 units were fed.

Liver storage of vitamin A was variable; practically no storage occurred with the feeding of 64 units or less. Liver stores were low in calves receiving up to 128 units, moderate when the vitamin A level was 256 and 512 units per kilogram per day, and high when the level was 1,024 units.

The authors conclude that "from the standpoint of both growth and liver storage, the daily intake of vitamin A for young calves should be about 250 U. S. P. units per kilogram of body weight or 11,000 units per 100 lb. of liver weight."

[Sheep husbandry in Great Britain] (*Jour. Roy. Agr. Soc. England*, 106 (1945), pp. 166-203).—Under the title of Crossbreeding of Sheep (pp. 166-184), T. L. Bywater gives a brief survey of current breeding problems. Hill Sheep Problems are discussed (pp. 185-203), M. Griffith dealing with the Welshman's view, A. R. Wannop with problems of the Highlands of Scotland, and H. C. Pawson with the improvement of enclosed areas.

Starting right with sheep, W. M. TELLER (Noroton, Conn.: Ed. Robinson's "Have-More" Plan, 1945, pp. 40+).—This is a popular manual for the beginner.

Body temperature and respiration rate, and their relation to adaptability in sheep, J. C. MILLER and L. MONGE. (Univ. Tenn. et al.). (*Jour. Anim. Sci.*, 5 (1946), No. 2, pp. 147-153, illus. 2).—Body temperature and respiration rate determinations were made on six uniform breed groups of five ewes each in the summer of 1943 and on seven groups in 1944. Purebred groups consisted of Southdown, Hampshire, Merino, and Rambouillet. Crossbred groups consisted of Southdown × Rambouillet, Dorset × Rambouillet, and Suffolk × Rambouillet. Determinations were made at different hours of the day from 8 a. m. to 5 p. m. on each ewe, and average values for each breed group were used for comparisons. Atmospheric temperature and relative humidity recordings were made.

With few exceptions Southdown and Hampshire groups in that order showed the highest body temperature and respiration rate at all hours of the day. Rambouillet and Merino groups were quite comparable on body

temperature and respiration rate, and somewhat lower than the Southdown and Hampshire groups. The crossbred groups had lower respiration rate than the purebred groups, but their body temperature was quite comparable to that of the fine wool breeds (Merino and Rambouillet).

Body temperature and respiration rate in purebred groups were influenced more by atmospheric temperature changes than in the crossbred groups. Suffolk  $\times$  Rambouillet ewes maintained the lowest respiration rate of all groups at all times and were least affected by atmospheric temperature changes. They also maintained a relatively low body temperature which fluctuated very little with atmospheric temperature changes. Merinos showed the lowest body temperature and respiration rate, and the least daily fluctuation among purebred groups.

The correlation between thermoregulatory efficiency and flock record is deemed more than a coincidence.

The influence of high-protein and low-protein high-starch diets on blood glucose and acetone bodies of pregnant ewes, J. C. SHAW and F. C. DAUGHERTY. ([Conn.] Storrs Expt. Sta.). (*Jour. Anim. Sci.*, 5 (1946), No. 2, pp. 180-186, illus. 1).—Two groups of four pregnant mature Dorset ewes each were maintained on a low-protein diet for approximately 100 days prior to parturition. Neither hypoglycemia nor ketonemia developed during the period of pregnancy even when the energy intake was limited to 50 percent of requirements, but a mild hypoglycemia was noted following parturition in both these groups and two similar groups which had received high-protein rations.

Fattening lambs in Montana, R. T. CLARK, R. R. WOODWARD, and D. HANSEN. (Coop. U. S. D. A.). (*Montana Sta. Bul.* 433 (1945), pp. 34, illus. 3).—The results of 16 separate lamb-feeding trials are summarized. In a comparison of grains, oats consistently gave better results than hard or soft wheat, barley, or corn, with very little difference in the effectiveness of these other grains. Protein and mineral supplements failed to improve the effectiveness of a ration of grain, wet beet pulp, and good alfalfa hay. Self feeding a ration of equal parts of oats, dried molasses-beet pulp, and chopped alfalfa proved to be a desirable practice and is particularly recommended where hay prices are relatively high. While dried beet pulp and wet pulp proved to be the most desirable beet byproducts, beet tops and beet top silage proved to be satisfactory feeds for lamb fattening. Alfalfa hay produced slightly cheaper gains than native hay plus a protein supplement, although the latter resulted in slightly higher gains.

Dehydrated potatoes and alfalfa silage for lambs, A. L. ESPLIN and W. E. CONNELL (*Colo. Farm Bul.* [Colorado Sta.], 8 (1946), No. 2, pp. 3-4, 5, 6-9, illus. 4).—In a single test with 11 lots of 20 lambs each and covering 84 days, dehydrated potato cubes proved surprisingly good, both when fed by themselves and in grain mixtures, and were superior to dehydrated shredded potatoes. Alfalfa-acid silage ranked with, or better than, corn silage and wet beet pulp produced good and cheap gains. Sulfur fed in a grain mixture in a concentration of 2 percent reduced grain consumption and greatly increased the cost of gains.

Pigs: Their breeding, feeding, and management, V. C. FISHWICK (*London: Crosby Lockwood & Son*, 1946, 2. ed., rev., pp. 222, about 50 illus.).—This revision (E. S. R., 82, p. 523) incorporates more recent information and adds a chapter on costs and returns.

Nicotinic acid and the level of protein intake in the nutrition of the pig, M. M. WINTROBE, H. J. STEIN, R. H. FOLLIS, JR., and S. HUMPHREYS. (U. S.

D. A. et al.). (*Jour. Nutr.*, 30 (1945), No. 6, pp. 395-412, illus. 3).—A detailed study has been made on 61 pigs showing the influence of various vitamin supplements, with and without nicotinic acid, upon the effects of high or low protein diets. The standard basal diet previously described (E. S. R., 88, p. 799) was used. In the high protein diet, 26.1 percent crude casein was fed, while the low protein diet contained only 10 percent.

Young pigs fed a high protein diet supplemented with thiamine, riboflavin, pyridoxine, choline, and pantothenic acid showed no signs of nutritional deficiencies with the exception of slightly lower growth rates in certain instances. The addition of inositol and p-aminobenzoic acid produced no significant changes. The addition of nicotinic acid seemed to increase the average growth rate to some extent.

On a low protein diet (10 percent casein), the omission of nicotinic acid alone produced characteristic signs of nutritional deficiency (greatly impaired growth, rough coats, diarrhea, loss of appetite, and severe anemia). In these animals, a marked and consistent reduction was noted in the urinary excretion of nicotinic acid derivatives.

A discussion of the close nutritional relationship between protein and nicotinic acid metabolism is presented. Thirty-eight references are cited.

The effects of a vitamin B mixture, of level of protein, and of proportion of protein of animal origin in the supplements to barley and to wheat in the bacon hog ration, E. W. CRAMPTON and G. C. ASHTON (*Sci. Agri.*, 26 (1946), No. 1, pp. 43-49).—A feeding trial involving 128 Yorkshire pigs was carried on to determine the comparative effects of various factors on carcass quality when wheat or barley was the basal feed. The following conclusions were drawn:

"Season may be an important factor in the excellence of bacon carcasses produced. If pigs are finished in winter in cold pens the rate of gain may be sufficiently reduced to result in a superior carcass. Carcasses from male pigs are by nature fatter than those from females. The tendency for wheat as compared to barley to damage carcass excellence is more pronounced with male than with female pigs. Special supplementation with a mixture of thiamine, riboflavin, and niacin tended to aggravate the already greater tendency of wheat than of barley to produce fat carcasses. Reduction of the protein level of the ration from 15 percent to 13 percent was reflected in lower feed intake and slower gains, but did not affect carcass excellence regardless of whether wheat or barley was the basal feed. Halving the proportion of the protein from animal origin had no measurable effect either on the progress of the live pigs or on the excellence of the carcasses. Apparently 1.4 percent of protein of animal origin in the ration—equivalent to only 9 percent of the protein of a ration carrying 15 percent protein—is as satisfactory as is double this amount."

The relative antiarthritis potency of irradiated ergosterol ( $D_2$ ) and irradiated 7-dehydrocholesterol ( $D_3$ ) for growing pigs, E. W. CRAMPTON and G. C. ASHTON (*Sci. Agr.*, 26 (1946), No. 1, pp. 16-24, illus. 1).—The tests reported were undertaken with the specific object of comparing the effectiveness of vitamin  $D_2$  and  $D_3$  in preventing rickets in pigs placed on rachitic diets at a weaning age of about 56 days. In no case, however, did rickets develop, so that "these tests offer no basis for a comparison of the antiarthritis potency for swine of vitamin  $D_2$  or  $D_3$ ." It is thought that when weaned at 8 weeks from mothers which during pregnancy and lactation have received daily about 15,000 International Units of vitamin A and 3,000 I. U. of vitamin D, young pigs confined indoors have a considerably lower vitamin D requirement than

present standards call for if their diets contain at least 0.57 percent P; the Ca : P ratio is not wider than 0.5 : 1; and bone ash values of the order of 57 percent, and normal trabecula, are taken as indicating normal bone metabolism.

**Biotin deficiency syndrome in pigs fed desiccated egg white,** T. J. CUNHA D. C. LINDLEY, and M. E. ENSMINGER. (Wash. Expt. Sta.). (*Jour. Anim. Sci.*, 5 (1946), No. 2, pp. 219-225, illus. 4).—A biotin deficiency was produced in two pigs by feeding 30 percent of desiccated egg white in the ration. The deficiency symptoms included alopecia, spasticity of the hind legs, cracks in the feet, and a dermatosis of the skin characterized by dryness, roughness, and a brownish exudate. This syndrome was prevented by intramuscular injection of 100  $\mu$ g. of biotin per pig per day. The deficiency resulted in 50 percent more feed being required per pound of gain and a decrease of 45 percent in rate of daily gain.

**The effect of fineness of grinding on the utilization of oats by market hogs,** E. W. CRAMPTON and J. M. BELL (*Jour. Anim. Sci.*, 5 (1946), No. 2, pp. 200-210, illus. 4).—When pigs of 50 lb. initial weight were fed on coarse, medium, or finely ground oats, adequately supplemented by proteins and minerals, significantly faster gains were obtained as the modulus became finer. Pigs fed coarse, medium, and fine modulus reached 121, 132, and 155 lb. live weight, respectively, in 60 days of feeding. Feed consumption over the 60-day growth period increased as the modulus became finer, but this was due almost entirely to the increased size of pig because of faster growth rates. Pigs of equal size ate approximately equal amounts of feed daily. Fibrous portions made up largely of hulls were decidedly unpalatable to the younger pigs, and unless they were finely ground they were sorted out and refused. Grinding oats to various degrees of fineness did not affect the extent to which the older pigs digested the dry matter, and when the young pigs were unable to separate the hulls, because of fine grinding, no age differences were noted in dry matter digestibility. The importance of considering feed refusals in the evaluation of a ration is discussed, as is also the possibility of a factor, or factors, contained in oat hulls which affects nutrient utilization.

**Cull peas as a protein supplement for fattening hogs,** W. M. BEESON and C. W. HICKMAN (*Idaho Sta. Cir.* 105 (1945), pp. 4).—Tests comparing various combinations of meat meal and ground cull peas in the protein-mineral supplement fed free choice with rolled wheat to fattening pigs in dry lot led to the conclusion that ground cull peas make an excellent protein supplement for fattening hogs if properly balanced with a small amount of meat meal. A mixture composed of meat meal, 10 lb.; ground peas, 57 lb.; ground alfalfa, 25 lb.; oystershell, 4 lb.; steamed bonemeal, 2 lb.; and salt, 2 lb., was the most satisfactory ration tested. It gave as good results as one containing 50 percent meat meal and was superior to one containing only 5 percent meat meal. Field peas were not satisfactory as the only protein concentrate in the ration.

**The value of shark meal in swine rations,** S. P. MARSHALL and G. K. DAVIS. (Fla. Expt. Sta.). (*Jour. Anim. Sci.*, 5 (1946), No. 2, pp. 211-218, illus. 1).—In a 16-week test by the paired-feeding method, the ration containing shark meal as the principal source of protein produced growth in pigs comparable to that in pigs receiving roller process dried skim milk. The average growth of the pigs exceeded that shown by the Ittner and Hughes standard growth curve for swine (E. S. R., 81, p. 93). Even in rations which contained 5.9 to 13.98 percent of this new protein supplement, the shark meal did not produce any off- or fishy flavor in the lean or fat of the animals.

Factors affecting farm horse power, R. S. HUDSON and B. GOOD (*Michigan Sta. Quart. Bul.*, 28 (1946), No. 3, pp. 208-215, illus. 2).—This phase of the study dealt with the possibility of lower costs in producing horses of light and heavy types. It is concluded that colts can be raised to maturity more profitably out-of-doors on pasture during the summer and from uncut meadows and stacked hay during the winter. Colts can be so raised without sacrifice in final weights, and as compared with housing in single and box stalls had better legs and feet. Colts receiving grain the first winter as weanlings had greater resistance to distemper than those wintered on hay and pasture. When developed on roughage they were not in ready condition for sale as yearlings or 2-year-olds, but "at present low prices for draft horses the cost of producing them is more likely to be under the selling price."

Blood and tissue chemical studies in fowl, G. R. HERRMANN (*Soc. Expt. Biol. and Med. Proc.*, 61 (1946), No. 3, pp. 229-230).—Normal blood and tissue levels of the usual organic constituents, with special reference to total cholesterol and cholesterol esters and other lipids, were determined as a basis for contemplated fat metabolism studies.

The utilization of food elements by growing chicks.—X, A comparison of open-pollinated and hybrid corn in a ration for growing chicks, C. W. ACKERSON, W. E. HAM, and F. E. MUSSEHL (*Nebraska Sta. Res. Bul.* 144 (1946), pp. 5).—The effect of replacing open-pollinated corn with hybrid corn in an otherwise complete ration was studied in a growth and body analysis experiment with two lots of newly hatched chicks fed identical amounts of the pelleted rations. At the end of a 6-week feeding trial, there were significant differences in the growth rate of the chicks in favor of the lot fed open-pollinated corn.

The effect of the pantothenic acid content of eggs on the amount in newly hatched chicks, P. B. PEARSON, V. H. MELASS, and R. M. SHERWOOD. (*Tex. Expt. Sta. and Tex. A. & M. Col.*). (*Arch. Biochem.*, 7 (1945), No. 2, pp. 353-356).—Hens were fed rations containing 3.9, 8.6, and 15.7  $\mu\text{g}$ . of pantothenic acid per gram of diet. Assays were made on the eggs laid by these hens and on the entire chick at the time of hatching. Results showed that the amount of pantothenic acid in the egg was dependent upon the diet, and that no change occurred during incubation prior to hatching. The pantothenic acid values found in the egg and the newly hatched chick were, respectively, 4.9 and 5.2, 7.9 and 8.3, and 14.0 and 13.6  $\mu\text{g./gm.}$  for the three levels of vitamin fed the hen.

New Jersey egg-laying tests, 1916 to 1943: Production and mortality of White Leghorn, Rhode Island Red, and Barred Plymouth Rock pullets, C. S. PLATT (*New Jersey Stas. Bul.* 720 (1945), pp. 24, illus. 3).—A study of the records of 29,714 White Leghorn, 4,948 Rhode Island Red, and 3,002 Barred Plymouth Rock pullets entered in the New Jersey egg-laying tests of Vineland, Passaic County, and Hunterdon County from 1916 to 1943 indicated an increase in production on the part of the respective breeds of 46.0, 93.3, and 67.2 eggs annually per bird entered. Winter egg production showed the greatest gain over the years, and occurred without any lowering of spring or summer production. Most of the improvement is attributed to changes in management resulting from the practice of earlier hatching, the more careful selection of pullets for entry, the use of artificial light, and the shifting of the months of operating the tests from November to October, inclusive, to October to September, inclusive. Mortality in all three breeds exhibited a tendency to increase during the first few years of the operation of the tests,

or from 1916 to approximately 1930. After 1930 there was a gradual decline, with considerable variation from year to year.

**Artificial control of egg production,** G. O. HALL. ([N. Y.] Cornell Expt. Sta.). (*Farm. Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 17-18, illus. 1).—In this study restricted feeding, and restricted feeding combined with restricted lighting, were tested as means for the artificial control of egg production during the summer months and the effects of such controls on fertility, hatchability, and egg production during the fall months. Three pens of 30 birds each of high-producing 2-year-old Single-Comb White Leghorns were used each year over a 3-yr. period. Observations were taken over three periods of 7 mo. each from June 1 to January 31, during the years 1943 to 1946. Records were kept of changes in body weight, molting, feed consumption, egg production, fertility, and hatchability.

In pen A, restricted feeding, and pen B, restricted feeding and lighting, there was a marked decline in body weight. In pen A the molt was slow and erratic, in pen B it was both rapid and complete, and in pen C, the control, there was little or no molting until relatively late in the fall. Mortality was relatively high in all pens, but lowest in pen B.

Egg production was significantly lower in pen A, as compared with the other two groups. In 2 of the 3 yr. the birds in pen B produced more eggs than did those in the control group. Also, the birds in pen B produced more eggs during months of high egg prices. The value of the eggs from pen A as compared with the control indicated that restricted feeding alone is not a satisfactory procedure for the artificial control of the distribution of egg production, and that it is not economically sound if based entirely on the market value of eggs.

The average infertility for all treated pens during the 3 yr. was 24.7 percent, and for the control pens 47.3 percent. Percentage hatchability of both total eggs and fertile eggs was significantly higher in the treated pens than in the control. Owing to lower infertility, higher hatchability, and very much higher egg production during the period from September 1 to January 31, the number of chicks from pen A was double the number from the control, and from pen B slightly more than three and one-half times the number from the control.

The results indicate that it is possible to control egg production artificially during the summer months, and that such control may be used as a means of greatly increasing the number of fall chicks which may be hatched from hens. "This makes possible the hatching of chicks from hens during the fall for research purposes, or where there is a demand for fall chicks from hens it may materially increase economic returns."

**The effect of artificial light on egg production of late hatched White Leghorn pullets,** J. E. PARKER (*North Dakota Sta. Bimo. Bul.*, 8 (1946), No. 4, pp. 15-18, illus. 1).—A group of 67 late-hatched White Leghorn pullets, which were exposed to artificial lights so as to provide 14 hr. of total light per day commencing October 19, laid 64 eggs per bird to February 7, whereas a similar group of 67 unlighted pullets laid 47 eggs. The percentages of egg production were 57 and 42, respectively. For the entire 48 weeks of the experiment the average egg production was 199 for the lighted pen and 181 for the unlighted pen, and the percentages of production for the two pens were 59 and 54, respectively. The use of artificial lights had little influence on mortality rate, body weight, egg weight, intensity of egg production, or persistency, and the increase in production was due largely to a hastening of sexual maturity. Feed consumption per bird was higher in the lighted pen,

but the amount of feed to produce a dozen eggs was less than in the unlighted pen.

**Annual molt in Rhode Island Reds,** F. A. HAYS and R. SANBORN (*Massachusetts Sta. Bul.* 429 (1945), pp. 24, illus. 4).—Molting behavior in its relation to first-year egg production was studied in seven generations of Rhode Island Reds. A comparison was made between stocks bred for exhibition color and stocks bred for high fecundity. Both males and females were included in the study and all records were made on the first annual molt. Observations were taken at biweekly intervals beginning in the last week of July and extending through the month of December.

Molting behavior was more consistent in the 10 wing primary feathers than in 5 other feather tracts studied. The time of onset of wing primary molt had a significant effect on first-year egg production, and date of completion of wing primary molt was probably the most important consideration from the standpoint of antecedent egg production. Birds bred for high fecundity had the ability to lay for a considerable period after wing molt began, and superior layers did not usually stop laying until three or more primaries had been lost. Males and females bred for high fecundity completed their annual molt later than stock bred for exhibition color. Males usually completed their molt more than a month earlier than females. A decline in body weight during annual molt was characteristic of exhibition males and females. Males bred for production did not exhibit this decline, but females showed a slight decline at the height of the molt.

Evidence was inconclusive that selective breeding can increase the length of the laying period during wing primary molt. There was evidence, however, that the date of completion of molt is governed by inheritance. Hatchability during the second laying year may be reduced by extremely long periods of molt as well as by a very late termination of molt.

**Percentage of edible meat in relation to meat type score of chickens,** E. W. HENDERSON (*Michigan Sta. Quart. Bul.*, 28 (1946), No. 3, pp. 176-180, illus. 1; also in *Amer. Egg and Poultry Rev.*, 7 (1946), No. 4, pp. 44, 46, illus. 1).—Supplementing a previous study of scoring systems (E. S. R., 94, p. 516), mathematical proof of a valid relationship between the meat type score of live and dressed chickens and the percentage of edible meat is presented by means of calculated significant correlation coefficients. The correlation between dressed meat type score (range 1-5) and the percentage edible meat was  $-0.62$  and that for live meat type score  $-0.48$ . Selection methods for improving meat type by breeding are discussed.

**Starting right with turkeys,** G. T. KLEIN, edited by E. ROBINSON (*New York: Macmillan Co.*, (1946), pp. 129+, about 100 illus.).—This popular treatise by the extension poultry husbandman at the Massachusetts State College deals with the growing and utilization of turkeys, especially on a small scale.

## DAIRY FARMING—DAIRYING

**Effect of warm weather on grazing performance of milking cows,** D. M. SEATH and G. D. MILLER. (La. Expt. Sta.). (*Jour. Dairy Sci.*, 29 (1946), No. 4, pp. 199-206).—Observations on three Jersey and three Holstein milking cows during early September in 1945 at Baton Rouge, La., are reported.

Cows showed a progressive rise in body temperature throughout the day. When they left the milking barn at 5:45 a. m. it averaged  $101.7^{\circ}$  F.; upon entering the shade of trees at 9:20 a. m. it was  $102.4^{\circ}$ ; after a period of 1

hr. in the shade, 102.6°; at 2 p. m., 103.3°; and upon entering the milking barn at 3 p. m. it was 103.5°. During these same respective periods respiration rates were 63, 64, 71, 78, and 79 per minute. Atmospheric temperatures during these periods increased from 73° at 5:45 a. m. to a high of 86.7° at 2 p. m.

Observations of 24-hr. grazing periods showed that during 2 relatively warm days cows grazed less than 2 hr., 1.9 and 1.8 hr. during daytime (between a. m. and p. m. milking periods), but grazed three times as much, 5.7 and 5.5 hr., at night (between p. m. and a. m. milking). Data on 2 cool days showed daytime grazing 2.4 times as great as for warm days, and 24-hr grazing totals more than 1 hr. longer than for warm days.

The number of grazing periods averaged 1.4 for daytime and 2.7 for night. Cows seldom had but one important grazing period during the daytime. Three grazing periods were the most common at night and the time spent grazing averaged 5.5 hr., while 3.5 hr. were spent lying down and 0.7 hr. standing without grazing. "Results of the study suggest the need for good pasture at night and, especially on warm days, an excellent daytime pasture. There appears to be a need for experimental trials to test the best method of providing supplemental feed to cows during their long periods in shade during warm summer days, and to determine the best methods for making them more comfortable during this same period."

See also an article by Atkeson et al. (E. S. R., 88, p. 671).

Simple versus complex grain mixtures in dairy rations.—II, Summer feeding to milking cows on pasture, C. F. MONROE and W. E. KRAUSS (*Ohio Sta. Bimo. Bul.* 339 (1946), pp. 31-35, illus. 1).—The comparison of simple v. complex grain mixtures for winter feeding previously noted (E. S. R., 95, p. 98) has been extended to summer feeding with 56 cows on pasture. In two successive pasture seasons a simple grain mixture containing ground shelled corn and soybean oil meal was compared with one containing corn, oats, bran, linseed oil meal, and soybean oil meal. Performance, as measured by production, live weight gains, and persistency of production was similar on both mixtures. "Inasmuch as the cows used produced at a high level (milked three times daily) and the trials were continued throughout the pasture season, it is felt that when adequate pasture is available and supplementary roughage is fed, satisfactory performance can be expected on simple grain mixtures."

Methods of making potato silage and tests of its feeding value for dairy cows, J. B. SHEPHERD, T. E. WOODWARD, and C. G. MELIN (*U. S. Dept. Agr., Tech. Bul.* 914 (1946), pp. 13).—Comparing the keeping quality, palatability to milking cows, and effects on milk production of potato silage prepared in various ways, it was found that the best silages were obtained when potatoes were ensiled with 15 to 22 percent of added hay or other dry forage. These silages were similar in appearance to good grass silage but somewhat heavier. They were consumed in large quantities by dairy cows which made good gains in live weight and maintained milk production. Also, such silage had no undesirable effect on composition and quality of the milk. Ensiling potatoes alone, or with 3 percent of corn meal, or with 0.75 percent of salt did not prove practical. Such silages were heavy, soft, and mushy, and hard to handle, and lost an excessive amount of nutrients through drainage of juice. They were moderately palatable to cows, but when consumed exerted an undesirable effect on the quality of milk, particularly by depressing the percentage of fat with resulting high iodine values and low saponification values in the milk.

Raw chopped potatoes were eaten readily and compared favorably with corn silage insofar as live weight and milk production was concerned. Also, the composition of milk was unaffected, although the milk developed some off-flavors. It is concluded that when the quantity of potatoes available for feeding is small they can be fed to best advantage in the fresh raw state. When the quantity is large they can be preserved satisfactorily as silage and fed over a longer period of time. For best results they should be ensiled with 20 to 25 percent of good quality hay or other dry forage.

The therapeutic effect of yeast and pyridoxine on poikilocytosis in dairy cattle, J. T. REID, C. F. HUFFMAN, and C. W. DUNCAN. (Mich. State Col.). (*Jour. Nutr.*, 30 (1945), No. 6, pp. 413-423).—Poikilocytosis was found to be most common in cows with large open fistulas of the rumen and in young calves fed a restricted diet (whole milk and breakfast cereal). The blood picture was similar to that noted previously (E. S. R., 93, p. 770). Treatment of the affected animals with nicotinic acid, riboflavin, or a mineral mixture containing Fe, Cu, Co, and Mn had no influence on the progress of the disease.

The feeding of dried brewers' yeast or live yeast effectively ameliorated the disease within 3 to 4 weeks. The substitution of 5 to 20 mg./day of pyridoxine produced a slow recovery, while the ingestion of 40 mg. of pyridoxine daily produced complete recovery and normal erythrocyte formation in 3 to 4 weeks.

As normal cattle are considered to be able to synthesize pyridoxine in the rumen, the authors suggest, from the results noted above, that the "primary defect responsible for the occurrence of poikilocytosis in dairy animals is due to a lack of, or an interference with, normal ruminal activity."

The effect of the prepartum diet of the cow on the vitamin A reserves of her newborn offspring, G. H. WISE, M. J. CALDWELL, and J. S. HUGHES. (Kans. Expt. Sta.). (*Science*, 103 (1946), No. 2681, pp. 616-618).—Feeding vitamin A at the rate of a million U. S. P. units daily to individual dairy cows in the later stages of gestation augmented significantly the vitamin A concentration in the blood and the livers of their four newborn calves, but pasture grazing, providing an abundance of carotene in the prepartum diet of the dams failed to effect an increase over that observed in eight calves from dams restricted to a standard winter ration. The explanation for these divergent results is deemed obscure, but it is suggested that the placental membrane may be more permeable to the ester form of vitamin A than to the alcohol form. "This high initial vitamin A reserve in the newborn calf should have practical value in the maintenance of its postnatal health."

Controlled experiments on the value of supplementary vitamins for young dairy calves, C. L. NORTON, H. D. EATON, J. K. LOOSLI, and A. A. SPIELMAN. (Cornell Univ.). (*Jour. Dairy Sci.*, 29 (1946), No. 4, pp. 231-238, illus. 1).—Studies are reported involving approximately 60 heifer calves of various dairy breeds, largely Holsteins, which showed that supplementing a normal diet with capsules or tablets containing vitamins A, D, and E, ascorbic acid, and several of the B-vitamins did not reduce the incidence or severity of scours. Extra vitamins in the amounts fed had no certain effect on the rate of growth or the general appearance of the calves during the early months of life. Under the feeding and management conditions involved, there was no advantage to calves from adding extra vitamins to the normal ration.

Tests show young calves need butterfat, T. W. GULLICKSON and J. B. FITCH (*Minn. Farm and Home Sci. [Minnesota Sta.]*, 3 (1946), No. 2, pp. 12-13, illus. 2).—Tests with calves about 2 weeks old resulted in much poorer physical condition for those receiving homogenized vegetable oils. The calves

fed tallow, lard, or hydrogenated vegetable oils made almost as satisfactory gains in weight as those receiving milk fat, and were on the whole quite thrifty and healthy, although somewhat inferior in appearance and less fat was deposited in their carcasses. The calves fed coconut oil and peanut oil were on the whole inferior in condition to those fed lard, tallow, and hydrogenated vegetable oils, but definitely superior to animals fed the other vegetable oils.

The average daily gains in weight for the groups for ages up to 90 days were as follows: Butterfat 1.3 lb.; tallow, lard, and hydrogenated vegetable oil 1.2; coconut oil 0.96; peanut oil 0.80; corn oil 0.40; soybean oil 0.32; and cottonseed oil 0.31 lb.

**Secretion of milk,** D. ESPE (*Amcs, Iowa: Collegiate Press, 1946, 3. ed., pp. 314+*, illus. 62).—The third edition of this book follows the same general plan of subject matter presentation as the second edition (E. S. R., 87, p 105). The bibliography has been extended to include 1,294 citations.

**Studies of the carbohydrate metabolism of mammary gland tissue in vitro, II-III,** C. B. KNOTT and W. E. PETERSEN. (Minn. Expt. Sta.). (*Jour. Dairy Sci.*, 29 (1946), No. 2, pp. 115-128).—These two papers deal, respectively, with work on tissue slices prepared and incubated in accordance with the method described in paper I (E. S. R., 93, p. 488) of the series, and citric acid determined by the Pucher, Sherman, and Vickery method (E. S. R., 76, p. 585); and with experiments on the isolated and perfused bovine gland.

II. *The metabolism of citric acid and  $\beta$ -hydroxybutyric acid in tissue slices* (pp. 115-120).—It is shown that the mammary gland can synthesize citric acid from substances in the tissue. Addition to the slices of glucose, lactic acid, pyruvic acid, maltose or glycogen increased citric acid formation, indicating that these substances may serve as precursors. When large proportions of citric acid were added, its degradation during incubation was observed. Increments in added  $\beta$ -hydroxybutyric acid were used in increasing quantities by the incubated tissue slices. Part of the added  $\beta$ -hydroxybutyric acid is converted into acetone and acetoacetic acid, the quantity thus changed decreasing with increased concentration and use. Conversion of  $\beta$ -hydroxybutyric acid into citric acid by the mammary gland is considered questionable.

III. *Glycogen as an intermediary in the formation of lactose* (pp. 121-128).—In paper III, the results of a series of 17 perfusion experiments are reported. The effects of insulin upon lactose formation and tissue glycogen storage were studied. The effects of insulin administered in a series of 5 experiments were compared with the results in 5 experiments in which insulin was omitted but glucose was added to maintain normal or subnormal blood levels. In 7 experiments the effect of large additions of glucose, together with insulin, was studied.

Administration of 120 to 160 units of insulin markedly reduced the percentage of lactose in the milks even though the bloods contained adequate amounts of glucose for normal lactose production. The accumulation of tissue glycogen was greater in the insulinized glands than in the controls. The evidence obtained is held to indicate that the increase in tissue glycogen was not due to glycogenic properties of insulin but more likely to its blocking of glycogenolysis. It is believed that lactose is formed from degradation of glycogen, and the lowered lactose production in experiments where insulin was administered is accounted for by a blockage of glycogen breakdown.

Lactic acid, pyruvic acid, amino acids, acetone bodies, oxygen, carbon dioxide, and hemoglobin in arterial and mammary venous bloods of cows

under various physiological conditions, J. C. SHAW. ([Conn.] Storrs Expt. Sta.). (*Jour. Dairy Sci.*, 29 (1946), No. 4, pp. 183-197).—The respiratory quotient of the active mammary glands of both normal and fish-oil-fed cows under nembutal anesthesia exceeded unity, with mean values of 1.27 and 1.31, respectively. In experiments with nonanesthetized cows in which the percentage of fat and the low fatty acids of milk fat had been depressed by feeding fish oil, the respiratory quotient exceeded unity in 9 of the 15 experiments, with a mean quotient of 1.16. On the basis of these data, the suggestion that a metabolic relationship exists between the respiratory quotient of the gland and the synthesis of the lower fatty acids of milk is regarded as still in doubt.

Numerous experiments on cows under anesthesia confirmed the earlier report of Powell and Shaw (*E. S. R.*, 90, p. 243) that the mammary gland does not utilize a significant amount of blood lactic acid. The mean arteriovenous value for 22 experiments was +0.18 mg. percent. The mean arteriovenous difference for pyruvic acid in 26 experiments was +0.047. Consequently, blood pyruvic acid appears to be of little significance in the metabolism of the active mammary gland.

The arteriovenous differences of lactic acid and pyruvic acid were not altered significantly on fish-oil-fed, fasted, or nonlactating cows from that observed on normal lactating cows. Neither the utilization of amino acids nor acetone bodies were altered significantly by depressing the percentage milk fat and the lower fatty acids by feeding fish oils. Arteriovenous hemoglobin studies on anesthetized cows confirmed earlier observations that little or no arteriovenous change occurs in unagitated cows. The percent hemoglobin difference for 42 experiments on anesthetized cows was 0.40 and exceeded 1 percent in only 5 cases.

The distribution pattern of fatty acids in glycerides of milk fat, E. I. JACK, J. L. HENDERSON, and E. B. HINSHAW. (Univ. Calif.). (*Jour. Biol. Chem.*, 162 (1946), No. 1, pp. 119-123).—The authors present data showing the fatty acid composition, the percentage of fully saturated glycerides, and the fatty acid composition of the fully saturated glycerides of milk fat fractions separated from the solvent. The mole percentage of fully saturated glycerides found was as follows: —7° precipitate 75.4 percent, —13° precipitate 40.5 percent, —23° precipitate 40.3 percent, —53° precipitate 25.8 percent, —53° filtrate 4.6 percent, and original milk fat 31.3 percent. Acids in milk fat tend to be distributed among the glycerides as widely as possible. Patterns for the distribution of the fatty acids among the glycerides in the different fractions, based on the supposition that the fatty acids are distributed as widely as possible, are postulated. The hypothetical patterns are compared with the experimental data.

The rate of autoxidation of milk fat in atmospheres of different oxygen concentration, P. S. SCHAEFFER, G. R. GREENBANK, and G. E. HOLM. (U. S. D. A.). (*Jour. Dairy Sci.*, 29 (1946), No. 3, pp. 145-150, illus. 3).—The authors obtained data indicating that an autoxidation of milk fat by which it is combined with as little as 0.8 percent by volume of oxygen is enough to render the fat inedible. It is pointed out that in the atmosphere of a container of dried milk this is equivalent to 0.20 percent of oxygen; and that so low a level of oxygen concentration is difficult to attain even by "regassing" procedures. Studies of the relative keeping quality of samples of milk fat and samples of a dried milk in atmospheres of different oxygen concentration indicated that the keeping quality increases markedly with decreases in the oxygen concentration below 5 percent, however. The relationship of keeping

quality in days to the initial oxygen concentration of the container atmosphere in percentage appeared to be of a reciprocal nature, that is, the time required to produce tallowy flavors in packed dried milks or to reach a given peroxide value of pure milk fat, and the oxygen concentration used, appeared to be inversely proportional to one another. The data presented were considered to indicate that the rate of autoxidation of milk fat varies directly with the oxygen concentration.

Keeping quality of milk, L. H. BURGWARD and D. V. JOSEPHSON. (Ohio State Univ.). (*Milk Dealer*, 35 (1946), No. 5, pp. 44, 100-101, illus. 1).—A test of 184 bottles of milk from eight lots and five plants is reported in which it was found that regular grades of pasteurized milk would stay sweet for 7 to 28 days under conditions such as might normally be imposed by the average consumer. Home refrigeration temperatures below 45° F., and preferably down to 40°, are deemed desirable. The treatment the milk received and the temperatures of the refrigerator were greater factors than the number of bacteria present in the milk when the tests were started. There was no appreciable increase in the bacterial count up to 4 days in any of the samples, and no change in the flavor until the lots were from 4 to 17 days old. The vitamin C content of the fresh milk and on storage varied greatly, while the riboflavin content was practically the same for all lots and little was lost in storage.

Factors which contribute to the physical stability of frozen cream, R. W. BELL and C. F. SANDERS. (U. S. D. A.). (*Jour. Dairy Sci.*, 29 (1946), No. 4, pp. 213-220, illus. 3).—Extending recent work on much smaller samples held in frozen storage for periods of less than 48 hr. (E. S. R., 93, p. 763), the authors here report upon results of freezing of 150-cc. cream samples in small cans at -17° C. in air and in ethanol, and at -29°. the freezing requiring 4 hr., 50 min., and 25 min., respectively, followed by storage during periods of from 2 days to several months at temperatures of -8° and -17° in air and of -29° in ethanol.

Factors found to contribute to the stability of cream frozen and held under the experimental conditions stated were: (1) The use of freshly drawn milk which contains small, unclumped fat globules; (2) maintenance of these globules in a fluid, completely dispersed state until freezing time; (3) quick-freezing to retain this degree of dispersion; and (4) a storage temperature sufficiently low to prevent the physical changes which cause localized crowding, distortion, and disruption of the fat globules and consequent oiling off on thawing. It was concluded that frozen cream which is prepared and maintained under these conditions will have a stable emulsion and a good body when thawed after several months storage.

Studies on compressed whole milk powder, C. C. THIEL (*Jour. Council Sci. and Indus. Res. [Austral.]*, 18 (1945), No. 4, pp. 391-406, illus. 3).—"Compression of spray-dried whole milk powder to a density of 1:15 to 1:20 reduced the interstitial oxygen as effectively as the usual gas packing in tins, but neither cellophane nor waxed paper wrapping prevented uptake of atmospheric oxygen or moisture. Blocks containing 20 percent of cane sugar were much more friable and kept better than those made entirely of milk powder. Vanillin also improved the keeping quality of the blocks."

The keeping quality of Australian milk powders, C. C. THIEL and E. G. PONT (*Jour. Council Sci. and Indus. Res. [Austral.]*, 18 (1945), No. 4, pp. 373-390).—"A preliminary survey of the relative keeping qualities of several Australian spray-dried and roller-dried, skim and whole milk powders has been made. Gas packing did not materially improve the storage life of skim

milk powders but greatly increased the life of whole milk powders. In commercial practice, the advantages of gas packing were largely nullified by the presence of leaking tins. Skim milk powders when reconstituted after storage with fresh flavoured butterfat were no better in flavour than reconstituted gas-packed whole milk powders stored under identical temperature conditions. Variations in the keeping quality of powders made at different times by any one factory were considerable and great differences in the keeping quality of whole milk spray-dried powders from different factories were noticed. The roller-dried whole milk powders examined were inferior in flavour to the better quality spray-dried whole milk powders. The influence of storage temperatures (15°, 30°, and 37° C.) was not marked either with the skim or whole milk powders. No correlation between bacterial counts and initial quality or condition after storage was observed."

The oxygen content of the atmosphere in containers of dried milk packed in nitrogen, P. S. SCHAFER and G. E. HOLM. (U. S. D. A.). (*Jour. Dairy Sci.*, 29 (1946), No. 4, pp. 207-212, illus. 4).—The preliminary observations noted on page 384, made in direct measurement of the volumes and composition of container gases, were confirmed with respect to the relative importance of time, temperature, and degree of evacuation in reducing the oxygen concentration of the container gases. That the quantities of adsorbed gases do not decrease to a great extent with increases in the value of these factors within practical limits was also indicated by the desorption values obtained. It was pointed out that if equilibrium had been attained in each case, the rate of decrease of the final oxygen content in the containers should have been of a logarithmic nature, since the percentage oxygen removed in each evacuation was a constant. However, the rate obtained practically was not of a logarithmic nature. This result is attributed tentatively to the fact that the values for the percent oxygen in the container atmospheres were not equilibrium values. The relatively high efficiency of a second evacuation stage in decreasing the percent oxygen content of the container gases was indicated. The rate of desorption seemed to vary with different dried milks, however. The efficiency of gassing procedures should have been established for the product concerned in each case, therefore. The use of two stages of evacuation at 3 mm. pressure, with a 3- to 4-day intervening holding period, produced a final oxygen concentration in the container of approximately 1 percent. Increasing the duration of the holding period further reduced the final oxygen concentration.

## VETERINARY MEDICINE

Lander's veterinary toxicology, rev. by J. A. NICHOLSON (*Chicago: Alexander Eger, 1945, 3. ed., pp. 329+, illus. 39*).—This is a third revised edition (E. S. R., 55, p. 776).

The role of disinfection in veterinary medicine,—I, Sterilization of surgical instruments, E. C. McCULLOCH. (Wash. Expt. Sta.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 829, pp. 242-249, illus. 4).—This discussion includes experimental data as to the time and temperature required for dry heat sterilization.

[Miscellaneous papers] (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 828, pp. 148-151, 152, 157-160, 162, 169-171, 179-183, illus. 13).—These include A Newly Developed Anesthetic for Horses, by E. W. Millenbruck and M. H. Wallinga, in which the new anesthetic consisted of freshly prepared chloral hydrates (1.0 oz.), magnesium sulfate (0.5 oz.), pentobarbital sodium

(100 gr.), and distilled water to make 1,000 cc.; Anomalous Posterior Vena Cava of a Dog, by J. H. Burt (Kans. State Col.); An Embryonal Mixed Tumor in the Lungs of a Calf, by H. R. Seibold (U. S. D. A.); Use of DDT to Control Sarcoptic Mange, by E. N. Moore; Report on the Use of a New Acid-Ester Preparation in Certain Dermatological Conditions in Animals, by L. R. and W. R. Haubrich, in which favorable results are reported from the use of Cerbinol in the treatment of foot rot in cattle and sheep, ringworm in cattle, and moist eczema and ear canker in dogs; and Further Tests on a Fit-Producing Dog Food, by A. F. Morgan and M. Groody (Univ. Calif.).

[Miscellaneous papers] (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 830, pp. 324-325, 327-328, 334-338, illus. 5).—The following contributions are noted: A Method for the Aseptic Bleeding of Animals, by W. E. Maderious (Univ. Calif.); The Treatment of Enteritis with Sulfathalidine, by N. L. Garlick; and Lymphocytoma (Leucemia) in the Cow, by D. E. Jasper, J. H. Sautter, and W. A. Malmquist (Minn. Expt. Sta.).

[Miscellaneous papers] (*North Amer. Vet.*, 27 (1946), No. 3, pp. 159-161, 162-164, illus. 4).—These include discussions entitled Urinary Calculi [in Steers], by H. E. Jensen; and Systemic Blastomycosis in Dogs—A Report of Two Cases, by H. R. Seibold (U. S. D. A.).

[Abstracts of papers on parasitology] (*Jour. Parasitol.*, 31 (1945), Sup., pp. 7-9, 10-11, 12, 13, 15, 17, 18-19, 20, 21, 22, 23).—Abstracts of papers presented at the 1946 meeting of the American Society of Parasitologists included the following of interest to veterinary science: Pathogenicity of Pure Culture *Trichomonas gallinae* Orally Administered to Clean Pigeons, by R. M. Stabler and F. E. Engley, Jr. (pp. 7-8); Further Studies on the Inoculations of *Trichomonas foetus* (Protozoa) in Heifers, by B. B. Morgan (p. 8); Toxicity of Cecal Cores From Chickens Infected With the Protozoan *Eimeria tenella*, by M. J. Bradford and C. A. Herrick (p. 8), and Studies on the Cytochrome Oxidase of the Pig Ascaris, by C. A. Herrick and M. Thede (pp. 18-19) (all Univ. Wis.); Dosage of *Eimeria stiedae* Related to Severity of Liver Coccidiosis, by H. A. Jankiewicz (p. 8); Cryptozoites and Metacryptozoites of *Plasmodium relictum* in Canaries and Pigeons, by F. Coulston and C. G. Huff (pp. 8-9); *Plasmodium circumflexum* in the Ruffed Grouse in Ontario, by A. M. Fallis (p. 9); Studies on *Plasmodium gallinaceum* Brumpt—IV, Parasitemia and Survival in Blood-Induced Infections in Young Chicks, by W. C. Cooper and G. R. Coatney (p. 9) (*E. S. R.*, 94, p. 664) V, Quinine Standardization in Screening Tests Against Blood-Induced Infections in Young Chicks, by G. R. Coatney and W. Clark (p. 12), and VI, A Study of the Pathology in Young Chicks, by L. R. Hershberger and G. R. Coatney (p. 9); *Plasmodium elongatum* in Pekin Ducks, by F. Wolfson (p. 10); The Relations Between Pantothenic Acid and *Plasmodium gallinaceum* Infections of the Chicken, by S. Brackett and E. Waletzky (pp. 10-11); The Relative Activity of Sulfanilamides and Other Compounds in *Eimeria tenella* Infections of the Chicken, by E. Waletzky and C. O. Hughes (p. 11); Aspects in the Control of Intestinal Coccidiosis in Commercial Rabbitries by the Use of Phthalylsulfathiazole, by E. E. Lund (p. 11); The Biological Status of *Sarcocystis*, by L. A. Spindler and H. E. Zimmerman, Jr. (p. 13), Ecology of the Metacercariae of *Fasciola hepatica* in Southern Texas and Its Relationship to Liver Fluke Control in Cattle, by O. W. Olsen (p. 20), The Thermal Death Point of *Cysticercus bovis*, by R. W. Allen (p. 21), and A Note on the Genus *Axine* Abildgaard (Trematoda: Monogenea), by E. W. Price (p. 22) (all U. S. D. A.); Liver Coccidiosis Prevented by Sulfasuxidine, by H. A. Jankiewicz (p. 15); Treatment of Canine Filariasis With Trivalent Arsenicals (*p*-Arsenosobenzamides),

by G. F. Otto and T. H. Maren (p. 17); Studies of Sheep Parasites—VI, Observations on Weather in Relation to Untreated Nematode Infections, by P. A. Hawkins (p. 17) (Mich. State Col.) (E. S. R., 93, p. 622); Hydrogen Ion Concentration as a Factor in Age Resistance to the Fowl Ascarid, by B. B. Riedel and J. E. Ackert (p. 18) (Kans. State Col.); An Anomalous Experience With Phenothiazine, by P. D. Harwood (p. 18); Additional Studies on the Effects of Nodular Worm Infections on Calves During the Prepatent Period, by R. L. Mayhew (p. 19) (La. State Univ.); The Nature of the Mechanism of Encapsulation in Trichiniasis, by W. W. Wantland, C. L. Bardes, and R. S. Levine (pp. 21–22); and Parasite Studies of Quail, *Colinus virginianus* and *Colinus virginianus teranus*, in Mississippi, by J. W. Ward (p. 23) (Miss. State Col.).

Lentin in veterinary medicine: A review, K. MAYER (North Amer. Vet., 27 (1946), Nos. 2, pp. 81–89; 3, pp. 151–158).—The physiological basis for the use of lentin is discussed, and its application to specific diseases is reviewed in detail. There are 32 references.

Efficacy of various agents for delaying absorption of penicillin, E. R. DOLL and W. W. DIMOCK. (Ky. Expt. Sta.). (Jour. Amer. Vet. Med. Assoc., 108 (1946), No. 830, pp. 310–313).—Serum levels resulting from the combination of several agents with saline solution of penicillin are tabulated. It is concluded that “the use of vasoconstrictor drugs, adrenalin and neosynphrin, with saline solutions of penicillin produces only a short prolongation of the effective blood level period in the horse, and offers very little advantage in therapeutic use of the drug. Concentrated solutions of dextrose caused no prolongation of the detectable blood levels over that obtained with saline solutions. The use of dextrose or gelatin in combination with vasoconstrictor drugs offers no significant advantage over saline preparations. Erratic absorption and low blood levels following their administration would be distinct disadvantages in therapeutic use of penicillin. A suspension of calcium penicillin in oil appears to be a satisfactory preparation, having about double the efficiency of saline solutions for maintaining an effective blood concentration in horses.”

Some toxicological and pharmacological properties of streptomycin, H. MOLITOR, O. E. GRAESSLE, S. KUNA, C. W. MUSHETT, and R. H. SILBER (Jour. Pharmacol. and Expt. Ther., 86 (1946), No. 2, pp. 151–173, illus. 8).—In these tests, the pharmacological and toxicological properties of streptomycin were found to be greatly influenced by the presence of traces of impurities and varied considerably in different animal species. The signs and symptoms produced by repeated daily administration of streptomycin over periods of 5–80 days also varied with the animal species. “Weanling rats show a slight retardation of growth and develop a pronounced nervous hyperexcitability. No such changes were noted in adult rats or in mice. Monkeys exhibit a slight impairment of hepatic and renal function and show upon autopsy a fatty infiltration of the liver and, to a lesser degree, of the kidney. These changes are reversible. Dogs develop a mild to severe impairment of renal function, and show upon autopsy lipid deposits in the kidney and liver. In addition, they exhibit signs of cerebellar or labyrinthine disturbance.”

Other findings are also reported and discussed in detail.

Chromates in animal nutrition, W. G. GROSS and V. G. HELLER. (Okla. Expt. Sta.). (Jour. Indus. Hyg. and Toxicol., 23 (1946), No. 2, pp. 52–56, illus. 1).—This problem was studied because of possible toxicity from stream contamination by industrial wastes and included tests with rats, mice, and rabbits. In digestion trials with rabbits, up to 500 p. p. m. of potassium chromate did not affect the utilization of food, but 1 percent zinc chromate

markedly lowered digestion coefficients on practically all components of the feed.

**DDT: A review, with special reference to veterinary medicine, L. A. KANEGIS and M. H. ROEPKE.** (Minn. Expt. Sta.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 830, pp. 316-321).—This review includes 32 literature references.

**Toxicity of rancid fats, F. W. QUACKENBUSH.** (Purdue Univ.). (*Oil & Soap*, 22 (1945), No. 12, pp. 336-338).—This review indicates that one of the chief adverse effects of rancid fats is the destruction of vitamins and other dietary essentials. Certain types of anemia, dermatitis, and reproductive failure are not readily so explained, and it is thought that rancid fats are able to exert a direct toxic effect.

**Human encephalitis of the western equine type in Minnesota in 1941: Clinical and epidemiological study of serologically positive cases, C. M. EKLUND** (*Amer. Jour. Hyg.*, 43 (1946), No. 2, pp. 171-193, illus. 11).—In this extensive study, "no evidence was obtained that would indicate that domestic animals are the important factor in causing human infection."

**Chemotherapy of Erysipelothrix rhusiopathiae infections in mice, M. WOODBINE** (*Vet. Jour.*, 102 (1946), No. 4, pp. 88-93).—Tests in vitro and in mice with seven strains of *E. rhusiopathiae* did not "justify the conclusion that infections of *E. rhusiopathiae* in swine will prove readily amenable to chemotherapy with penicillin."

**The incidence, type, and bacteriology of Salmonella infection in the Army in India, W. HAYES and J. F. FREEMAN** (*Indian Jour. Med. Res.*, 33 (1945), No. 2, pp. 177-193, illus. 1).—In connection with this survey, it is pointed out that almost without exception *Salmonellas* which have been proved to be pathogenic for man have also been incriminated as the cause of disease in animals.

**Natural occurrence of an "induced" antigen in Salmonella cultures, P. R. EDWARDS and A. B. MORAN.** (Ky. Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc.*, 61 (1946), No. 3, pp. 242-243).—The present note records the occurrence in nature of antigens apparently identical with those obtained by cultivation of *Salmonella* in agglutinating serum. It is thought that other antigens hitherto observed only in cultures exposed to agglutinating serum probably also occur in nature. The transformability of apparently distinct types is discussed, and it is stated that a reexamination of some of these types is indicated.

**Trypanosoma equiperdum antigen for complement fixation.—I, Preliminary report: Preparation and titration, V. B. HARTRIDGE and M. D. SCHNEIDER** (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 829, pp. 224-226).

**Sour milk and the tubercle bacillus, A. T. R. MATTICK and A. HIRSCH** (*Lancet* [London], 1946, I, No. 12, pp. 417-418).—An experiment was carried on to test the effect on the tubercle bacillus of actively growing inhibitory streptococci in milk in which guinea pigs were injected intramuscularly with the centrifuged deposit from clotted milk samples containing either 500 or 2,000 tubercle bacilli per cubic centimeter and 1 percent by volume of a 24-hr. culture of either the control *Streptococcus cremoris* or a similar inoculum of one of the streptococci used for the production and isolation of the antibiotic substance 1354. When, after 8 weeks, the animals were killed and examined, it was found that the inhibitory streptococcus had produced sufficient antibiotic substance to kill or render avirulent up to 2,000 tubercle bacilli per cubic centimeter in 50 cubic centimeters of milk, but that no such effect was produced by the lactic streptococcus, which merely formed acid to a somewhat

larger extent. It is therefore concluded that "acidity as such does not destroy the tubercle bacillus in milk, but that if streptococci producing the inhibitory substance previously reported on are present these organisms are destroyed or made avirulent."

**Changes of the serum phosphatase level after infection of cows with *Brucella abortus*, W. BRAUN.** (Calif. Expt. Sta. coop. U. S. D. A.). (*Jour. Immunol.*, 52 (1946), No. 3, pp. 137-144, illus. 1.).—Observations on the serum phosphatase levels of cows before and after infection with *B. abortus* were made as part of an experiment which involved periodical testing of 23 blood constituents of 49 animals. The age of the animals used ranged from 18 mo. to 13 yr.

It was found that 39 cows which showed agglutinative titers after infection with *B. abortus* had a significantly lowered average phosphatase level for approximately 2 mo. after infection, compared with pre-exposure levels and average levels of 9 noninfected control animals. One exceptional animal which failed to show agglutinins after infection exhibited a rapid rise of its phosphatase level for 5 mo., up to 300 percent above the level of all other animals. A second overwhelming infection of this animal with *B. abortus* again caused a rapid increase of its phosphatase level. Six weeks later, however, this animal suddenly showed a rapidly ascending agglutination titer and the phosphatase level decreased simultaneously with the appearance of the titer. These results are discussed (1) on the basis of possible similarities between antibodies and phosphatase molecules, and (2) on the basis of the concept that antigens act as biocatalysts and that specific antibodies formed as final reaction products in response to antigenic stimuli fulfill the function of specific inhibitors of enzymes.

The relationship of dosage and site of inoculation to the agglutinin response to *Brucella abortus* strain 19 vaccine: A comparison of the subcutaneous, intracutaneous, and intracaudal routes, A. D. CAMPBELL and A. W. RODWELL (*Jour. Compar. Pathol. and Ther.*, 55 (1945), No. 4, pp. 277-289, illus. 5).—In order to determine the influence of dosage and route of inoculation upon the agglutinin response to *B. abortus* strain 19 vaccine, groups of adult cattle were inoculated either subcutaneously (5, 1, 0.2, or 0.04 cc.), intracutaneously (0.2 cc.), or intracaudally (1, 0.2, or 0.04 cc.). Maximal mean titers 14 days after inoculation were compared statistically.

The agglutinin response was found to be closely related to dosage and to route of inoculation. The most efficient route for agglutinin production was the intracaudal, which in addition has technical advantages and is free from severe and persistent local reactions. One cc. intracaudally was much more efficient than 5 cc. subcutaneously, was more economical, and caused a transient diminution of milk yield at least no greater than that reported after 5 cc. subcutaneously. Doses of 0.2 cc. or even 0.04 cc. intracaudally appeared to be at least as efficient as 5 cc. subcutaneously or 0.2 cc. intracutaneously. "In our experience the greater the agglutinin response the longer the period necessary for return to negative agglutinin status. Local reactions after subcutaneous inoculation were frequently considerable, but after intracutaneous or intracaudal inoculation they were unimportant and transient." Of 90 cows vaccinated during pregnancy 89 calved normally. Strain 19 was not found in the mammary secretion of any of the cows vaccinated.

Immunity in cattle vaccinated with *Brucella abortus* strain 19 and a note comparing this strain with 45/20, S. J. EDWARDS, A. MCDIARMID, R. S. de ROPP, and D. H. MCLEOD (*Vet. Rec.*, 58 1946), No. 13, pp. 141-146, illus. 1).—Continuing the work with strain 45/20 (E. S. R., 93, p. 621), this study

tested the immunizing value of strain 19. It is concluded that a vaccine prepared from this strain confers a substantial degree of immunity in cattle against a virulent infection applied 35 weeks after vaccination. No evidence of the establishment of a persistent infection from this vaccine strain was obtained.

The transference of agglutinins for *Brucella abortus* from cow to calf and their persistence in the calf's blood, A. McDIARMID (*Vet. Rec.*, 58 (1946), No. 13, pp. 146-149, illus. 3).—Using 16 heifers exposed to a virulent infection during pregnancy in the test of strain 19 vaccine, by Edwards et. al., noted above, no agglutinins were demonstrated in the blood of the calf till it had ingested colostrum containing immune bodies. Agglutinins then commonly appeared in from 1 to 3 hr., reaching their maximum by 24 hr. and then receding as a logarithmic curve over periods varying from days to months. The period of persistence depended to a large extent on the titer of the colostrum.

The survival of *Corynebacterium pyogenes* in discharges from the udder and the uterus of the cow, R. W. ROACH (*Vet. Rec.*, 58 (1946), No. 15, pp. 169-171).—Results are given of the effect of acriflavine, iodine, metholyl, dettol, crystal violet, Milton, and lysol on *C. pyogenes* when this organism was present in discharges from the udder and uterus. With the exception of iodine (the use of which is suggested) and lysol, none of the above disinfectants had any appreciable effect on the organisms. The organism was shown to remain alive for at least 19 days in a sample of summer mastitis milk kept at room temperature. While readily destroyed by heat of 80° C., clotting of the discharge at this temperature may assist the organism to survive for longer periods. Instruments contaminated with *C. pyogenes* discharges were found to be difficult to sterilize.

The intramammary therapy of bovine mastitis (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 828, pp. 127-135).—This is a report of a subcommittee of the Committee on Animal Health of the National Research Council, consisting of R. B. Little (chairman), C. S. Bryan (Mich. State Col.), W. E. Petersen (Univ. Minn.), W. N. Plastring (Univ. Conn.), and O. W. Schalm (Univ. Calif.). Its purpose is set forth as "to point out the value and limitations of intramammary therapy and to summarize results obtained in controlled investigations on each of the chemotherapeutic and antibiotic agents available for use in the treatment of bovine mastitis." Following a discussion of available chemotherapeutic and antibiotic agents, it is stated that treatment is not the answer to the bovine mastitis problem. "With udders suitable for medication, in which a diagnosis of the infection has been made, proper medication can be expected to salvage many cases of chronic mastitis and thus prolong the usefulness of cows previously regarded as hopeless. With regret, it is necessary to point out that, up to the present, treatment cannot be regarded as the answer to the problem of mastitis, for the real answer is still, now as before, prevention of infection."

Studies on bovine mastitis.—III, Penicillin therapy in streptococcic mastitis, H. J. HARDENBROOK, J. O. ALBERTS, and H. S. BRYAN. (Univ. Ill.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 828, pp. 140-142, illus. 1).—Continuing this series (E. S. R., 93, p. 497), results of the treatment of 44 *Streptococcus agalactiae* positive quarters of 18 cows are reported.

The udder infusion of 25,000 units of sodium penicillin in each quarter proved to be relatively nonirritating. Milk production diminished only 2.54 percent the week following treatment. Twenty-seven quarters became negative after one udder infusion, 7 required two infusions, and 3 required three

infusions before becoming negative. Seven quarters remained positive following three separate udder infusions at intervals of 12 and 14 days. Fourteen of the 18 cows became negative, while 4 cows remained positive as judged by microscopical and bacteriological examinations 1 mo. after treatment. Therapeutic results did not correlate with the number of lactations, which varied from first to fifth or with the stage of lactation which varied from the first month to the seventeenth month. Equally good results were obtained regardless of the condition of the udder or pathological change which had developed within the udder.

Effects of infusion of penicillin in the bovine mammary gland, D. E. JASPER and F. J. WEIRETHER. (Minn. Expt. Sta.). (*Vet. Student*, 8 (1945), No. 2, pp. 73-76, *illus.* 2).—From this review it is concluded that penicillin is relatively nontoxic and large amounts may be infused without danger of disturbing reactions. The concentration in the gland is reduced most rapidly during the first 10-hr. period following infusion and may be accounted for chiefly by dilution with milk being secreted and by migration out of the gland. Distilled water is regarded as a more satisfactory diluent than is physiologic saline.

Om streptokokmastitis [Streptococcic mastitis], P. L. HANSEN (*Norsk Vet. Tidsskr.*, 58 (1946), Nos. 2, pp. 43-59, *illus.* 1; 3, pp. 79-94).—A review of the literature is supplemented by observations on the effect of the disease on milk production and other phases.

Tennessee's mastitis control plan, A. W. MURRAY (*Jersey Bul.*, 65 (1946), No. 4, pp. 244, 259-260, 262, 264-265).—A program initiated on March 16, 1945, is outlined whereby 15 herds have been selected to demonstrate "just what could be done to eliminate, control, and prevent mastitis through good herd management and proper treatment."

Effects of stilbestrol in retained placenta, G. R. MOORE. (Kans. State Col.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 327, pp. 79-83). Observations on the therapeutic effects of stilbestrol on cases of bovine retained placenta indicated that it had little if any value in the expulsion of the placenta and may sometimes be definitely harmful.

Effects of stilbestrol on pyometra following retained fetal membranes, G. R. MOORE. (Kans. State Col.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 328, pp. 153-156).—Forty-three cows suffering from pyometra following the manual removal of retained placentae were treated with stilbestrol 2 weeks after removal. In this group 97.8 percent retained their fertility as compared to 86 percent in a control group of 50 cows. In the controls, an average of 144.8 days per cow elapsed from parturition to the next conception following treatment, while only 86.2 days on the average elapsed in the treated group.

Effects of chorionic gonadotropin on cystic ovaries in the cow, G. R. MOORE. (Kans. State Col.). (*Vet. Med.*, 41 (1946), No. 5, pp. 163-164).—A group of 18 dairy cows was treated for cystic ovaries with chorionic gonadotropin. Twelve showed improvement within 11 days following a single treatment, with 2 animals relapsing. Eight were treated a second time, with 7 recoveries. One cow was treated a third time without success. Of the 18 cows, 17 experienced normal cycles following the first or second treatment, and 12 are known to have conceived.

Tick-transmitted protozoa in the peripheral blood of clinically healthy cattle in Palestine, I. H. PATTISON (*Jour. Compar. Pathol. and Ther.*, 55 (1945), No. 4, pp. 243-249, *illus.* 4).—This examination of single blood smears from 550 clinically healthy cattle and of repeated smears from 7

healthy cattle indicated that a high percentage of animals were carrying tick-transmitted parasites. *Anaplasma marginale* and *Theileria annulata* are very commonly found, but are never numerous, and *Babesia bigemina* parasites may be found occasionally. *Babesiella berbera* parasites were found in no case. The forms of parasites found are described, and certain abnormalities of the red blood cells noted.

**Scoffing at bovine tuberculosis eradication** (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 829, pp. 227-228).—This is mainly a reply to the article by Rainey (E. S. R., 94, p. 379).

**Some observations on the poisonous properties of bracken (*Pteris aquilina*)**, G. D. SHEARER (*Jour. Compar. Pathol. and Ther.*, 55 (1945), No. 4, pp. 301-307).—Freshly cut bracken (*P. aquilina*) was fed to two heifers. One of these ate 915 lb. as an exclusive diet with no definite signs of illness till the sixty-eighth day but eventually died. The other, receiving a ration of 50 percent bracken, consumed 678 lb. in 78 days without showing any symptoms of poisoning.

Chemical analysis of the plant during the growing season showed it to be of low nutritive value and to contain varying amounts of a catechol tannin, but no other substance to which its poisonous properties could be ascribed was found.

**Chronic molybdenum poisoning in cattle**, J. W. BRITTON and H. GOSS. (Univ. Calif.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 828, pp. 176-178).—Excessive amounts of molybdenum were found in the forage and in the viscera of affected cattle in a localized area of Kern County, Calif., and it is assumed that the disease observed in these young animals resulted from the ingestion of excessive amounts of molybdenum in the forage. A portion of the disease, as observed in the field, was reproduced by administering daily doses of sodium molybdate to a heifer calf.

**Incidence of pathogenic bacteria in market milk of Cairo**, A. M. WAHBY and A. ROUCHDY (*Vet. Jour.*, 102 (1946), No. 4, pp. 94-102).—An examination of 200 samples of Cairo market milk, of which 76 were raw, 44 boiled, and 80 mixed and boiled, revealed that "all samples from which pathogenic organisms were actually isolated or their presence was highly probable (high agglutination titers) were either of raw or of mixed (raw and boiled) milk."

**The serological diagnosis of Johne's disease of sheep**, B. SIGURDSSON, H. VIGFUSSON, and S. THEODORS (*Jour. Compar. Pathol. and Ther.*, 55 (1945), No. 4, pp. 268-276).—The results of a new diagnostic complement fixation test for Johne's disease among sheep are described. The antigen used was extracted from the infected intestinal mucosa, and the study was carried out on an infected flock of 55 sheep. Out of 31 sheep found to be infected on slaughter, 30 had proved to be serologically positive, the remaining one not having been subjected to an adequate test. The sera from 4 more sheep in which no lesions could be found in the intestines were also found to be strongly positive. Of 118 sheep from healthy areas tested as controls, only 4 showed serological reactions and these were very weak. Thirty-nine sheep of the experimental flock were also tested by means of the intradermal johnin test, using johnin PPD as described. Only about 50 percent of the infected sheep reacted to the various johnins in the strengths used.

**Studies in louping-ill.**—I, Cultivation of louping-ill virus in vitro. II, Pathogenic properties of culture virus, D. R. WILSON (*Jour. Compar. Pathol. and Ther.*, 55 (1945), No. 4, pp. 250-267, illus. 2).—Studies in immunity to louping-ill were carried out to determine whether tissue culture virus could be used as an efficient substitute for sheep tissue virus in vaccine therapy.

The paper here presented as part of that investigation deals with (1) cultivation of the virus in vitro with the object of obtaining sufficient quantities to warrant a study of its antigenic and immunizing value; and (2) observations on the pathogenic properties of culture virus.

**Contagous ovine pneumonia caused by a filterable virus, Z. MORCOS and O. A. and R. ZAKI** (*Vet. Med.*, 41 (1946), No. 6, pp. 202-204).—Outbreaks of contagious pneumonia in Egypt are described as caused by a filterable virus present in the blood and internal organs of sheep. This virus was pathogenic to rabbits, but not to cavies, white rats, mice, or pigeons, on experimental inoculation. Secondary organisms were isolated which played an important part in complicating the disease. Formalized tissue vaccine prepared from liver and spleen gave promising results in immunization.

**Etude de l'action de la phénothiazine sur la strongylose gastro-intestinale du mouton [Action of phenothiazine on the gastrointestinal strongyles of sheep], M. ROSE** ([Algeria] *Inst. Agr. et Serv. Rech. Expt. Agr. Algérie Ann.*, 2 (1945), No. 1, pp. 5-12, illus. 2).—From tests carried on with three lots of two sheep each, it is concluded that phenothiazine is an efficacious vermicide for gastrointestinal strongylosis, though more than one dose is always necessary.

**Transmission of Brucella suis from swine to cattle under pasture conditions, C. ELDER** (*Missouri Sta. Res. Bul.* 398 (1946), pp. 15).—Eight cows were kept in close contact in a small pasture with swine artificially infected with *B. suis*. There was no evidence of spread of infection from the swine, and all attempts to isolate *Brucella* organisms from the cattle were negative, although control negative gilts acquired the infection when running in the same pasture. Cultures of *B. suis* were isolated from both infected hogs and previously negative gilts which served as controls.

Three abortions in the cattle occurred while the experiment was in progress, but in no case was it possible to isolate *Brucella* organisms from the aborted fetuses or the cows. There was no evidence of any sterility or breeding difficulty, and cases of retained placenta were not observed. Several of the cows on experiment developed low blood agglutination titers and varied from negative to complete agglutination in dilutions of 1-160, but there was no proof that these low titers were actually due to *B. suis*.

**A transmissible gastroenteritis in pigs, L. P. DOYLE and L. M. HUTCHINGS** (*Ind. Expt. Sta.*). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 829, pp. 257-259).—A sporadic disease having clinical and pathologic features of gastroenteritis has been observed to cause heavy death losses in baby pigs. Swine more than a few days old are also affected, but less severely.

The disease developed promptly in baby pigs following pen exposure, and also following per os administration of either triturated gastrointestinal tract and content or the filtrate of the triturated gastrointestinal tract. One effort to transmit the disease to a calf failed.

**Concentration of hog-cholera virus in the blood of artificially infected swine at different stages of the disease, C. G. COLE, R. R. HENLEY, and E. D. HUBBARD** (U. S. D. A.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 828, pp. 143-147).—Each of five pigs was injected with 2 cc. of regular BAI hog-cholera virus and bled at different intervals ranging from 3 to 9 days after injection. Various dilutions were made of each blood, and selected dilutions were tested for virulence in doses ranging from 1/25,000 cc. to 1/10,000,000 cc. of the original virus-blood. All pigs that remained normal following injection of the diluted fractions were later injected with a known virulent virus. All developed cholera, and with few exceptions all died or

were killed for virus. Necropsies were held on all pigs that died or were killed, and with one exception all showed lesions characteristic of hog cholera.

Evidence obtained indicated that blood from cholera-infected pigs contains the most virus when drawn on the sixth to eighth day, inclusive. With the use of blood drawn on the sixth to ninth day, hog cholera was produced in eight pigs injected with 1/500,000 cc., in eight pigs injected with 1/750,000 cc., in eight pigs injected with 1/1,000,000 cc., and in two pigs injected with 1/2,500,000 cc. Of six pigs injected with 1/5,000,000 cc., five remained normal, and one developed cholera due perhaps to accidental exposure. Of six injected with 1/10,000,000 cc., all remained normal. A minimum lethal dose between 1/1,000,000 cc. and 1/2,500,000 cc. of virus was indicated.

Trichinae killed by 120-deg. F. dehydration, L. A. SPINDLER, C. F. DUNKER, and O. G. HANKINS. (U. S. D. A.). (*Food Indus.*, 18 (1946), No. 3, pp. 86-88, 210, 212, illus. 3).—Tests of the effect of dehydration on the viability of trichinae in pork showed that the larvae exhibited considerably greater resistance to dehydration at 102° and 70° F. than at 120°, and temperatures below this point are not recommended as a practicable procedure at this time. A temperature of 120° or higher, however, is considered safe, so far as infection by trichinae is concerned, in pork dried to a moisture level of 2 percent. "Even a moisture content as high as 7 or 8 percent would appear satisfactory from this point of view when the dehydration temperature does not fall below 120° F."

Further observations on the incidence of parasitic aneurysm in the horse, C. W. OTTAWAY and M. L. BINGHAM (*Vet. Rec.*, 58 (1946), No. 14, pp. 155-159, illus. 3).—An account is given of the examination of 87 ponies for evidence of infestation with *Strongylus vulgaris*, in which particular attention was paid to the location of parasitic aneurysms. Little correlation could be found between the physical condition of the animal, the number of eggs per gram of feces, the percentage of blood eosinophils, and the presence of aneurysms, and it is considered that the comparisons of such findings can be of small value for diagnostic purposes.

Penicillin therapy in fatal case of equine tetanus, D. L. LICHTY ([U. S.] *Off. Surg. Gen.*, U. S. Army Med. Dept. *Bul.*, 5 (1946), No. 4, pp. 486-487).—An acute case in a 4-year-old gelding was treated with penicillin sodium, a total of 4,100,000 units being used. No appreciable gain or improvement was noted at any stage and the animal died on the eighth day.

Potassium deficiency in the dog, W. R. RUEGAMER, C. A. ELVEHJEM, and E. B. HART. (Wis. Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc.*, 61 (1946), No. 3, pp. 234-238, illus. 1).—Dogs fed the basal ration used by S. G. Smith<sup>5</sup> failed to grow and developed a paralysis curable by potassium therapy. One animal receiving biotin became paralyzed and responded to potassium therapy.

Quick protection and therapeutic effect of distemperoid virus, R. G. GREEN. (Univ. Minn.). (*North Amer. Vet.*, 27 (1946), No. 3, pp. 165-168).—This reports experiments with dogs from which it is concluded that "the distemperoid virus appears to be a tool of unprecedented value in the control and management of canine distemper," both as immunizing agent and, if used early in the course of infection, a specific therapeutic agent of great usefulness. See also a previous note (G. S. R., 94, p. 663).

Distemperoid virus interference in canine distemper, R. G. GREEN and C. S. STULBERG. (Univ. Minn.). *Science* 103 (1946), No. 2678, pp. 497-498).—Continuing the above study, it was found that a distemper virus modified by ferret passage so as to become a harmless vaccine for foxes and dogs

exhibits the interference or cell-blockade phenomenon with respect to a virulent distemper infection in foxes. Ten control foxes receiving virulent distemper virus died, while 30 foxes receiving distemperoid virus in addition lived.

**Rabies and its control**, H. N. JOHNSON ET AL. (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 830, pp. 293-302).—This is a report prepared by a special subcommittee of the Committee on Animal Health, National Research Council. Recommendations for the control of the disease in the United States are included.

**A rapid method for the diagnosis of rabies in animals**, N. VEERARAGHAVAN (*Indian Jour. Med. Res.*, 33 (1945), No. 2, pp. 295-297).—A cultivation technic is described as being as delicate as the biological test and yielding results within a few hours even in grossly decomposed brains.

**Poultry husbandry: Prevention and control of disease**, K. T. MADDY. (Iowa State Col.). (*Vet. Student*, 8 (1945), No. 2, pp. 77-81).—The principles and practices of poultry sanitation and hygiene are outlined as essential to an effective disease control program.

**A field case of nutritional encephalomalacia in chicks**. R. H. COMMON and H. G. LAMONT (*Vet. Rec.*, 58 (1946), No. 17, pp. 191-192).—The case history of an outbreak in Northern Ireland of "nonrachitic leg weakness" not associated with ariboflavinosis or perosis is presented in some detail. Clinical, pathological, and nutritional evidence is adduced in support of the diagnosis of nutritional-encephalomalacia, although this condition has been very rarely reported in the British Isles.

**Bone tumors in fowls injected intravenously with causative agent of Rous sarcoma**, M. PIKOVSKI and L. DOLJANSKI (*Soc. Expt. Biol. and Med. Proc.*, 61 (1946), No. 3, pp. 246-248, illus. 1).—The appearance of an osteoid sarcoma in a series of chickens injected intravenously with the causative agent of Rous sarcoma derived from sarcoma cell cultures is reported.

**A filtrable agent producing lymphoid tumors and osteopetrosis in chickens**. B. R. BURMESTER, C. O. PRICKETT, and T. C. BELDING. (U. S. D. A.). (*Cancer Res.*, 6 (1946), No. 4, pp. 189-196, illus. 7).—This report describes briefly the manifestations of a filtrable agent associated with a transplantable lymphoid tumor of the chicken, noted by Olson (*E. S. R.*, 86, p. 538) and demonstrated in three experiments involving 150 birds.

Inocula containing viable tumor cells induced tumor growth at the site of inoculation, metastasis to the viscera, and death to all birds in a relatively short time (average 10.2 days); whereas centrifuged extracts of the same tumors, or filtered plasma of birds bearing tumors, when injected intramuscularly, intraperitoneally, or intravenously into 2- to 3-day-old chicks, induced in 6 mo. a high incidence of osteopetrosis and lymphomatous tumors of the viscera (average of 81 percent on gross examination) but no tumors at the site of inoculation.

"These results suggest that the avian lymphoid tumor strain under study, which has been transferred serially in over 200 passages by transplantation of its cells carries with it a filtrable agent or agents capable of inducing osteopetrosis and lymphomatous tumors of the viscera after an incubation period of at least 2 mo."

**Neoplastic disease of the fowl with special reference to its history, incidence, and seasonal variation**, J. G. CAMPBELL (*Jour. Compar. Pathol. and Ther.*, 55 (1945), No. 4, pp. 308-321, illus. 1).—During a 5-yr. investigation of spontaneous neoplastic disease in the domestic fowl, 2,063 birds were submitted to detailed examination. In 386 cases of neoplastic disease encoun-

tered, with an incidence of 18.7 percent, 28 distinct types of neoplasia were observed. Neoplasms were most common in the Buff Rock breed (38.8 percent) and least in White Wyandottes (10.3 percent). The breed incidence for the various types of neoplastic disease was also investigated, but the only significant difference was the absence of leukemia in the White Wyandotte and Light Sussex breeds. The seasonal variation showed a maximum incidence in the spring months, particularly March, which was tentatively attributed to the stimulation of latent preneoplastic cells by sex hormones. A comparison of tumor distribution in visceral lymphomatosis (fowl paralysis) and lymphocytoma showed that in the latter the liver and intestines were involved more frequently than in fowl paralysis. A brief summary of the literature dealing with the incidence of neoplastic disease is given, and the problems associated with the classification of avian neoplastic disease are discussed.

**A Malayan virus disease of fowls,** W. ORR and K. T. JOHN (*Vet. Rec.*, 58 (1946), No. 11, pp. 117-119).—This paper, prepared in 1941 and delayed by the Japanese invasion of Malaya, discusses an epornithic disease which is believed to have been in existence in Malaya for an indefinite period prior to its recognition in 1934.

**Does meat and bone meal cause nutritional disorders in chickens?** E. J. SHEEHY, B. J. SENIOR, and E. M. BURKE ([Ireland] *Eire Dept. Agr. Jour.*, 42 (1945), No. 2, pp. 194-213).—Several series of feeding tests are reported from which it was concluded that neither meat and bone meal when fed in proper proportions (not more than 13 percent in the ration) nor meat meal is directly responsible for the production of any disorders in chickens. The need of providing a complete diet, including riboflavin and other members of the vitamin B complex, is emphasized. Results as to growth and progress were similar whether the origin of the meat and bone meal was the horse or ox. Meat meal from sound animals and manufactured under sanitary conditions was not found to be necessarily toxic to chickens if fed after decomposition, although "in the absence of fuller information as to the type of decomposition which took place in the sample under investigation it is emphasized that decomposed foods of any sort should not be fed to chickens."

**Experimental zinc phosphide poisoning in fowls,** A. ROBERTSON, J. G. CAMPBELL, and D. N. GRAVES (*Jour. Compar. Pathol. and Ther.*, 55 (1945), No. 4, pp. 290-300).—Using a modification of the method of Elmore and Roth (E. S. R., 91, p. 120) for the estimation of phosphide, the lethal dose of zinc phosphide for fowls was determined as lying between 7 and 17 mg. per kilogram of body weight and frequently was about 10 mg. Chronic effects were produced by repeated sublethal doses. The symptoms, lesions, and analytical findings are described, and their significance in toxicological work is discussed. See also a note by Hare and Orr (E. S. R., 92, p. 706).

**Comparison between in vitro and in vivo glycogen utilization in the fowl nematode *Ascaridia galli*,** W. M. REID (*Jour. Parasitol.*, 31 (1945), No. 6, pp. 406-410).—A comparison between in vivo and in vitro glycogen utilization in avian *A. galli* indicated that the in vitro technic for glycogen metabolism has probably reflected satisfactorily the conditions in vivo. *A. galli* apparently utilized the glycogen reserve much more rapidly than *A. lumbricoides*, which may account for its rapid expulsion after host starvation.

**Effect of sulfaguanidine on the course of infection in chickens with *Eimeria tenella*,** E. E. WEHR and M. M. FARR. (U. S. D. A.). (*Jour. Parasitol.*, 31 (1945), No. 6, pp. 359-365, illus. 1).—Continuing the studies of Farr and Allen (E. S. R., 86, p. 833), experiments were conducted with 388 birds. The feeding of 0.5 percent sulfaguanidine mash for 7 consecutive days decidedly

benefited young birds when treatment was begun 1 day before or within 2 days after experimental infection. Similar feeding of 1.2 percent mash prevented deaths among groups of birds placed on treatment 1 day prior to, on the day of, and 1 day after inoculation. The administration of this mash as late as the third day after infection markedly reduced mortality. The results apparently demonstrated a coccidiostatic action of sulfaguanidine.

**Sulfamerazine therapy in experimental cecal coccidiosis of chickens,** M. M. FARR and E. E. WEHR. (U. S. D. A.). (*Jour. Parasitol.*, 31 (1945). No. 6, pp. 353-358).—Experiments were conducted with 593 chickens to determine the effect of sulfamerazine on the course of infection with *Eimeria tenella*. When administered in the mash in a concentration of 1 percent it materially reduced mortality from cecal coccidiosis, but this percentage of the drug was toxic as indicated by the presence of spleen and liver lesions and retarded weight gains. When fed before or within 1 day after inoculation it was markedly coccidiostatic as long as it was being administered, but within 4 to 6 days after cessation of this treatment clinical coccidiosis developed. One-fourth percent sulfamerazine mash was an effective prophylactic agent for cecal coccidiosis and also was of benefit as a treatment when fed within 2 days after inoculation. This percentage was considerably less toxic than 1 percent, but an occasional bird showed spleen and liver lesions; some loss in weight gains was noted.

**Sulfamerazine as a prophylactic in pullorum disease in poults,** F. E. MULLEN (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 828, pp. 163-164).—Tests with 13,236 poults from pullorum-infected breeding stock receiving 0.5 percent of sulfamerazine in the starting mash for 5 days showed a loss of 3.9 percent as compared with 17 percent of 9,629 untreated birds. In this concentration sulfamerazine showed adverse effects if fed more than 5 days.

**Note on Salmonella in poultry products,** M. D. SCHNEIDER (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 830, pp. 332-333).—Examination of 199 samples of egg pulp revealed 60 cultures of *S. pullorum* and 1 of *S. oranienburg*. In 63 samples of powdered whole egg, *S. typhimurium* was isolated from the product of a drying plant in Missouri, and *S. montevideo*, *S. paratyphi* B, *S. cerro*, and 2 cultures of *S. oranienburg* from egg powder produced in Oklahoma.

**An outbreak of pasteurellosis in wild ducks,** E. R. QUORTRUP, F. B. QUEEN, and L. J. MEROVKA (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 827, pp. 94-100, illus. 8).—An outbreak in Texas is described as the first authentic record of pasteurellosis in wild ducks. A strain of *Pasteurella* which differs from *P. multocida* in its failure to grow on ordinary mediums, to produce  $H_2S$  and  $NH_3$ , and by producing a moderate degree of hemolysis is described. This organism is especially virulent, killing ducks after oral administration in about 18 hr.

**Treatment of Pasteurella multocida (fowl cholera) infection in wild ducks with autogenous bacterin and penicillin,** F. B. QUEEN and E. R. QUORTRUP (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 827, pp. 101-103).—In experiments carried on in connection with the outbreak noted above, autogenous bacterin and penicillin were both found to protect wild ducks against experimental infection with *P. multocida* (strain 800).

**Recent studies on the treatment of infectious sinusitis in turkeys,** E. MCNEIL and W. R. HINSHAW. (Univ. Calif.). (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 829, pp. 260-261).—In these comparative tests, 10 percent silver nitrate in freshly prepared aqueous solutions proved superior to five other drugs, although 7 percent Protargol showed some promise and

**Spirochetosis in turkeys** (a preliminary report), H. A. HOFFMAN, T. W. JACKSON, and J. C. RUCKER (*Jour. Amer. Vet. Med. Assoc.*, 108 (1946), No. 830, pp. 329-332, illus. 2).—This is preliminary report of observations on a mild infection encountered in a flock of turkey hens in California. The course of the disease together with convalescence approximated 10 to 21 days or longer. Careful search failed to reveal the presence of the several varieties of ticks known to transmit spirochetosis in other species of birds.

## AGRICULTURAL ENGINEERING

**"Common well" nomograph**, I. J. HOOKS and H. GRAY. (Univ. Maine). (*Civ. Engin.*, 16 (1946), No. 4, pp. 175-176, illus. 1).—The authors point out that of eight assumptions upon which the Dupuit analysis of well output and corresponding water-table drawdown is based, five are never exactly fulfilled by nature and two other are theoretically incorrect. If, however, the slope of the ground-water table is rather small, the Dupuit formula gives satisfac-

tory results. It is here stated in the form  $q = \pi k \frac{H^2 - h^2}{\ln(R/r)}$  in which  $q$  denotes

the rate of water-discharge from the well,  $k$  denotes the coefficient of permeability of the aquifer, and the coordinates of any two points on the drawdown curve are given by  $(R, H)$  and  $(r, h)$ , respectively. The values of  $H$  and  $h$  are measured vertically from the surface of the impervious stratum, and the values of  $R$  and  $r$  are measured from the center of the well. For preliminary computations this integration is somewhat cumbersome because of the difference of two squares and the  $\ln$  factor. The authors accordingly devised a nomograph by means of which: (1) If the coordinates of two points on the lowered water table are known, together with the coefficient of permeability, it is possible to find the discharge from the well; (2) if the coordinates of two points on the lowered water table are known, together with the discharge, it is possible to find the coefficient of permeability; and (3) if both the discharge and the permeability coefficient are known, together with the coordinates of one point on the drawdown curve, it is possible to find the depth of the water at a given distance from the well. The manner of using the figure for solutions of each of these three types is explained.

**Surface water supply of the United States, 1943, part 3, Ohio River Basin** (*U. S. Geol. Survey, Water-Supply Paper 973* (1945), pp. 652+, illus. 1).—This paper records measurements of stream flow for the year ended September 30, 1943.

**Surface water supply of the United States, 1944, parts 4, 7, 9, 10, 11, and 14** (*U. S. Geol. Survey, Water-Supply Papers 1004* (1946), pp. 228, illus. 1; 1007 (1946), pp. 378+, illus. 1; 1009 (1946), pp. 360+, illus. 1; 1010 (1946), pp. 181+, illus. 1; 1011 (1946), pp. 405+, illus. 1; 1014 (1946), pp. 223+, illus. 1).—These papers record measurements of stream flow for the year ended September 30, 1944, No. 1004 covering the St. Lawrence River Basin; No. 1007, the lower Mississippi River Basin; No. 1009, the Colorado River Basin; No. 1010, the Great Basin; No. 1011, the Pacific slope basins in California; and No. 1014, the Pacific slope basins in Oregon and lower Columbia River Basin.

**Quality of surface waters of the United States, 1943**, C. S. HOWARD and S. K. LOVE (*U. S. Geol. Survey, Water-Supply Paper 970* (1945), pp. 180+).—This report of analyses is concerned only with waters in the south Atlantic slope and eastern Gulf of Mexico basins the lower Mississippi River Basin,

the western Gulf of Mexico basins, and the Colorado River Basin. The data given include for each sample some or all of the following: Suspended matter, oxygen consumption, color, specific conductance, silica, iron, calcium, magnesium, sodium, potassium, bicarbonate, sulfate, chloride, fluoride, nitrate, dissolved solids, and total hardness as  $\text{CaCO}_3$ .

Water levels and artesian pressure in observation wells in the United States in 1943.—Part 5, Northwestern States, O. E. MEINZER, L. K. WENZEL, ET AL. (*U. S. Geol. Survey, Water-Supply Paper 990 (1946)*, pp. 279+, illus. 5).—This part covers the States of Colorado, Idaho, Montana, Oregon, Utah, Washington, and Wyoming.

Linings for small irrigation ditches, W. E. CODE (*Colo. Farm Bul. [Colorado Sta.]*, 8 (1946), No. 2, pp. 2, 14–15, illus. 2).—Lining a small irrigation ditch with concrete (thicknesses of 2, 2.5, and 3 in.) saved 91 to 95 percent of the water formerly lost through seepage. Road oil and bentonite linings saved 70 and 65 percent, respectively. Irrigating was made easier. All linings were in good condition after 1 yr., although holes appeared in the road oil lining, apparently caused by birds picking out grasshopper eggs.

In the preparation of the concrete linings, difficulty in trimming the subgrade to exact shape was encountered even when a template for the outside shape was used. This difficulty was overcome by means of a trimmer, rotating on a true center, with which the final inch of earth was removed. A troweling tool of semi-circular cross-section and made, like the trimmer, to swing on a true center, was devised for the smoothing of the inner surface of the concrete lining. Its use reduced the number of irregularities causing turbulence of water flow. Both tools were controlled by two-by-four lumberstrips laid to line and grade along the sides of the ditch.

The sawmill scale (index) board, R. C. JOHNSON. (Coop. U. S. D. A. et al) (*Michigan Sta. Quart. Bul.*, 28 (1946), No. 3, pp. 181–188, illus. 3).—The scale (or index) board here described is a modification designed to improve upon the accuracy and adaptability of existing equipment, and to be relatively simple and economical to construct. It is considered to afford a good starting point for the improvement of small sawmills, especially those producing softwood lumber or custom-sawed hardwood lumber for building purposes, but to have less application in the sawing of grade hardwood lumber (usually marketed random width). Improvements include the following: (1) the movement of the index pointer 2 in. for each inch movement of the knee, brought about by the pulley ratio. This device makes it possible to double the base scale of the index ruler so that the inch marks are actually 2 in. apart. (2) The tongue and grooved slip sticks between the inch scales are marked to indicate the number of boards of various thicknesses to the knee or to any desired last board thickness. (3) A window device shows the distance from the face of the knee to the saw. (4) Both the slip sticks and the glass or celluloid of the window frame are quickly removable to permit insertion of new combinations of lumber thicknesses or saw kerf changes.

Detailed instructions for building the new form of scale board are given.

Electric welding saves on cost of steel building frames (*Wisconsin Sta. Bul.* 468 (1946), pp. 17–19, illus. 2).—"Site welding" (electric welding of frame members, etc., at the building site) was found to effect a cost saving great enough so that steel framework for farm buildings may come into common use. It is pointed out that the new plan eliminates fabrication plant costs and lowers the heavy freight charges for transportation of bulky prefabricated roof trusses. Labor costs are also lowered. The trusses used in a new barn at the university farms were made up with an average of 2 man-hr. labor, compared with 10.5 man-hr. for bolted trusses.

**What's ahead in flame weeding, F. B. WRIGHT.** ([N. Y.] Cornell Expt. Sta.). (*Farm Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 1-2, illus. 1).—The experiments here discussed were made with a liquid-fuel type of flame cultivator, though a machine illustrated and described is of the gas-fuel type, burning a propane-butane mixture, provided with burners arranged in pairs for cultivating two rows at a time and equipped also with a hydraulic lift to handle the burners and runners.

In the trials carried out at Ithaca, the best results were obtained with corn, as when this was several inches higher than the weeds it was possible to kill practically all the weeds with no injury to the crop. Spinach, on the other hand, was found more sensitive to heat than most weeds, so that even small weeds could not readily be killed without damage to the spinach. The makers' claim that killing the first crop of weeds without so disturbing the soil as to bring more weed seeds up into the germination zone prevents further weed growth for the season was in some measure substantiated in the experiments. The machine used could be run by one man at from 2.5 to 5 miles per hour, permitting the coverage of large acreages in a day; the burner fuel consumption was from 5.5 to 6 gal. per hour: and "with improvements in the design of the machine it may be entirely possible to destroy weeds successfully and economically in more New York State crops than these tests indicate. The machine might also be useful for thinning crops and cleaning weeds out of nurseries."

**Barn cleaners help mechanize chores** (*Wisconsin Sta. Bul.* 468 (1946), pp. 19-20, illus. 1).—Various types of gutter-conveyor cleaners are briefly discussed, the conveyor dropping the litter, in all types, onto an elevator which loads it into a spreader. A small model of a type of conveyor making a complete circuit of a rectangular gutter layout, and a scoop cleaner, drawn along the gutter by electric power but pulled back by hand, are also noted.

**Complications can occur in barn-drying hay** (*Wisconsin Sta. Bul.* 468 (1946), pp. 20-21).—A new type of lateral duct, designed to prevent plugging of the vent with hay and dust, is described. The new duct is mounted at least 6 in. above the floor and the air vent consists of a 2-in. slot along the bottom of the duct. In three barns this duct permitted air flow from the duct into the hay with very little loss of pressure. Errors in barn hay-drying practice causing trouble under Wisconsin conditions included cutting chopped hay into too short a length, too high a moisture content in the hay when put up (indications being that it should not exceed 35 percent), putting in too great a depth of hay at one time, and failing to provide an air intake from fresh, dry outside air. It appeared that a depth of 8 ft. may be too great when the hay is quite green and chopped, or the weather rainy.

**Hay drying** (*Massachusetts Sta. Bul.* 428 (1945), p. 33).—Barn-curing of hay in 1944 was successfully carried out over ducts placed on the barn floor. About 40 tons of hay, of which the greater part was put into the barn at a moisture content of 45 percent, "was cured satisfactorily, and indications are that this system can be used in New England with considerable success." A set-up for curing baled hay has been added.

**Cranberry storage investigation** (*Massachusetts Sta. Bul.* 428 (1945), p. 32).—Berries were stored at 45° F. both in a normal atmosphere and in air of which the oxygen content had been reduced to 10 percent and the carbon dioxide content raised to 10 percent; others, in an air-cooled screenhouse. Of berries picked and stored September 9 and tested by screening on October 6, the losses were as follows: The 45-degree room, normal atmosphere, 4.4

percent; 45° room, controlled atmosphere, 2.9 percent; screenhouse, 7.1 percent. Berries stored in the controlled atmosphere had colored less than those stored in normal atmosphere. In the rooms designed to be held to 45°, actual temperatures reached 53° between September 14 and 25 because of power cut-off due to hurricane.

**Home freezers,** A. HUSTRULID and J. D. WINTER (*Minn. Farm and Home Sci. [Minnesota Sta.]*, 8 (1946), No. 2, pp. 1, 10-11, illus. 4).—The authors give a limited discussion of the principles which must be considered in low-temperature cabinet construction in order to have a satisfactory installation.

The accepted storage temperature for frozen food is 0° F. Any equipment must, therefore, be designed to maintain this temperature under all conditions of the surroundings. Cabinets with top-opening doors are easier to construct than those with side-opening doors. They also possess the advantages that very little warm air enters when the door is opened and that the doors need not be as carefully made and cheaper hardware can be used. On the other hand, the side-opening cabinet makes possible a better interior arrangement with easier accessibility. Cabinet capacity depends on the number of persons in the household, food habits, individual tastes, and whether or not the family is a producer of livestock, fruits, and vegetables. Surveys show that people generally buy or build units which are too small. A farm family should plan for 5 to 6 cu. ft. for each person in the household, including hired men. In any case, it is not economical to build a unit with a capacity of less than 25 cu. ft.

In the construction of a freezer box one of the most important features, is an efficient vapor barrier installed on the warm side of the insulation. Doors should fit well and a rubber gasket should be installed around the edges as a sealing seat and to prevent sticking. Sturdy rust-resistant hardware should be used for the side-opening doors, but ordinary barn-door hinges can be used on the top-opening box. Woods that do not give off contaminating odors should be used for the wood framing. Pine, fir, spruce, and hemlock are satisfactory. The outside of the box should be painted. Aluminum paint in a spar varnish vehicle gives a satisfactory and attractive finish. Paints for the interior should be of a special nonodor type.

The most economical thickness of insulation is determined by the relationship between cost of construction and heat transmission through the walls. Many good commercial insulating materials are available in rigid board and fill types. Refrigerating equipment is so designed to remove certain predetermined amounts of heat from the space maintained at a low temperature. A minute examination of the total heat load, namely, (1) leakage, (2) service, and (3) product loads result in an economic selection of equipment capacities to do the fixed job, and all factors in cabinet construction play an important role in the successful and economical operating experience of the special refrigerator installation.

## AGRICULTURAL ECONOMICS

**Current Farm Economics** [April 1946] (*Cur. Farm Econ. [Oklahoma Sta.]*, 19 (1946), No. 2, pp. 25-50+).—The usual discussion of the agricultural situation and tables of prices and price indexes are included, together with an article, Farm Returns from Pasturing Winter Wheat in Two Selected Areas of Oklahoma, 1944-45, by W. F. Lagrone (pp. 41-48) (coop. U. S. D. A.), analyzing the gain in weight and value of feeder lambs, yearlings, 2-year-olds, and beef cows, and selected costs and estimated gains and returns above costs per head and per acre for each of the different kinds of livestock.

**Peacetime adjustments in farming: Possibilities under prosperity conditions** (*U. S. Dept. Agr., Misc. Pub. 595 (1945), pp. 52+, illus. 17*).—This is a report prepared by the Department's Interbureau Committee on Postwar Programs in cooperation with the land-grant colleges. "Back of this national summary are 48 State reports, each representing careful work by a State Production Adjustment Committee—including in its membership production specialists, agricultural economists, extension workers, State statisticians, and other State and Federal agricultural workers who are thoroughly familiar with agricultural conditions in that State. The State-by-State appraisals of postwar farming possibilities under prosperity conditions were carried out by the same committees that have analyzed wartime production potentialities year by year. The information developed for the wartime studies served as background for the longer term analysis, 1943 being taken as representative of the war years." Part 1, Background, contains a general summary of the study and the principal conclusions. In part 2, Commodity Adjustments—Crop Production, the bench-mark acreage, yield, and production of each of the principal crops are analyzed in relation to wartime and prewar levels. Part 3, Commodity Adjustments—Livestock Production, is a similar analysis and discussion for different types of meat animals, poultry and eggs, and milk production.

**Decline and recovery of European agriculture: World Wars I and II**, N. JASNY (*U. S. Dept. Agr., Foreign Agr., 10 (1946), Nos. 4, pp. 50-55; 5, pp. 66-75, illus. 2*).—No. 4 discusses the decline and factors affecting it during each war. No. 5 discusses the recovery after World War I and factors that are affecting or will affect the recovery after World War II, and the possible rate and duration of the recovery in selected countries.

**Foreign Agriculture [April 1946]** (*U. S. Dept. Agr., Foreign Agr., 10 (1946), No. 4, pp. 49-64, illus. 2*).—In addition to the article noted above are an article on Agriculture of British Honduras, by C. H. Farnworth (pp. 55-64), and a note, Spanish Hops Self-Sufficiency Plan, by L. Corder (p. 64), describing the hops monopoly recently announced by Spain.

**Farm management in Oneida County, 1942-1943**, L. C. CUNNINGHAM and S. W. WARREN (*[New York] Cornell Sta. Bul. 830 (1946), pp. 28, illus. 5*).—More detailed analyses are made of the data for the 102 farms in Oneida County included in the study reported in Bulletin 818 (E. S. R., 93, p. 635). Tables are included and discussed showing for these farms the numbers and values of livestock, use of land, acreages and yields of crops, tenure of farmers, capital investment, receipts, farm expenses, labor income, and cost of producing milk. Analyses are made of the relationships to labor income and cost of producing milk of size of business, as measured by acres operated, crop acres, number of cows, and total work units; of labor efficiency, as measured by cows per man and work units per man; of rate of milk production per cow—seasonality of milk production and butterfat test; of crop yields—yield of hay per acre and crop index; of combination of enterprises—systems of farming, proportion of cow feed home-grown, and proportion of cows replaced annually.

"In the period of relatively favorable economic conditions in which this study was made, size of farm business had a more pronounced effect on labor income than did labor efficiency, the rate of milk production, or crop yields. The farmers whose businesses were good in each of several factors were the most successful. The seven farmers whose businesses were above average in size of business, labor efficiency, milk production per cow, and crop yields made an average labor income of about \$2,400, or twice the average of the

region." The eight farms with the four factors below the average had an average labor income of \$191. The average cost per 100 lb. of milk for the different groups were: The entire 102 farms, \$3; the 8 farms below average in the four factors, \$3.36; and the 7 with average or above in the four factors, \$2.59.

**Vegetable production and marketing in Georgia mountain counties, N. M. PENNY** (*Georgia Sta. Bul.* 240 (1946), pp. 29, illus. 1).—The objectives of the study were: "(1) To estimate the potential vegetable production capacity of the area; (2) to learn the present methods and practices in marketing; (3) to determine the kind and adequacy of present marketing facilities; (4) to ascertain the usual practices and labor requirements on snap beans, potatoes, and cabbage; and (5) to determine the costs of and returns from snap beans." The data were collected from the county agents, the cooperative purchasing and marketing organizations, private buyers, and 60 farmers in the eight counties covered. The area, the present acreages and production of vegetables, the possible acreages, the production operations, market outlets, marketing practices and facilities, facilities and operations of the cooperative organizations, and private buyers, etc., are described. Analyses for 1944 were made of the costs of growing, harvesting, and marketing snap beans, and of the labor requirements for beans, cabbage, and potatoes.

The estimated acreage of important vegetable crops in 1944 was 7,487 acres, of which 3,375 acres were in beans, 1,150 in cabbage, and 1,865 in potatoes. It is estimated the acreage in vegetables could be increased to about four times the present acreage with little change in farm organization in the area. The yields of beans obtained by 35 growers in 1944 averaged 94 bu. per acre. Growing costs were 54.3 ct. per bushel, harvesting costs 33.1 ct., and marketing costs 24.8 ct. Net returns averaged 45.8 ct. per bushel. "Net returns plus labor costs equaled 89.5 ct. per bushel return to labor."

**Costs, returns, and practices in growing snap beans on Cumberland Plateau, 1944, H. J. BONSER and C. C. MANTLE** (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog.* 196 (1946), pp. 56+, illus. 21).—The data on which the study was based were obtained mainly from 66 growers in the area. Officials of the canning company, the frozen food plant, and the cooperative bean auction association, county agents, etc., were also interviewed. The cultural practices, yields, and methods of marketing are described. The physical and labor inputs, cost of production, gross and net returns, and the factors associated with the profitableness of the enterprise are analyzed and discussed. Appraisals are made of the snap bean enterprise of the area from the standpoints of existing farm organization and of markets.

**Questions and answers on Government inspection of processed fruits and vegetables, F. L. SOUTHERLAND and E. T. LINDERER** (*U. S. Dept. Agr., Misc. Pub.* 598 (1946), pp. 26+, illus. 19).—Information regarding the purpose, operation, standards used, accomplishments, benefits, etc., of the Government inspection of processed fruits and vegetables is given through questions and answers, grouped under the headings: Why Government inspection; what is Government inspection; what are United States standards; how is inspection accomplished; how is labeling related to United States standards and inspections; and what is continuous inspection.

**Organization and management of poultry farms in Massachusetts (Massachusetts Sta. Bul. 428 (1945), pp. 6-7).—Comparisons are made of net farm income, labor income per hen, egg production, cost of feed per dozen eggs, etc., as shown by poultry account records for 1942, 1943, and 1944. In**

the comparisons, the farms were grouped by years, amount of income, type of poultry enterprise, etc.

**Costs and returns for the turkey enterprise,** E. G. MISNER ([*New York*] *Cornell Sta. Bul.* 827 (1946), pp. 30+, *illus.* 1).—Analyses and comparisons are made of the costs and returns on 30 farms for the year ended January 31, 1939, and on 32 farms for the year ended January 31, 1944. The analyses include costs and returns in raising turkeys, costs and returns from breeders, cost of incubation, costs and returns per farm, and costs for young stock. A table compares the business factors for the turkey enterprise. Among other items analyzed are number, breed, and value of breeders; eggs laid, incubated, sold for hatching, and used; number, breed, and value of poults started; mortality; and charges for use of buildings and equipment.

The net cost of raising a turkey per pound of live weight was 21.4 ct. in 1938 and 37.6 ct. in 1943. Feed comprised about one-half, labor charge about one-fifth, and cost of poults about one-sixth of the cost. The average price received by the growers studied in 1938 for market turkeys alive was 25.3 ct. per pound. The Office of Price Administration ceiling price in 1943 for live turkeys on the farms studied was 35.3 ct. per pound. The average price received for dressed turkeys was 31.8 ct. per pound in 1938. At the O. P. A. ceiling price in 1943, the average price was 41.9 ct. After other costs were met, the return for labor amounted to 11.6 ct. per pound of live weight in 1938 and 7.3 ct. in 1943. In 1938 the cost for breeders amounted to \$8.26 per breeder, or 30.36 ct. per hatching egg produced. The cost in 1943 was \$8.25 per breeder, and 21.7 ct. per hatching egg. Excluding value of eggs incubated, the net cost of incubation in 1938 was \$51.66 per 1,000 eggs, or 8.6 ct. per poult hatched. In 1943 the cost was \$50.02 per 1,000 eggs, or 9.5 ct. per poult hatched.

**Estimated gross cash income to Ohio farmers from the sale of agricultural products and from Agricultural Adjustment Agency payments, by counties—1943 and 1944** (*Ohio State Univ. and Sta., Dept. Rural Econ. Mimeog. Bul.* 190 (1945), pp. 22+).—A continuation of the series (E. S. R., 90, p. 540).

**Citrus fruits: Production, farm disposition, value, and utilization of sales, crop seasons 1909–10—1943–44** (*U. S. Dept. Agr., Bur. Agr. Econ., 1945, pp.* 44+, *illus.* 1).—Tables by States and for the United States show by crop seasons 1909–10 to 1943–44 the production, farm disposition, value, and utilization of sales of oranges, grapefruit, lemons, and limes.

**World trends in major oil crops,** P. L. HANSEN (*U. S. Dept. Agr., Bur. Agr. Econ., 1946, F. M.* 54, pp. 62+, *illus.* 5).—The past trends, current changes, and prospective developments in the production of each of the major oil crops are discussed, with tables showing the production and net exports by countries or areas, usually for the periods 1909–13, 1924–28, 1929–33, and 1934–38, and the author's estimate for about 1955. A general discussion includes such subjects as the nature of world competition in oils and fats, relative importance of oil meal and oil from different oil crops, the major oil crops, the leading oil-crop areas, production trends before the war, the relative yields of tropical and Temperate Zone oil crops, the impact of the war, prospective trends in production, and what an expanded world production will mean to the United States.

"The world trend in production of the major vegetable oils has been strongly upward since before the First World War. This movement has been particularly pronounced for palm, palm-kernel, and coconut oils which are produced in the tropics. . . . Looking ahead, total world production of the major oil crops may reach a level about one-third higher than that of the 5-yr. period

1934-38 by the end of the first decade following World War II, if conversion to settled peacetime conditions is successful and if a continuing condition of world prosperity prevails. The world net export of major oil crops may also expand considerably by 1955, perhaps about 20 percent. The higher rate of expansion is estimated for world production because of large increases in oil production in several important countries, which will be on a net import basis or will have a very small increase in net exports. India, China, and the United States are leading examples."

**Labor requirements for California crops: Major seasonal operations based on estimated acreages and production for 1945.** M. W. LENHART (*Berkeley 4: Calif. Agr. Col. Ext. Serv., 1946, pp. 17+*).—The included tables summarize: (1) By weeks, by areas and counties, and by different crops, the approximate number of workers required each week in 1945, and the total man-weeks of labor during the year; (2) similar information for different crops by counties; and (3) for the State, the number of laborers by weeks, and total man-weeks of labor during the year in the major nonfarm packing establishments.

**Wages and wage rates of seasonal farm workers in USDA labor supply centers at Arvin, Linnell, and Shafter, California, June 1945.** W. H. METZLER (*U. S. Dept. Agr., Bur. Agr. Econ., Surveys Wages and Wage Rates in Agr., Rpt. 6 (1945), pp. 19+, illus. 1*).—This sixth report of the series noted above is based on a survey of workers housed in three of the five U. S. D. A. labor supply centers in the southern part of the San Joaquin Valley in California.

**Wages and wage rates of farm workers in the citrus harvest, Los Angeles area, California, April-June 1945.** W. H. METZLER (*U. S. Dept. Agr., Bur. Agr. Econ., Surveys Wages and Wage Rates in Agr., Rpt. 5 (1945), pp. 21+, illus. 1*).—This fifth report of the series (E. S. R., 94, p. 673) covers the periods April 23 to May 5 for the lemon harvest, and June 6-23 for the Valencia orange harvest.

**Agricultural Finance Review [November 1945]** (*U. S. Dept. Agr., Bur. Agr. Econ., Agr. Finance Rev., 8 (1945), pp. 104+, illus. 6*).—Articles as follows are included: Short-Term Agricultural Loans of Commercial Banks, 1910-45, by N. J. Wall and L. A. Jones (pp. 1-14); Property Tax Developments Since 1932, by P. E. Malone (pp. 15-21); Federally Sponsored Farm-Mortgage Credit Agencies—Wartime Operations and Postwar Prospects, by D. C. Horton and H. C. Larsen (pp. 22-34); Historical Sketch of Farmers' Mutual Fire Insurance, by V. N. Valgren (pp. 35-42); and Financial Mechanisms Used by the Commodity Credit Corporation, by R. J. Burroughs (pp. 43-52). Several short statements and a statistical appendix, with 30 tables covering farm-mortgage credit, non-real-estate credit, farm cooperative credit, farm taxation, agricultural insurance, and related items are also included.

**Loan performance on low income farms in Massachusetts** (*Massachusetts Sta. Bul. 428 (1945), p. 5*).—From 1936 through 1943, the U. S. D. A. Farm Security Administration made 89 loans on cash-crop farms and 95 on livestock and livestock-crop farms. By June 1945, 66 of the farmers in the first group had paid their loans in full, 13 were classed as active borrowers who had received loans within the last 2 yr., 5 were collection cases, and 5 had defaulted after making some payments. For the second group, the respective numbers were 53, 25, 11, and 6.

**Twelfth annual report of the Farm Credit Administration, 1944-45** (*U. S. Dept. Agr., Farm Credit Admin., Ann., Rpt., 12 (1946), pp. 128+, illus. 1*).—This report to the House of Representatives, which continues the series (E. S. R., 93, p. 634), covers the operations of the production credit system, the Federal intermediate credit banks, banks for cooperatives, the farm mortgage

credit system, the emergency crop and feed loans, the Regional Agricultural Credit Corporation, the Agricultural Marketing Act revolving fund, loans to purchase stock in agricultural credit corporations, joint stock land banks, the central office of the Farm Credit Administration, and the Cooperative Research and Service Division of the Administration. Details regarding the operations of all the organizations, as well as statistics on farmers' cooperatives, are included in the appendix (pp. 55-123).

Wheat crop insurance in Tennessee and United States, B. D. RASKOFF and E. B. FICKLE (*Tennessee Sta., Agr. Econ. and Rural Sociol. Dept. Monog. 197* (1946), pp. 36+, illus. 12).—The development and organization of the Federal crop insurance program are described, and the principal provisions of the wheat insurance contract summarized. Analyses are made for the years 1940-43 for Tennessee, with comparisons with other States, of the participation, premium rates, percentage of farms receiving indemnities, indemnities paid, etc. Factors that should be considered in estimating losses are discussed. "Federal crop insurance, available to all Tennessee farmers on the wheat crops of 1940 to 1943 and 1946, was carried by 6,440 farmers. This represents an average participation in the program by wheat producers of less than 5 percent. Below 6 percent of the total wheat allotment acreage has been insured in any one year. . . . The proportion of farms insured receiving indemnities, for the State as a whole, averaged 10 percent over the 4-yr. period 1940-43. Indemnities paid, expressed as a percentage of insured production in bushels per acre, averaged 3.7 percent for the 4-yr. period."

Inheritance of farm real estate, 1920-1945: A list of references, A. M. HANNAY (*U. S. Dept. Agr., Libr. List 22* (1946), pp. 34).—A bibliography containing 219 selected references on inheritance of farm real estate in the United States and foreign countries. A few references to general inheritance are included.

Co-operative organisations and post-war relief. (*Internatl. Labor Off., Montreal, Studies and Rpts., Ser. H, No. 4* (1944), pp. 173+, illus. 2).—Part 1, Characteristics of the Cooperative Movement (pp. 4-36), "deals with the nature of cooperative association and examines the structure of the cooperative movement and certain organizational tendencies within it." Part 2, Cooperative Organizations Throughout the World (pp. 37-82), "provides a rapid survey of the manifold types of cooperative organization and gives the necessary information on their number, size, geographical distribution, and other features." Part 3, Cooperative Organizations in Relief Operations (pp. 83-144), "considers the possible role of the cooperative movement in the immediate postwar problem of relief. After a brief introductory chapter, it deals in turn with the cooperative distributive network in Europe, the cooperative sources of supply outside Europe, and the overseas connections of the European consumers' cooperative organizations."

The co-operative movement and present-day problems, with special reference to rehabilitation and reconstruction (*Internatl. Labor Off., Montreal, Studies and Rpts., Ser. H, No. 5* (1945), pp. 232+).—This study is a sequel to the one noted above. Part 1, Restoration of Basic Economic Functions (pp. 5-100), "analyzes the possibilities of cooperative action in the restoration of basic economic functions—agricultural production, fisheries, housing, transport, power, etc." Part 2, Social Problems of Rehabilitation (pp. 101-171), "is devoted to some of the social problems of rehabilitation—employment, improvement of standards of living, democratic management of the economy." Part 3, Conditions and Forms of the Cooperative Contribution to the Rehabilitation and Reconstruction Effort (pp. 173-221), "examines the conditions

under which and the forms in which the cooperative movement can most effectively contribute to the solution of some of the problems of the present and of the immediate future."

Research practices and problems of farmers' regional associations, M. A. ABRAHAMSEN (*U. S. Dept. Agr., Farm Credit Admin., Misc. Rpt. 96 (1946), pp. 73+, illus. 1*).—"In obtaining information as a basis for this study 13 farmers' regional purchasing associations were visited. . . . Managers and other key administrative officials were consulted relative to the nature and extent of research conducted by the associations they represented. Efforts also were made to obtain the views of these officials concerning possibilities for development of effective research programs. Depending upon the administrative organization of associations visited, in addition to managers, those interviewed usually included personnel in charge of the following departments: Feed, seed, fertilizer, petroleum products, farm machinery, miscellaneous farm and household supplies, manufacturing, purchasing, distribution, finance, credit, traffic, marketing of agricultural products, office management, and personnel." The several sections of the report discuss the meaning and importance of research for farmers' regional purchasing cooperatives, the research agencies available to farmers' regional purchasing cooperatives, the industrial and business research activities of such cooperatives, basic considerations in establishing effective research programs, and the application of research techniques to educational programs of cooperatives.

Proposals for reorganization of Bodega Cooperative Creamery Incorporated and Point Reyes Dairymen's Association, J. M. TINLEY and K. D. NADEN (*California Sta. Mimeog. Rpt. 86 (1946), pp. 38+, illus. 2*).—"The two associations were organized about two decades ago to manufacture cooperatively butter and other dairy products. Due to the transition from the manufacture of milk products to the shipping of market milk and cream since 1938, less than half of the volume of milk received by the two associations in 1945 was used for manufacturing purposes. The present study was undertaken to make analyses of the economic conditions under which the two associations were operating, with a view to recommending possible plans for reorganization. The trends in the California dairy industry, 1924-45, and the operations of each of the associations are analyzed and described. Four plans of reorganization are suggested, and the advantages and disadvantages of each discussed.

Delivery efficiency of petroleum cooperatives affiliated with Southern States Cooperative, Inc., J. W. MATHER (*U. S. Dept. Agr., Farm Credit Admin., Misc. Rpt. 95-A (1946), pp. 100+, illus. 19*).—"As a result of the increase in the use of power-driven farm machinery, 17 local farmers' petroleum cooperatives have been organized since September 1938, in Delaware, Maryland, Virginia, and West Virginia, and are affiliated with Southern States Cooperative, Inc., Richmond, Va. In connection with its postwar planning activities, the Petroleum Management Service of the Southern States Cooperative, Inc., requested this study of 10 of the affiliated local cooperatives. The report includes sections on economic factors affecting the petroleum service; efficiency of delivery operations, 1941-42 to 1943-44; organizing an efficient route system; facilities used in distributing petroleum products; the problem of loaning farm storage equipment; operating results and financial status of the cooperatives; and possibilities and problems of expanding petroleum service.

Delivering petroleum to farmers efficiently, J. W. MATHER (*U. S. Dept. Agr., Farm Credit Admin., Misc. Rpt. 95 (1946), pp. 15+, illus. 5*).—"A condensation of Miscellaneous Report 95-A, noted above.

Financial operations of Ohio farmer owned elevators during the fiscal year 1944-45, B. A. WALLACE (*Ohio State Univ. and Sta., Dept. Rural Econ. Mimeog. Bul. 189 (1945), pp. 22+*).—A continuation of the series (E. S. R., 93, p. 790).

Prices paid by farmers during two wars, R. E. JOHNSON (*U. S. Dept. Agr., Bur. Agr. Econ., Agr. Situation, 30 (1946), No. 5, pp. 4-7, illus. 3*).—A chart with discussion compares by years, 1914-21 and 1939-45, the prices paid by farmers for all commodities, exclusive of interest and taxes, for family living and for farm production. Other charts make the comparisons for family living and farm production by groups of commodities.

## RURAL SOCIOLOGY

Studies of rural social organizations in the United States, Latin America, and Germany, C. P. LOOMIS (*Ann Arbor, Mich.: Edwards Bros., 1945, pp. 392+*, over 100 illus.).—The bulletins and articles reproduced here have been assembled and published in the present form for classroom use. The book demonstrates the range of fields in which an investigator may be required to work over a period of 10 yr. in a government department.

Rural-urban migration and the marriage rate—an hypothesis, P. H. LANDIS. (Wash. Expt. Sta.). (*Amer. Sociol. Rev., 11 (1946), No. 2, pp. 155-158, illus. 4*).—"These data . . . suggest that migration across rural and urban lines is favorable to an early marriage, even in cases where the sex ratio is a decided liability. Migration to an area of unfavorable sex ratio increases the possibilities of a male's later marriage (after 25) and does not seem to hinder appreciably a woman's later chances of marriage (after 22). If this hypothesis seems untenable, the alternate hypothesis is that marriage itself is a factor producing migration."

The Negro population of Kentucky, H. W. BEERS and C. P. HEFLIN (*Kentucky Sta. Bul. 481 (1946), pp. 35, illus. 13*).—Negroes, only a small part of Kentucky's total population in 1940, were principally urban-dwellers. Next in importance as a place of residence was the rural nonfarm community. Farm communities had fewest Negroes. Since 1850, the Negro population has been growing steadily smaller as a part of the State's total population. In 1940 there were fewer Negroes in Kentucky than there had been at any other census year in the 80 yr. since 1860. The peak census year for Negro population was 1900. After that came steady decline. Since 1870 also the average age of the Kentucky Negro population has been rising. This has been due to a decrease in fertility, and to out-of-State migration of people in the younger-age groups, another factor incidentally which must have influenced fertility. Occupationally, Negroes were practically absent in the so-called middle ranks. They were numerous in the service, laborer, and operative class, and not conspicuously below the whites in the professional and semiprofessional classes. Clerical and sales categories had relatively few Negroes. In the class of farm operators, Negroes became relatively fewer from 1920 to 1940. From this study it is clear that treatment of any issue concerning Negroes in Kentucky requires recognition of several conspicuous trends and conditions—declining numbers, urbanward movements, declining birth rates, continuing out-migration, an increase in average age, an absence of Negroes in the middle ranges of the occupational ladder, a relatively low average level of school attainment, and a relatively low level of housing.

Rural health facilities in Missouri (*Missouri Sta. Bul. 491 (1945), p. 57*).—According to this study, records covering a year's experience for each of

1,500 families, or more than 5,000 persons, in five counties show that on the average each person was ill 41 days per year with an ailment that disabled him for his usual activities.

## AGRICULTURAL AND HOME ECONOMICS EDUCATION

Report of the Committee on Higher Agricultural Education in England and Wales, T. LOVEDAY ET AL. ([*Gt. Brit.*] *Min. Agr. and Fisheries, Com. Higher Agr. Ed. England and Wales, Rpt., 1946, pp. 86*).—This is the report from which some recommendations have been noted (*E. S. R.*, 94, p. 848).

Developing a farm plan, J. H. SITTERLY and J. I. FALCONER (*Ohio State Univ. and Sta. Dept. Rural Econ. Bul. 187 (1945), pp. 33+*).—A set of forms designed for use in teaching farm organization and management in vocational agriculture schools.

An examination of livestock-judging courses, E. H. HUGHES, C. E. HOWELL, and S. W. MEAD. (*Univ. Calif.*). (*Jour. Anim. Sci.*, 5 (1946), No. 2, pp. 233-235).—Suggestions given in 45 replies to a letter of inquiry are classified, and 11 specific recommendations are offered.

The new home economics omnibus, F. L. HARRIS and H. H. HUSTON (*Boston: D. C. Heath and Co., 1945, pp. 666+*, about 200 illus.).—A revision and supplement of a previously noted text (*E. S. R.*, 86, p. 700).

The home demonstration agent (*U. S. Dept. Agr., Misc. Pub. 602 (1946), pp. 38+*, illus. 8).—The origin and development of home demonstration work and its place in the program of the cooperative Extension Service of the Department and the States are described. The activities of the home demonstration agent, the methods used in carrying on the work, and some of the achievements, especially during 1944, are described and discussed.

## FOODS—HUMAN NUTRITION

Chemistry of food and nutrition, H. C. SHERMAN (*New York: Macmillan Co., 1946, 7. ed., pp. 675+*, illus. 47).—This seventh edition of this well-known text has been thoroughly revised, several chapters rewritten, and two new chapters added since the previous 1941 edition. The new chapters include: Nutritional Characteristics of the Chief Groups of Food and Causes and Extent of Variations in the Nutritive Values of Foods.

The discussions of nutritional needs and the tables of nutritive values have been revised in accordance with recent dietary recommendations and studies of food values. Many new data on the mineral and vitamin content of foods have been incorporated. The table on the vitamin value of foods gives the normal range of vitamin values likely to be found in most of the foods represented. The list of references and suggested readings have been greatly augmented to include a large number of recent articles of interest and importance in the different fields of nutrition.

Cereal-extended ground pork meat loaves: Their palatability, N. HOTALING and F. FENTON. (*Cornell Univ.*). (*Jour. Home Econ.*, 37 (1945), No. 10, pp. 629-638).—This study was made to determine the optimum extent to which several cereals could be substituted for meat in ground-meat loaves. Fresh, frozen, and canned meat loaves were studied for the purpose of reducing the time necessary for making a loaf of the maximum nutritive value with a minimum of ingredients. Soya flour and grits, oats, wheat kernels, and a mixture of equal weights of rolled oats, soya grits, and shredded wheat were the cereals used. Other ingredients, such as eggs, wheat germ, brewer's yeast, dried

skim milk, whole-wheat flour, and seasonings or monosodium glutamate, were added in varying amounts and combinations to 453.6 gm. of ground pork. Loaves made from the best 15 of the 50 recipes tested were frozen in the raw and precooked forms. Three mixtures were canned, and fresh meat loaves and thawed frozen loaves were baked.

Palatability tests were made, based on score cards, in which 5 percent was allotted for odor, 20 percent for surface appearance, 15 percent for consistency, 15 percent for moistness, 25 percent for flavor, and 20 percent for general acceptability. The formula is given for soy-extended loaf containing about 18 percent soya grits and having the highest nutritive value. The use of long-cooking rolled oats resulted in a higher scoring product than did the quick-cooking variety, with 10 percent rolled oats proving optimum. The wheat-extended loaves scores averaged less than the soy- or the oat-extended loaves, the flavor being less meat-like. Loaves made with a cereal mixture scored lower than did those with the soya grit extender but slightly higher than did those with the oat or wheat extenders. Palatability scores and formulas are shown for loaves containing varying amounts and forms of eggs (dried whole, screened, or collector powder), seasonings, water, fat, and temperatures. Except for one type each of the frozen oat- and wheat-extended loaves, the total scores were higher for the frozen loaves than for the fresh made with these ingredients. The frozen prebaked loaves had a desirable consistency in most combinations. Flavor scored high in the canned loaves, but the texture was rated poor. The yield of the baked soy-extended loaf was 80 percent.

Quality of eviscerated poultry obtained from defrosted, dressed stock, R. D. TRELEASE and C. H. KOONZ (*Food Res.*, 10 (1945), No. 5, pp. 373-378).—Aroma and flavor scores, made after four inspections of each of the 60 fryer-size battery raised birds studied, demonstrated that warm evisceration performed immediately after dressing was an excellent method for handling poultry in that visceral taints are not imparted to the edible tissues. The quality of the poultry was seriously impaired by visceral taints when defrosted-dressed poultry was held at 10° C. for 1 day or more prior to evisceration, and impaired to a lesser degree when the defrosted-dressed poultry was held at 2.2° for 1 day or more.

Flours from Missouri wheats for baking purposes (*Missouri Sta. Bul.* 491 (1945), pp. 45-47, illus. 3).—To ascertain the cake-baking performance of new and old wheat varieties for cake flours produced in Missouri, standard angel food cake formulas were used in tests, and the volume of the resulting product was noted. As standard control, a score of 100 was used representing the volume of an angel cake made from commercial cake flour, and the wheat varieties tested as follows: Fulcaster, 93; Early Premium, 92; Michigan Wonder, 91; Clarkan, 88; and Kawvale, 78. The same methods for measuring volume was applied in tests with white cakes and cookies. The results of the tests indicate that the variety of wheat influenced the quality of the flours.

A concentrated nutritious loaf (*Missouri Sta. Bul.* 491 (1945), pp. 47-48, illus. 1).—The objective of this study was to determine if a loaf of yeast bread could be made that would give nutritive value which would furnish one-half of the daily nutritive requirements of a moderately active man (N. R. C. standards). A formula was developed and sufficient bakings were made to produce an acceptable loaf made of enriched flour, dried whole eggs, dried whole milk, fortified margarine, and yeast. No chemical tests have been made to determine whether the finished loaf contained these values.

Bread baking quality of dry milk solids, O. E. STAMBERG. (Univ. Idaho). (*Baker's Digest*, 20 (1946), No. 2, pp. 31-32).—Skim milk, dried into powder

form by the spray and roller type processes, is a product now being used largely by the baking industry in the production of milk bread. Dry milk solids are classified into three groups: (1) Powders having low absorption and poor baking quality, (2) powders having fairly high absorption and poor baking quality, and (3) powders having high absorption and good baking quality, which group comprises the majority of the powders used for bread baking. A baking test is necessary to determine the bread baking quality of milk solids, although recording laboratory dough mixers and chemical tests are also used. Research shows that the proper heat treatment previous to drying is the main factor responsible for the absorption property of the milk solids. The casein portion of the milk proteins, constituting about five-sixths of the total proteins, is related to variations in the absorption of the dry milk solids. Usually 6 percent milk solids, as based on the quantity of flour, is recommended for the amount to be used in the production of milk bread. Whey proteins, constituting about one-sixth of the total milk proteins, are of importance in relation to that factor in unheated milk which affects the gluten structure adversely and thus produces poor quality bread.

Physical properties of starch from potatoes of different culinary quality, A. M. BRIANT, C. J. PERSONIUS, and E. G. CASSEL. (Cornell Univ.). (*Food Res.*, 10 (1945), No. 5, pp. 437-444, illus. 2).—Studies were made on the physical properties of starch extracted from 22 samples of potatoes of different degrees of mealiness. The distribution of particle size, determined by hydrometer analysis, was found to follow a sigmoid curve when the percentage of particles below a specified diameter was plotted against the diameter of the granules. Determinations showed that the temperature at which the first starch grains lost anisotropy ranged from 53.9° to 61.5° C.; final disappearance of anisotropy was found from 63.4° to 72.3°. Sixteen percent suspensions of starch, heated in a boiling-water bath, were found to thicken at temperatures ranging from 64° to 63.5° and became translucent at temperatures ranging from 65.1° to 70.8°. After allowing the starch pastes to cool their rigidity varied from  $61 \times 10^2$  to  $286 \times 10^2$  dynes per square centimeter, and penetration values ranged from 84 to 152 gm. The results of this study indicated that degree of mealiness of cooked potatoes may be associated with some of the physical properties of the starch of the raw tubers.

Investigations on the nutritive value of tapioca (*Manihot utilissima*), V. V. SREERAMAMURTHY (*Indian Jour. Med. Res.*, 33 (1945), No. 2, pp. 229-238, illus. 4).—Nitrogen was extracted from fresh tapioca roots by triple 15-min. extractions of 200-gm. portions of the ground root with 200 cc. of solvents such as water, 5 percent NaCl, 70 percent alcohol, or 0.2 percent NaOH. The amount of nitrogen left unextracted in the residue varied from 5.40 percent with 0.2 percent NaOH extractant to 16.78 with the water extractant. Protein fractions in the extracts were determined by precipitating with a number of reagents. Attempts, by five methods described, to isolate the protein in pure form from the water extract failed to yield a preparation of low ash content. Amino-acid composition of the tapioca protein was found to be: Arginine 17.0, tyrosine 1.6, tryptophan, 1.1, and cystine 1.3, expressed as percentage of the total N extracted. Analysis of the non-protein nitrogen in the water-extracted tapioca also showed fair amounts of these amino acids.

Digestibility experiments on the whole tapioca powder were made using two proteolytic enzymes. The results showed that tapioca proteins were readily proteolytic enzymes. The results showed that tapioca proteins were as readily digested by pepsin.

The digestibility of the carbohydrate in the finely powdered tapioca root

by taka diastase and by pancreatic amylase was studied; the latter enzyme was found to hydrolyze 48.3 percent of the carbohydrates in the raw state and 77.9 percent after cooking. The tapioca starch was digested to a greater extent by taka diastase than by pancreatic amylase.

Peanut butter improved by changing flavor and texture, J. G. WOODROOF, H. H. THOMPSON and S. R. CECIL. (Ga. Expt. Sta.). (*Food Indus.*, 18 (1946), No. 4, pp. 109-110, 218-224, illus. 1).—Essentially noted elsewhere (E. S. R., 94, p. 828).

Influence of supplementary calcium and magnesium fertilizers upon nutritive value of kale, A. D. HOLMES, L. V. CROWLEY, and J. W. KUZMESKI. (Mass. Expt. Sta.). (*Food Res.*, 10 (1945), No. 5, pp. 401-407).—Kale seed was sown directly on experimental plots and harvested 49, 51, 56, 59, and 63 days later. Plot A fertilized with a 4-9-7 commercial fertilizer served as control; in addition, plot B received magnesium sulfate; Plot C, magnesium sulfate and limestone; and plot D, limestone.

Assays were made for moisture, calcium, iron, magnesium, phosphorus, and carotene in the freshly picked kale samples. Results showed that the supplementary fertilizers had no effect on the carotene content of kale. Samples from plots B and C were higher in magnesium, and those from plots C and D higher in calcium and phosphorus than the control samples.

Vitamin content of field-frozen kale, A. D. HOLMES, B. V. McKEY, K. O. ESSELEN, L. V. CROWLEY, and C. P. JONES. (Mass. Expt. Sta.). (*Amer. Jour. Diseases Children*, 70 (1945), No. 5, pp. 298-300).—The kale had been field-frozen seven times before being picked in the month of November. Assays for ascorbic acid, carotene, nicotinic acid, and pantothenic acid were made on the immature and extremely mature leaves.

Average results in milligrams per 100 gm. of kale on a fresh-weight basis were for ascorbic acid 212.2 and 158.6, carotene 5.6 and 6.3, nicotinic acid 2.21 and 1.94, and pantothenic acid 0.91 and 0.73 mg. for the immature and very mature leaves, respectively.

The authors emphasize that "these values supply evidence that field-frozen kale can contribute essential nutrients to the human diet, especially when the supply of fresh green leafy vegetables grown in this area is limited."

Factors in the preparation of maple cream, F. W. HAYWARD (*New York State Sta. Bul.* 720 (1946), pp. 8).—Maple cream is a soft fondant prepared from pure maple sirup by boiling rapidly until a temperature of 232° F. is reached. It is then quickly cooled to room temperature and stirred until crystallization is complete. It is principally used as a spread for waffles, pancakes, cakes, and sandwiches.

Recommendations given for the preparation of a maple cream of uniformly high quality include the use of good quality sirup with true maple flavor and with a low invert sugar content, rapid boiling to an accurately determined temperature, rapid cooling before stirring is begun, seeding with a little dry maple sugar immediately before stirring, and continual stirring or heating until crystallization is complete.

Experimental studies showed that when the amount of invert sugar present is over 3 percent, or if the final boiling temperature is under 232°, the cream becomes increasingly fluid and tends to separate.

How sugars affect dispersibility of pectins in gel powders, C. W. WOODMANSEE, G. L. BAKER, V. E. POLLARI, and W. G. MURRAY. (Del. Expt. Sta. et al.). (*Food Indus.*, 18 (1946), No. 3, pp. 100-101, illus. 3).—Further investigations are reported here relative to powdered gels with higher sugar concentrations than those previously described by Pollari et al. (E. S. R., 94, p.

534). Two types of sugar, namely, sucrose and dextrose, were used separately or in various combinations as a means of dispersing high-methoxyl intermediate-methoxyl, low-methoxyl apple pectins, as well as citrus pectin. From the volume-weight standpoint, a total sugar content of 60 percent in the finished gel represented the highest practical limit of sugars. On this basis, gel strength values with varying ratios of sugars and pectins were tested. A grainy texture developed when sucrose was used as the only sweetening agent. Variations in pH and type of pectin also influenced texture. Of various sugar concentrations used, dispersion of intermediate-methoxyl pectin was best in a 70 sucrose-20 dextrose combination with a sugar-pectin ratio of 90 : 1 and low pH value. Gels containing dextrose as the sole sugar showed surface crystallization in a short time.

Collected papers of the Canadian Committee on Food Preservation containing papers 55-108, with 2 appendices, II, 1940-1944 ([Ottawa?]: *Canad. Com. on Food Preservation*, [1945], vol. 2, pp. 567, illus. 124).—This collection consists of reprints of articles dealing chiefly with the preservation of meats, eggs, fish, and other perishable foodstuffs. Volume 1 of these papers appeared under the title *Collected Papers of the Canadian Committee on Storage and Transport of Food*.

Peacetime food compression, C. A. MAGOON et al. (U. S. D. A.). (*Food Indus.*, 18 (1946), No. 3, pp. 106-108, 216, 218, 220, illus. 3).—Bulk reduction of dehydrated foods by compression effects a saving in warehousing and transportation costs and is advantageous where high temperatures prevail and refrigeration facilities are limited. Compression processes do not materially affect the quality of the product if properly done. Vegetables with a low moisture content and low natural sugars become brittle when subjected to compression. Production of satisfactory compressed foods depend upon overcoming fragmentation; methods of processing for eliminating breakage are described. Satisfactory reconstitution depends upon the rapid disintegration of the food block—the degree of density varies with different products. Larger and thicker units require more time for reconstitution. Proper temperature and moisture content of the food and air-tight metal containers contribute to satisfactory storage. Considering the absence of waste, loss of storage, and convenience in use, the high prices of compressed dehydrated foods appear justified, providing the product is of high table quality.

Processing equipment used in emergency meat dehydration research by United States Department of Agriculture, W. A. NOEL, W. E. GRAY, O. G. HANKINS, and R. S. HOLLINGSHEAD. (U. S. D. A.). (*Food Res.*, 10 (1945), No. 5, pp. 379-391, illus. 13).—This paper discusses the types of processing equipment and operational procedures used in an investigation of meat dehydration. It is the first in a series of technical articles which describe all essential details of the various phases of a study previously reported in a somewhat condensed semitechnical form (E. S. R., 92, p. 578).

Producing dehydrated meats by vacuum-rotary, plate-vacuum, and kettle-cabinet methods, C. F. DUNKER, O. G. HANKINS, and O. L. BENNETT. (U. S. D. A.). (*Food Res.*, 10 (1945), No. 5, pp. 445-456).—This article continues the above series, giving the details of three methods of producing dehydrated meats.

Producing dehydrated meats by drum-cabinet, retort-cabinet, and other methods, O. G. HANKINS, C. F. DUNKER, and O. L. BENNETT. (U. S. D. A.). (*Food Res.*, 11 (1946), No. 1, pp. 1-13).—This study completes the series on producing dehydrated meats.

The effect of wheat germ oil antioxidants and natural reducing substances on the stability of whole milk powder, R. A. CHAPMAN and W. D. MCFARLANE (*Canad. Jour. Res.*, 24 (1946), No. 1, Sect. F, pp. 47-60, illus. 6).—Storage trials of roller and spray-process whole-milk powders at various temperatures were made. The accelerated tests at 65° C. were found to give an accurate indication of the relative keeping qualities of the samples. Wheat-germ oil alone and in combination with citric acid and lecithin was effective in inhibiting oxidation catalyzed by copper contamination. "Reducing substances that develop in milk powders during storage in a moist atmosphere or at elevated temperatures are strong antioxidants and may offset the effect of added antioxidants. The riboflavin content of several powders with a high concentration of reducing groups decreased appreciably during storage."

The keeping quality of dehydrated mixtures of egg and milk, J. A. PEARCE, J. WHITTAKER, H. TESSIER, and W. A. BRYCE (*Canad. Jour. Res.*, 24 (1946), No. 1, Sect. F, pp. 70-76, illus. 5).—"The storage life of a dehydrated mixture of egg and milk, when assessed by both palatability and fluorescence measurements was shorter than the life of milk powder of similar protein, fat, and carbohydrate content. Increased quantities of egg in the mixture decreased the quality of the mixture, both initially and during 16 weeks' storage. These effects were noticeable at all temperatures studied between 40° and 140° F. but were most marked above 80°. After 16 weeks at 80°, material packed under carbon dioxide usually had better palatability than the air-packed products. The effect of added sugar was most noticeable at 120° and 140°. Lactose had a slightly beneficial effect; sucrose was more effective."

Dried whole egg powder, XVI-XIX (*Canad. Jour. Res.*, 23 (1945), Nos. 2, Sect. F, pp. 104-108, illus. 2; 4, pp. 239-242, illus. 2; 24 (1946), Nos. 1, Sect. F, pp. 39-46, illus. 2; 3, pp. 168-182, illus. 7).—In continuation of this study (E. S. R., 92, p. 729), three papers are presented.

XVI. *Relative stability of powders of different quality*, M. W. Thistle, W. H. White, D. A. Fletcher, and J. A. Pearce.—Samples of dried whole egg powder of varying initial qualities and origin were stored at 24° C. for 1 mo. Fluorescent materials developed at much the same rate in all samples studied. Samples stored at 24° for 4 mo. which had previously been heat-treated to provide definitely good, questionable, and poor samples showed that all qualities deteriorated at the same rate, regardless of moisture contents.

XVII. *Objective tests and baking quality*, M. Reid and J. A. Pearce.—"Potassium chloride value, refractometric value, the fluorescence of defatted egg powder in 10 percent potassium chloride, and the fluorescence of untreated dried material correlated equally well with the foaming volume of a mixture of dried egg, sugar, and water, and with the loaf volume of the sponge cake prepared from the powder ( $r$  values from 0.81 to 0.90). A significantly closer relationship was observed between foaming volume and loaf volume ( $r=0.96$ ). Since foaming volume was more precise and easier to determine than baking volume, it was concluded that foaming volume was a more desirable test of baking quality."

XVIII. *The keeping quality of acidulated, gas-packed powders of low moisture content*, J. A. Pearce, M. Reid, and W. H. Cook.—Investigations on the effect of acidifying liquid eggs prior to drying showed that no improvement of subsequent storage life occurred, although pH measurements revealed that powder from untreated egg became acid more rapidly. The storage life of the dried whole egg powder (as assessed by fluorescence tests) doubled when the moisture content was reduced from 4.7 to 3.0 percent, and tripled after a 4.7 to 1.7 reduction. "The maximum storage life predicted for the

low moisture powder by this test was only 36 weeks at 27° and 5 weeks at 38°. Palatability tests suggested that the product was somewhat less perishable, as a powder of 1.7 percent moisture was considered fit for use as an egg dish after 64 weeks at 27°. Gas-packing low moisture powders in an atmosphere of carbon dioxide appeared to be slightly more effective as a means of retaining palatability than packing in an atmosphere of air or nitrogen but was particularly effective in preventing loss of solubility (assessed by potassium chloride values) during storage."

XIX. *Accelerated storage tests to assess the effect of heat treatment, moisture content, and materials on the quality of dried sugar-egg mixtures.* R. L. HAY and J. A. PEARCE.—Dried egg powder (2.8 percent moisture), containing 33 percent sugar, and control samples of plain egg powder (3.9 percent moisture) were stored at 80°, 100°, 120°, and 140°F. for 7 days. At 140°, the sugar inhibited the initial fluorescence development; at 120° and lower, the sugar had a marked effect in retarding decrease in the quality of the egg powder, as assessed by fluorescence, potassium chloride, pH, and foaming volume measurements.

Dried egg powder containing 33 percent sugar was adjusted to moisture levels of 1.4, 2.8, and 3.2 percent and stored at 80° and 120° for 7 days. From the results obtained, it is recommended that sugar-egg powder be dried to the lowest moisture content compatible with the production of good quality powder, less than 2.8 percent and preferably 1.4 percent.

Loss in quality was less for sugar-egg powders (2.8 percent moisture) prepared with granulated sugar than those prepared with sucrose sirup when they were stored at 80°, 100°, 120°, and 140° for 7 days. Powder made from fresh shell eggs was more desirable than that prepared from frozen melange.

Making biscuits for canning, T. MALONE and J. KETCHEN (*Jour. Home Econ.*, 37 (1945), No. 10, pp. 640-641).—Using a basic recipe, 36 variations in proportions of single-acting and double-acting baking powder and animal and vegetable fats were combined for experimental purposes to determine the cause of rancid flavor and poor texture evident in home-canned biscuits. The experiment showed that vegetable fat produced a better canned biscuit than the animal fat, and single-acting was more satisfactory than double-acting baking powder.

Ration biscuits, II-III (*Canad. Jour. Res.*, 23 (1945), Nos. 2, Sect. F, pp. 123-131, illus. 3; 4, pp. 286-294, illus. 3).—In continuation of this series (E. S. R., 93, p. 219), two papers are presented.

II. *Effect of type and concentration of shortening on keeping quality*, G. A. Grant, J. B. Marshall, and W. H. White.—"Ration biscuits prepared by two manufacturers and containing 8 to 23 percent of one compound animal-vegetable and three all vegetable shortenings were stored at 43.3° C. (110° F.) for 36 weeks. Keeping quality was assessed by flavor, peroxide oxygen, and pH determination.

"The type of shortening was found to have a greater effect on keeping quality than the fat concentration or plant practice. Biscuits made with stabilized hydrogenated vegetable shortening were more stable than biscuits made with a compound animal-vegetable shortening. All biscuits became objectionable to the tasters after storage for 22 weeks."

III. *Effect of moisture content on keeping quality*, J. B. Marshall, G. A. Grant, and W. H. White.—Ground biscuits made with (1) a highly stable hydrogenated vegetable oil product and (2) with a much less stable, compounded animal-vegetable shortening were adjusted to moisture contents of approximately 0, 3, 6, 9, 12, 15, and 18 percent. After 56 weeks' storage at 43.3° C.,

keeping quality of these biscuits was assessed by flavor tests, peroxide oxygen, pH, and fluorescence measurements. Although the behavior was similar, and variations in moisture content had small effect on flavor scores, biscuit (1) gave differentially higher scores at moisture levels below 6 percent, indicating that a moisture content of 6 percent was most suitable for storage. The formation of the fluorescing substances reached a maximum at a moisture content of 12 percent and decreased at higher levels.

Microbiology of prunes during handling and drying, H. J. PHAFF, E. M. MRAK, R. ALLEMANN, and R. WHELTON. (Univ. Calif. coop. U. S. Army). (*Fruit Prod. Jour. and Amer. Food Mfr.*, 25 (1946), No. 5, pp. 140-141, 155).—Studies on the effect of commercial drying and handling practices on prunes showed that living yeasts or molds are not present after commercial dehydration. Sun drying, however, did not kill the yeasts on the fresh prunes, and they may possibly increase temporarily during the process. Poor plant sanitation enhanced recontamination during grading, but with improved sanitary conditions dried prunes with relatively few yeasts and molds were obtained.

Quality of canned orange juice, J. M. BOYD and G. T. PETERSON (*Indus. and Engin. Chem.*, 37 (1945), No. 4, pp. 370-373, illus. 1).—Investigations of the factors affecting the flavor of orange juice canned by commercial practices showed that subjecting the fruit to a hot water treatment of 1 to 2 min. at 180°-185° F. wilted the peel and reduced the amount of peel oil entering the juice during extraction. Juice extractors which could be so operated that appreciably little oil would be pressed out into the juice were found desirable for commercial application. Investigations of the juice showing a volatile oil content as low as 0.01 percent revealed that off-flavors developed on prolonged storage, while experimental packs with an oil content of 0.007 percent did not develop off-flavor after 18 months' storage. Further studies indicated that off-flavor in the juice, detected after these storage periods, was possibly due to other factors as well. Determinations made on the effect of oxygen on the juice indicated that extraction in the presence of inert atmosphere (nitrogen and carbon dioxide), deaeration prior to flash pasteurization, and filling by use of nonaerating equipment gave less off-flavor to the juice. Complete exclusion of head-space air decreased the flavor change, the loss of ascorbic acid, and the rate of can corrosion. The temperature to which the juice was heated during processing was a more minor cause of off-flavor than was the length of time it was held at elevated temperatures. Rapid cooling of the sealed cans to 100° or lower and storing at the lowest temperature practical to processors led to improved quality of canned orange juice.

Germans using improved methods to preserve fruit juices, Z. I. KERTESZ. (N. Y. State Expt. Sta.). (*Food Indus.*, 18 (1946), No. 4, pp. 80-82, 216, 218, illus. 3).—This article deals with the developments in the German fruit products industries during the war years. Unfermented fruit juices of improved quality were produced by methods unknown or unused in this country. These include mellowing by mold enzymes and storage in carbon dioxide under pressure.

Blanching and cooling for frozen pack, W. V. CRUESS. (Univ. Calif.). (*Fruit Prod. Jour. and Amer. Food Mfr.*, 25 (1946), No. 5, pp. 134-135).—Factory and laboratory experiments of blanching and cooling of various fruits and vegetables are summarized by the author. "(1) Water cooling and fluming is objectionable from the standpoint of loss of nutrients and damage to flavor. (2) Air cooling avoids these objections and appears to be practicable commercially."

**Locker and home freezing of farm products**, C. L. BEDFORD, J. A. BERRY, M. M. BOGGS, H. CAMPBELL, T. J. CUNHA, M. MCGREGOR, E. L. OVERHOLSER, M. F. POOL, D. G. SORBER, R. P. STRAKA, and B. M. WATTS. (Coop. U. S. D. A.). (*Washington Sta. Pop. Bul.* 180 (1945), pp. 46).—The rate of refrigerated-locker development in the United States has approximately doubled since 1940, with one-half billion pounds of foods frozen in 1943. The material in this bulletin, derived from suggestions and information available from research and industrial practice, deals with the special technics of food freezing of suitable farm products (fruits, vegetables, meats, poultry, and eggs). These include vegetable scalding by steam and boiling water, and dry and brine pack preparation procedures; and fruit sugar and sirup packs, and dry sugar and sirup pack preparations. Special directions are given for packaging, freezing, storage, care, and thawing of these foods.

**Home freezing of fruits and vegetables** (U. S. Dept. Agr., 1946, A1S-48, pp. 34, illus. 47).—This publication is a revision of a former booklet dealing with the preparation of vegetables and fruits for freezing (E. S. R., 91, p. 612). Illustrated steps for freezing corn, peas, broccoli, peaches, and strawberries are given, and other vegetables and fruits are listed with their specific preparation methods and scalding times noted. Information relative to washing, sorting, peeling, trimming, slicing, prevention of darkening, sweetening, chilling, packaging, container head space, and storage temperatures are discussed.

**Committee on Food Research Conference on deterioration of fats and oils** ([War Dept. U. S.], Army Serv. Forces, Q. M. Corps, QMC 17-7 (1945), pp. 153+, illus. 39).—This volume comprises the papers and discussions presented at the conference of the Committee on Food Research devoted to summarizing the present status of information pertinent to the Army's food problems. The papers presented at the several sessions gave a definition of the problem; discussed the mechanism of autoxidation reaction in fat; methods and their evaluation; factors affecting fat deterioration—including Pharmacological Considerations of Antioxidants, by H. O. Calvery, (pp. 113-114) (U. S. D. A.); and fat deterioration in food products other than separated fats and oils—including Toxicity of Rancid Fats, by F. W. Quackenbush, (pp. 149-150) (Ind. Expt. Sta.), and Fat Deterioration in Milk Products, by G. E. Holm (pp. 151-153) (U. S. D. A.).

**Good food and nutrition for young people and their families**, E. P. AMIDON, D. E. BRADBURY, and V. V. DRENCKHAHN (New York: John Wiley & Sons; London: Chapman & Hall, 1946, pp. 323+, illus. 32).—This book is an account of how the principles of good nutrition may help young people to eat correctly and of how they affect practices in marketing, cooking, gardening, and preserving foods.

[Nutritional status of aircraft workers in southern California].—[I], Diets of a group of aircraft workers in southern California, D. G. WIEHL (*Milbank Mem. Fund Quart.*, 20 (1942), No. 4, pp. 329-366), illus. 6.—This is the first in a series of articles dealing with an investigation begun at the Lockheed Aircraft Corporation, Burbank, Calif., in November, 1941. An analysis of the diet histories of approximately 1,100 workers was made by comparing the reported use of foods with those recommended in the dietary pattern prepared by the National Research Council.

**Nutritional status of aircraft workers in southern California, II-IV** (*Milbank Mem. Fund Quart.*, vols. 21 (1943), No. 2, pp. 115-157, illus. 1; 23 (1945), pp. 113-160, illus. 1; 24 (1946), No. 2, pp. 99-185).—Continuing the above series, these studies are presented.

II. *Clinical and laboratory findings*, H. Barsook, E. Alpert, and G. L. Keighley.—These examinations consisted of the following: Medical histories, physical examination, biomicroscopic examination of the conjunctiva and cornea, plasma ascorbic acid, serum protein concentration, hemoglobin, red cell count, red cell volume, and serological tests for syphilis. The reliability of some of the above tests as diagnostic methods of mild or chronic nutritional deficiency are discussed, and findings on the nutritional condition of the men at the time they were first examined are summarized.

III. *Effects of vitamin supplementation on absenteeism, turnover, and personnel ratings*, H. Borsook.—The first part of this report explains the position of this phase of the study and compares the workers with the general industrial population. It explains the nature of the vitamin supplement used, the nature of the placebo given one control group, the selection and composition of the vitamin and placebo groups, and the second control group selected to appraise the psychotherapeutic effect of a vitamin supplement as distinguished from the putative therapeutic. Part 2 presents the data on absenteeism, turnover, and Merit Review scores, and discusses the differences which occurred in these respects between the groups during the year of the study.

IV. *Effects of vitamin supplementation on clinical, instrumental, and laboratory findings, and symptoms*, H. Borsook, J. W. Dubnoff, G. Keighley, D. G. Wiehl, E. B. Goolden and J. G. Williams.—The clinical, instrumental, and laboratory findings at the end of a year's vitamin or placebo supplementation are compared with the findings in the two groups at the end of the study in addition to comparing each group with those before the supplementation was begun. On the basis of these data, the effects of the vitamin supplement on the physiological and anatomical conditions used for the appraisal of nutritional status, the psychological effects of the vitamin supplement and the placebo are appraised.

Nutritive value of dextri-maltose determined by the single-food choice method, C. P. RICHTER (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 2, pp. 260-263, *illus.* 1).—Experiments using the single-choice method of determining the nutritive value of foods (E. S. R., 95, p. 136) have been continued. When dextri-maltose was fed as the sole source of nourishment 12 female rats survived, on the average, 85 days, as compared with 37 days when dextrose or sucrose was fed. This was 11 days longer than the survival time of rats fed dextrose plus thiamine hydrochloride (0.02 percent solution). The dextri-maltose fed rats had a higher food intake and lost weight less rapidly than the dextrose- and thiamine-fed rats. Their activities, water intakes, and vaginal smears were essentially the same. The author interprets the results to indicate that "dextri-maltose contains sufficient amounts of thiamine to utilize to its fullest available carbohydrate."

Nutritional studies with the duck.—I, Purified rations for the duck, D. M. HEGSTED and F. J. STARE (*Jour. Nutr.*, 30 (1945), No. 1, pp. 37-44, *illus.* 3).—On a highly purified diet composed of sucrose, vitamin-free casein (18 percent), salt mixture, corn oil,  $\text{CaHPO}_4$ , cod-liver oil, choline chloride, and a vitamin mixture, ducks showed practically no growth until a liver extract was added. Purified liver extract, treated with alcohol to remove the biotin present was ineffective in promoting growth. Inclusion of biotin in the ration was necessary for normal growth. The extracted liver fraction could be replaced by a concentrate of "*L* [*actobacillus*] *casei* factor." A deficiency in this factor resulted in anemia.

Additional amino acids, above those supplied by 18 percent casen, were necessary for good growth. These could be supplied in part by 0.5 percent arginine, or by 10 percent gelatin.

In biotin deficiency, no symptoms other than very poor growth were noted.

The authors conclude that the nutritional requirements for the duck are apparently similar to those of the chick.

**Nutritional studies with the duck.—II, Pyridoxine deficiency,** D. M. HEGSTED and M. N. RAO (*Jour. Nutr.*, 30 (1945), No. 5, pp. 367–374, *illus.* 1).—Pyridoxine was excluded from the vitamin supplement in the ration described above in order to provide a pyridoxine-deficient diet. When day old ducklings were fed this ration, acute signs of deficiency appeared in a few days. The severe acute symptoms noted were growth failure and severe anemia (hemoglobin dropping to around 4 percent). No dermatitis or nervous disorders were noted in acute pyridoxine deficiency. Chronic deficiency, obtained with older ducklings (2–3 weeks old), was characterized by lack of growth, paralysis, convulsions, severe microcytic anemia, and poor feather development. This last was not thought to be due specifically to the lack of pyridoxine, but to some other deficiency of undetermined origin.

The pyridoxine requirements of young ducklings were found to be similar to that of chicks; approximately 250  $\mu$ g./100 gm. of ration.

**Dental caries in the cotton rat.—III, Effect of different dietary carbohydrates on the incidence and extent of dental caries,** B. S. SCHWEIGERT, J. H. SHAW, P. H. PHILLIPS, and C. A. ELVEHJEM. (Wis. Expt. Sta.). (*Jour. Nutr.*, 29 (1945), No. 6, pp. 405–411).—Various factors influencing the susceptibility of the cotton rat to dental caries have been investigated in this series of studies.

Technics previously reported (E. S. R., 94, 130) were used. The diet 802 (containing 67 percent of sucrose) has been modified by the substitution of various other carbohydrates—soluble starch, coarse or fine dextrin, glucose, maltose, dextrimaltose, fructose, and lactose. To insure better growth, 4 percent of a 1 : 20 liver extract was also added.

Results indicated that approximately the same rate of growth was observed when dextri-maltose, glucose, fructose, maltose, and sucrose diets were fed, but inferior growth occurred with fine dextrin, stock, or soluble starch rations. High incidence and extent of tooth decay were noted with glucose, dextri-maltose, fructose, maltose, or lacto-sucrose diets, but with the fine dextrin and coarse dextrin diets a very low incidence and extent of the lesions were observed. There was no appreciable difference in the results obtained when either coarse or fine dextrin were used.

The replacement of one-half of the sucrose with fine dextrin did not reduce the severity of tooth decay as compared to animals which received the sucrose diets. The replacement of three-quarters of the sucrose with fine dextrin reduced the incidence and extent slightly.

**Dental caries in the cotton rat, IV–V.** (Wis. Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 1, pp. 44–47, pp. 89–92).

**IV. Inhibitory effect of fluorine additions to the ration,** J. H. Shaw, B. S. Schweigert, P. H. Phillips, and C. A. Elvehjem (pp. 89–92).—Fluorine in amounts ranging from 22.5 to 450 p. p. m. was added to the basal ration 802 plus 4 percent 1 : 20 liver extract—dextrin or sucrose being the sole source of carbohydrate.

Results showed that at 22.5 p. p. m. level fluorine had no appreciable effect on the carious lesions produced on the sucrose diet. The inhibitory effect upon dental caries was progressively greater as the amount of fluorine rose from 45 and 90 to 135 p. p. m. Maximum effects were obtained at the 225 or 450 p. p. m. levels and caused a 90 percent decrease in caries incidence. Depigmentation effects began to appear at the 45 p. p. m. level, while mottling

of the third molars occurred at the two highest levels fed. The inhibitory effect of the dextrin diet upon the incidence of caries could not be explained on the basis of its fluorine content, which was only 1 to 2 p. p. m. while the fluorine content of sucrose averaged 3 to 4 p. p. m.

V. *Influence of strain variation on the caries susceptibility*, B. S. Schweigert, J. H. Shaw, C. A. Elvehjem, and P. H. Phillips (pp. 44-47).—The rats tested were obtained from the stock colony and from Florida and Michigan. On the usual cariogenic diet, wide variations in degree of susceptibility to dental caries was noted. Among the stock animals, certain rats and their inbred offspring gave evidence of increased resistance to caries when compared with more susceptible animals. In general, the offspring of the Florida and Michigan stock animals showed less susceptibility to dental caries than the susceptible Wisconsin strain. The results are considered to be statistically significant.

The need for manganese in bone development by the rat, M. O. AMDUR, L. C. NORRIS, G. F. HEUSER. ([N. Y.] Cornell Expt. Sta.). (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 2, pp. 254-255).—Weanling rats were paired according to weights and fed low- and high-manganese diets. The feed consumption of the rat on high manganese was limited so that it gained weight at the same rate as its pair mate. Thirteen pairs of female and 5 pairs of male rats were studied, and the average results obtained are briefly tabulated. The authors conclude that the length, density, breaking strength, and phosphatase content of the bones of manganese-deficient rats were lower than in pair mates of the same weight receiving adequate manganese. No differences were found between the two groups in the percentage of ash, calcium, phosphorus, and magnesium in the fat-free dry bone.

Carbonate content of bone in relation to the composition of blood and diet, A. E. SOBEL, M. ROCKENMACHER, and B. KRAMER (*Jour. Biol. Chem.*, 158 (1945), No. 2, pp. 475-489).—These studies were carried out to determine whether a relationship existed between the carbonate content of bone and the composition of serum. Groups of rats were maintained on: (1) Low Ca-low P (basal) diet, (2) high Ca-low P diet, and (3) low Ca-high P diet. Paired litter mate rats were fed these diets with or without vitamin D supplement. Analyses were made of Ca, P, and  $\text{CO}_2$  in serum and Ca and  $\text{CO}_3$  in bone.

Results showed that the Ca and P content of the diet as well as vitamin D influenced the  $\text{CO}_3$  : Ca ratio of bone. Changes in the ratio of bone  $\text{CO}_3$  : Ca appeared to be related to serum  $\text{CO}_2$  : P ratios. Bones of animals fed high calcium diet (2) showed a significantly higher  $\text{CO}_3$  : Ca ratio than the other two groups. Vitamin D lowered the  $\text{CO}_3$  : Ca ratio of the bones in the animals on all three diets.

The implications of these findings on the understanding of the mechanism of bone formation are discussed.

Comparison of bone in relation to blood and diet, A. E. SOBEL, M. ROCKENMACHER, and B. KRAMER (*Jour. Biol. Chem.*, 159 (1945), No. 1, pp. 159-171).—The experiments described above were extended to include analyses of phosphorus, total base, and ammonia as well as calcium and carbonate in bone. The methods employed were those previously outlined (E. S. R., 92, p. 755).

In six out of seven experimental groups studied, the composition of bone showed an excess of base over that required by the calculated formula  $\text{CaCO}_3 \cdot n [\text{Ca}_3(\text{PO}_4)_2]$ . In the bone, the residual total base : P ratio ranged from 1.52 to 1.57, and the residual Ca : P ratio ranged from 1.48 to 1.52, whereas the theoretical residual total base : P ratio = 1.50.

Excess phosphate over that required by the above formula was demon-

strated in one group of animals and indicated the bone composition to have the empirical formula  $[(\text{CaHPO}_4)_{1.6}(\text{Ca}_3(\text{PO}_4)_2)_2\text{CaCO}_3]$ . In this group, the bone residual total base : P ratio was 1.36, and the residual Ca : P ratio was 1.33.

" $n$  as measured by the  $\text{PO}_4 : \text{CO}_3$  ratio in the bone appears to be correlated to the serum inorganic P :  $\text{CO}_2$  ratios.  $n$  ranged from 1.86 to 3.33 in the various experimental groups. . . .

"The significance of these findings in the mechanism of the deposition of bone salt has been discussed."

The effect of fat upon the utilization of galactose by the rat, L. P. ZIALCITA, JR. and H. H. MITCHELL. (Univ. Ill.). (*Jour. Nutr.*, 30 (1945), No. 2, pp. 147-150).—Weanling rats were fed a basal ration consisting of 48 percent lactose, 20 percent ether-extracted casein, 4 percent salt mixture, and adequate vitamins. The remaining 28 percent of the diet consisted of either butterfat, corn oil, or glucose. With a galactose intake varying from 3.12 to 5.04 gm. of galactose daily, the average daily urinary excretion amounted to 30.7, 20.7, and 28.6 percent of the amount ingested on the butterfat, corn oil, and glucose diets, respectively. The authors conclude that "fats, as such, do not seem to be concerned in the metabolism of galactose. . . .

"Under the conditions of this experiment, corn oil, but not butterfat, decreases the urinary loss of galactose on a diet containing 48 percent lactose by about one-fourth. This may be an effect of some nonglyceride constituent of corn oil."

The effect of choline intake and environmental temperature on the excretion of choline from the human body, B. C. JOHNSON, T. S. HAMILTON, and H. H. MITCHELL. (Univ. Ill.). (*Jour. Biol. Chem.*, 159 (1945), No. 1, pp. 5-8).—Choline was assayed by the microbiological method of Horowitz and Beadle (E. S. R., 92, p. 8). Choline balance studies were made on four adult male subjects fed an adequate diet under "comfortable" and under "hot moist" environmental conditions.

With a choline intake averaging about 735 mg., only 0.7 to 1.5 percent of the intake was excreted as choline. No increase in total choline excretion was obtained under "hot moist" conditions.

Choline in undiluted sweat ranged from 2.7 $\gamma$  to 15.30 $\gamma$  of choline per 100 cc.

The utilization of choline analogues by cholineless mutants of *Neurospora*, N. H. HOROWITZ, D. BONNER, and M. B. HOULAHAN (*Jour. Biol. Chem.*, 159 (1945), No. 1, pp. 145-151).—Two mutants of *Neurospora*, strain 34486 (cholineless-1) and strain 47904 (cholineless-2), were found to differ in the gene responsible for the cholineless characteristic. A study was made of the biochemical reactions of the two strains with relation to choline and numerous related compounds.

Results showed that, in liquid media, cholineless-2 responded to much lower concentrations of most of the active compounds than the cholineless-1 strain. The authors adduced from this that the mechanism for choline synthesis in cholineless-2 is incompletely blocked. In agar media, the requirements for the two strains were reversed, but no explanation was found for this reaction.

Significant differences were noted in the ability of the mutants to utilize mono- and dimethylaminoethanol; cholineless-2 showing a higher requirement and smaller growth with both compounds than the cholineless-1 mutant.

Vitamin potency of pork as influenced by rations (*Missouri Sta. Bul.* 491 (1945), p. 49).—Swine were fed rations high in vitamin A and riboflavin, or low in riboflavin, and vitamin assays were made on the liver, kidneys, heart,

orain, loin, ham, and shoulder. Only in the liver was there any significant increase in the riboflavin content of those animals fed a high riboflavin ration.

The vitamin content of dehydrated eggs (*Missouri Sta. Bul. 491 (1945), p. 49*).—Rats fed fresh eggs, freshly dried eggs, or freshly dried scrambled eggs showed essentially the same rate of growth. Storage tests on dehydrated eggs were made at 35°–40°, 70°, and 100° F. After 6 months' storage, vitamin A losses amounted to 50, 50, and 82 percent, respectively, and after 12 mo. to 50, 67, and 88 percent.

Biological assays for thiamine showed values of 4.7  $\mu\text{g./gm.}$  dry weight for both fresh liquid and freshly dried eggs. After 3 months' storage at the temperature noted above, only those samples stored at 100° showed a loss (30 percent) of the original thiamine content.

A survey of the vitamins A and D potencies of the liver oil of Atlantic cod (*Gadus morrhua* L.), L. I. PUGSLEY, C. A. MORRELL, and J. T. KELLY (*Canad. Jour. Res.*, 23 (1945), No. 4, pp. 243–252).—Data on the vitamin A and D potencies of authentic samples of oil from the livers of codfish brought into ports in the Gaspé Peninsula, Nova Scotia, and New Brunswick showed that an increase in the vitamin A potency was paralleled by an increase in the vitamin D potency. An increase in the oil content of the liver and of the liver content of the fish was accompanied by a decrease in the concentration of vitamins A and D in the oil. Yields of the vitamins, expressed per 100 gm. of fish, indicated that there was no apparent seasonal change in potency other than those changes due to dilution. A relationship was observed between the stages in the spawning cycle and the oil content of the liver; fish do not feed during the spawning period, thus using the stores of fat in the liver. Fish classed as "steaks" yielded a liver oil higher in vitamins A and D potencies than "market cod," and the liver of "scrod" had the lowest vitamins A and D potencies.

The nutritional value of telang livers, P. L. PAVCEK, E. J. HERBST, and C. A. ELVEHJEM. (*Wis. Expt. Sta.*). (*Jour. Nutr.*, 30 (1945), No. 1, pp. 1–9, illus. 2).—Experiments previously reported (*E. S. R.*, 93, p. 517) are described in detail. The toxic symptoms produced by feeding telang livers to rats could be duplicated when standard stock rations or nontoxic livers were fed along with high doses (20,000 International Units per day) of crystalline vitamin A. Additional data are presented on the fat, mineral, and vitamin content of normal and telang livers. With the exception of iron and vitamin A values, no significant differences were found in the other substances studied. A range of 0.2 to 2.15 mg. of carotene and 15 to 30 mg. of ascorbic acid per 100 gm. fresh tissue is reported. On a dry-weight basis, other vitamin values given are choline, 1500 to 1600 mg.; pantothenic acid, 14 to 18 mg.; niacin, 40 to 50 mg.; and biotin 0.34 to 0.63 mg./100 gm. Fat content ranged from 15.0 to 27.6 percent, while copper values varied widely from 2.0 to 16.0 mg./100 gm. dry weight. In the telang livers, iron values ranged from 27.5 to 35.0 mg., while in normal livers the range was from 21.0 to 24.0 mg./100 gm. dry matter. Two-thirds of the telang livers had vitamin A values of 10 to 60 mg./100 gm. fresh liver, while a majority of the samples of the normal livers contained less than 10 mg. percent of vitamin A.

The nutritive value of snap beans (*Missouri Sta. Bul. 491 (1945), pp. 5–6*).—Snap beans were harvested from July to October. With increasing maturity, the following changes in vitamin values occurred: Carotene decreased; absorbic acid increased, paralleling dry matter; and thiamine and nicotinic acid increased.

Prolonged cooking (3 hr.) of the snap beans destroyed 50 percent of the

ascorbic acid, but caused no appreciable destruction of the other vitamins if the cooking liquids were retained. Discarding the liquid from beans boiled 40 min. resulted in losses of ascorbic acid, thiamine, riboflavin, and nicotinic acid amounting to 67, 34, 30, and 35 percent, respectively. Little loss of B vitamins occurred in canning, whereas, 35 percent of the ascorbic acid was destroyed. Progressive loss of all vitamins occurred in storage of the canned beans. Home freezing procedures resulted in a 35 percent loss of ascorbic acid and 30 percent loss of thiamine. Dehydration produced nearly complete loss of ascorbic acid, but showed excellent retention of the other vitamins. Brining or pickling the beans caused practically total destruction of ascorbic acid. The salted beans, after soaking and cooking, retained 55 percent of the thiamine and 63 percent of the riboflavin present in the original beans. The pickled beans retained only about 20 percent of the B vitamins present in the raw beans. This study was directed by A. G. Hogan and L. M. Flynn with the assistance of S. Hulen and C. Bilbey.

**Vitamin C and carotene in rose hips and products, O. E. STAMBERG.** (Idaho Expt. Sta.). (*Food Res.*, 10 (1945), No. 5, pp. 392-396).—Studies were made on two varieties of rose hips—*Rosa spoldingii* and *R. megalantha*—harvested when green, orange-red, or red. Vitamin C assays were made by the colorimetric method of Loeffler and Ponting (*E. S. R.*, 89, p. 515).

In the rose hips, the meats represented about  $\frac{2}{3}$  and the seeds  $\frac{1}{3}$  of the weight of the fresh material. In the ripe meats, ascorbic acid values ranged from 1,105 to 1,498 mg. per 100 gm. and carotene from 30.3 to 38.3 mg. per 100 gm.

Rose hips, sealed in quart jars and stored at  $-20.6^{\circ}$  C showed good retention of vitamin C over a 6-mo. period. A palatable jam was prepared and stored in a fruit cellar for 6 mo. The vitamin C value of the jam ranged from 106.3 to 125.5 mg. per 100 gm. and showed little loss on storage.

Juices and purees prepared from the rose hips, also were found to be high in vitamin C, palatable, and able to withstand storage in the ice box for several days with little loss of vitamin C.

The author recommends the use of rose hips in various fruit combinations such as fruit salads, sherbets, juices, jams, and jellies because of their high vitamin C and carotene content.

**Stability of added vitamins in beer, F. M. YOUNGER and E. H. HARVEY** (*Food Res.*, 10 (1945), No. 5, pp. 397-400).—Analyses of commercially produced beer of approximately 4 percent alcoholic content showed the following vitamin values per 12 fluid oz. bottle: Thiamine 0.008 mg., riboflavin 0.115 mg., and niacin 1.81 mg. The beer was fortified with 0.425 mg., 0.915 mg., and 19.5 mg. of thiamine, riboflavin, and niacin, respectively. It was then bottled in clear or amber glass, both of which were stored at room temperature in the light, while the amber bottles were also stored in the dark or in a refrigerator at  $40^{\circ}$  F.

Results showed that a 29 percent loss of thiamine occurred in the clear bottles stored in the light at room temperature for 6 mo.; no loss was noted in the other bottles. Riboflavin destruction amounted to 50 percent in the clear bottles during the first week of storage, and increased to 85 percent by 12 weeks. The corresponding amber bottles lost 40 percent in 12 weeks, while those stored in the dark or in the refrigerator each lost 23 percent.

No change in niacin values occurred under any of the storage conditions during the 6 mo. test period.

**Physiological availability of the vitamins—study of methods for determining availability of vitamins in pharmaceutical products, B. L. OSER, D.**

MELNICK, and M. HOCHBERG (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 7, pp. 405-411, illus. 3).—In these preliminary studies various in vitro and in vivo disintegration tests and roentgenograms were compared with the bioassay technic (described below). This latter procedure measures the urinary excretion of a test dose of pure vitamin in relation to the excretion of a comparable amount of the vitamin ingested in food or in tablet form. Results showed that the bioassay test was a more accurate index of the physiological availability of the vitamins than the other methods.

The in vitro tests often showed incomplete disintegration of the vitamin tablet after digestion with gastric and pancreatic juices when chemical assay indicated that 99 percent of the water-soluble vitamins present were in solution. In other in vitro tests, showing nearly complete solubility of riboflavin, the urinary excretion test indicated that only 55 percent of the riboflavin present in that particular product was available. Certain B-complex vitamin capsules (containing fuller's earth) had only 40 percent of the thiamine content in a readily available form.

Tested by bioassays on rats, an indirect procedure has been proposed for the estimation of the availability of fat-soluble vitamins in multivitamin tablets. It is based upon the relative availability of the water-soluble vitamins in the same tablets.

Physiological availability of the vitamins, I-VI (*Jour. Nutr.*, 30 (1945), Nos. 2, pp. 67-88, illus. 1; 3, pp. 193-208; 4, pp. 225-238).

I. *The human bioassay technic*, D. Melnick, M. Hochberg, and B. L. Oser (pp. 67-79).—Using human subjects, a method has been devised to measure the biological availability of one or several of the water-soluble vitamins—ascorbic acid, thiamine, riboflavin, and nicotinamide. The urinary excretion of these vitamins as such or as their derivatives, was found to be directly proportional to the quantity consumed provided the subjects subsisted on an adequate diet. The linear dose-response relationship established by feeding the pure vitamins is the basis of the test for the availability of the vitamin in other forms (food or tablets).

Subjects (five or more) on an adequate vitamin intake were fed a prescribed adequate test diet, and the basal 24-hr. urinary excretion of the vitamin was assayed. A known amount of the pure vitamin was fed (immediately after the noonday meal), and the subsequent increase in the 24-hr. excretion of the vitamin was measured. After a 2-week period on a normal adequate diet, the test diet was again fed and excretion measured. The food containing approximately the same amount of vitamin (by chemical assay) as that previously tested in the pure form was then fed, and the difference in the vitamin excretion calculated.

The difference in the percentage of urinary excretion of the test substance in comparison with that excreted when equal amounts of the pure vitamin was ingested indicated the availability of the vitamin in that food. Results were considered to be as good or superior to those obtained in most animal assays.

II. *The effect of dietary thiaminase in fish products*, D. Melnick, M. Hochberg, and B. L. Oser (pp. 81-88).—The thiaminase in certain fish products (clams and herring) is capable of causing rapid and complete destruction of thiamine in vitro when incubated with certain food mixtures. More than eight times the minimal daily requirement of thiamine was destroyed when a homogenous mash of a daily ration was prepared to which both clams and thiamine had been added.

Human availability studies were carried out by the procedure outlined

above in which raw clams provided the thiaminase and heated clams served as controls. About 50 percent destruction of the ingested thiamine occurred in the gastrointestinal tract following the concomitant ingestion of raw clams. The use of the thiaminase of raw clams in the study of vitamin B<sub>1</sub> methodology, as well as its possible conditioning factor in certain kinds of malnutrition when raw or partially heated fish are consumed is discussed

III. *The effect of dietary ascorbic acid oxidase*, M. Hochberg, D. Melnick, and B. L. Oser (pp. 193-199).—In vitro tests with diets containing substantial amounts of raw vegetables (cabbage, green beans, pepper, and carrot as well as tomato, cucumber, and lettuce) showed that most of the ascorbic acid was oxidized to the dehydro form by simple homogenization. Further incubation of the homogenized diet for 6 hr. produced a further conversion of over 60 percent of the dehydroascorbic acid to biologically inactive forms.

In vivo studies carried out as described in Part 1 indicated that the activity of the ascorbic acid oxidase is either destroyed or inhibited in the gastrointestinal tract. No greater destruction of either naturally occurring ascorbic acid or of added ingested ascorbic acid took place prior to absorption when active enzymes were present in the diet, comparable results being obtained on diets containing heat-inactivated or active ascorbic acid oxidase.

IV. *The inefficiency of live yeast as a source of thiamine*, M. Hochberg, D. Melnick, and B. L. Oser (pp. 201-208).—In vitro experiments were carried out with regular and high vitamin yeasts. Known amounts of thiamine were added to an aqueous suspension of the yeast cells, and the thiamine present in the solution or cell suspension was estimated by the thiochrome method. Results showed that a suspension of cells of nonenriched bakers' yeast was capable of removing nearly all of the added free thiamine from the solution. Cocarboxylase tests indicated that practically all of the absorbed vitamin was transformed to the phosphorylated form. In vivo experiments carried out as described in Part 1 supported these findings. In this study, an enriched live yeast was tested. The sample was found to have a large part of its thiamine in the free form and was practically ineffective in phosphorylating thiamine when in solution. In spite of these conditions, considered to favor the presence of available thiamine, only 17 percent of the total amount present in the yeast was found to be physiologically available. This lowered availability of thiamine could not be attributed to a slower rate of absorption of the vitamin from live yeast.

V. *The effect of copper on extra dietary ascorbic acid*, M. Hochberg, D. Melnick, and B. L. Oser (pp. 225-231).—In vitro studies showed that the addition of 7 mg. of copper to homogenized mixtures of a day's ration produced a slight destruction (approximately 20 percent) of the ascorbic acid present. This destruction was considered to be absolute as no further destruction occurred when 200 mg. of ascorbic acid was added to the mixture. Comparisons between blanched and unblanched samples of the diet indicated that the marked loss of ascorbic acid occurring in the unblanched mixture was due to the presence of ascorbic acid oxidase. As the addition of copper produced only slightly greater destruction of the total ascorbic acid present, the authors adduce that the ascorbic acid oxidase is a specific enzyme.

In vivo studies on humans showed that as much as 7 mg. of copper could be taken concurrently with 200 mg. of ascorbic acid without impairing the availability of the ascorbic acid present.

VI. *The effect of adsorbents on thiamine*, D. Melnick, M. Hochberg, and B. L. Oser (pp. 233-238).—Kaolin and fuller's earth, two commonly used adsorbents, were tested in the presence of thiamine by in vitro and in vivo as-

says. *In vitro* results showed that relatively small amounts of fuller's earth were capable of adsorbing all of the thiamine in the test solution. Similar amounts of kaolin (0.5 gm.) produced less complete adsorption.

Bioassay tests on humans, made to test the availability of the thiamine present in a B-complex capsule containing fuller's earth, showed that only 27 percent of the thiamine present was available to the human body. When similar tests were made with kaolin, taken postprandially and followed immediately by a test dose of thiamine, the thiamine was found to be 133 percent available when compared to a similar dose taken without kaolin. The authors, having found comparable greater-than-theoretical values in other experiments, conclude that thiamine can exhibit variable degrees of stability in the intestinal tract prior to absorption. Various materials ingested concurrently apparently are able to protect the vitamin during its passage through the gastrointestinal tract.

Effects of food intake and anoxia upon ascorbic acid excretion, acidity of urine, and survival of male albino rats, K. E. LANGWILL, C. C. KING, and G. MACLEOD (*Jour. Nutr.*, 30 (1945), No. 2, pp. 99-109).—Studies were made on the influence of diet upon the effects of anoxia induced by breathing a gas mixture low in oxygen at atmospheric pressure. Groups of male albino rats were fed "(1) dog chow alone, (2) a chow diet plus a daily supplement of 5 gm. of raw horse meat, (3) a chow diet plus a preexposure supplement of 2 gm. of sucrose, and (4) dehydrated carrots as the sole source of food." Incidence of survival, ascorbic acid excretion, pH, titratable acidity of the urine were noted.

Results showed that anoxia caused an increase in the pH of the urine and a decrease in titratable acidity, which was accompanied by polyuria. The ascorbic acid concentration of the urine varied inversely as the pH, a high pH being accompanied by a low ascorbic acid value. Increased alkalinity of the urine of animals fed a horse meat supplement, compared with animals fed chow alone, was not accompanied by protection of the animals against marginal lethal exposures to anoxia. A preexposure sugar supplement did not affect the altitude tolerance of rats on a chow diet.

When the consumption of chow was regulated equicalorically with the consumption of dehydrated carrots fed ad libitum, the two groups of animals survived severe anoxia almost equally well under some conditions of testing. In other tests where repeated exposures and more gradual ascent provided an opportunity for adaptation, there was evidence of added protection as a result of the carrot diet. The increased alkalinity, high potassium content, and low protein content of the carrot diet afford a tentative basis of accounting for the increased tolerance.

Biomicroscopy of the eyes in evaluation of nutritional status [Conjunctival changes and corneal vascularization], R. K. ANDERSON and D. F. MILAM (*Jour. Nutr.*, 30 (1945), No. 1, pp. 11-15, 17-24).—This study forms part of a previously reported survey (E. S. R., 93, p. 653) on nutritional status in a rural community in North Carolina.

*Conjunctival changes.*—Tabulated data are presented showing the severity and incidence of conjunctival changes detected with the slit lamp, the level of vitamin A found in the plasma, and the estimated daily dietary intake of vitamin A. No correlation could be established between the eye lesions observed and the dietary intake or plasma level of vitamin A. In general, the frequency and severity of the conjunctival changes were greater in the Negro than in the white subjects studied.

*Corneal vascularization.*—Similar lack of correlation was observed between

riboflavin intake and corneal changes. In general, more frequent evidence of corneal invasion was noted in the white than in the Negro subjects.

The amounts of vitamin B<sub>1</sub> in cereals and the extent to which they supply human requirements in various dietaries, W. I. M. HOLMAN (*Nutr. Abs. and Rev.*, 15 (1946), No. 3, pp. 387-410, illus. 1).—This comprehensive review presents data showing the effects of stage of growth, varietal differences, soil and environmental conditions, degree of milling, and storage on the thiamine content of the common cereal grains.

Data on the human requirements for B<sub>1</sub> are presented, and the proportions of cereals in various dietaries are tabulated. The contribution of cereals (in the diets of various groups) to the total B<sub>1</sub> requirement is estimated.

The bibliography contains over 200 references, most of them of recent origin.

The retention of thiamine, riboflavin, and niacin in cooking pork and in processing bacon, S. H. JACKSON, A. CROOK, V. MALONE, and T. G. H. DRAKE (*Jour. Nutr.*, 29 (1945), No. 6, pp. 391-403).—A study was made on the effect of variations in preparation, cooking, and processing upon the B vitamins in pork. Comparisons were made between cuts from different carcasses, cuts from the same carcass taken from opposite sides, different methods of roasting or frying pork, and various methods of processing bacon.

Average values per gram of raw pork loin or butt, respectively, were: Thiamine, 6.95 and 6.22  $\mu\text{g.}$ ; riboflavin, 1.36 and 1.21  $\mu\text{g.}$ ; and niacin, 26.3 and 30.8  $\mu\text{g.}$

The pork butts were roasted correctly, underdone, or overdone. Average vitamin retentions were, respectively, 46.0, 57.5 and 36.8 percent for thiamine; 96.0, 105, and 92.0 percent for riboflavin; and 78.0, 94.0, and 75.2 for niacin. When loin pork chops were fried under similar conditions, greater retention of thiamine and niacin was noted, and considerably greater loss of riboflavin occurred. Correctly fried chops average 56.8, 76.9, and 96.6 percent retention of thiamine, riboflavin, and niacin, respectively.

Bacon samples were taken from the shoulder end of the full sides or back, or from the ham ends. One sample was wet cured and two samples were dry or box-cured following standard Canadian procedures. Values for the processed bacon averaged highest for the dry-cured back samples, being 7.37, 1.08, and 40.1  $\mu\text{g./gm.}$  bacon for thiamine, riboflavin, and niacin, respectively. Average values for wet- or dry-cured bacon sides were, respectively, 3.53 and 3.40  $\mu\text{g./gm.}$  for thiamine, 1.10 and 0.80 for riboflavin, and 21.9 and 22.3  $\mu\text{g./gm.}$  for niacin. Vitamin retentions for the wet- and dry-cure methods averaged, respectively, 74.1 v. 84.0 percent for thiamine, 89.0 v. 56.6 for riboflavin, and 80.8 v. 96.4 percent for niacin.

The authors conclude that prolonged cooking increases the loss of B vitamins. Frying gives a higher retention of thiamine than roasting.

The riboflavin, niacin, and thiamine content of dried leguminous seeds, L. DANIEL and L. C. NORRIS. (Cornell Univ.). (*Jour. Nutr.*, 30 (1945), No. 1, pp. 31-38).—Seventeen varieties of legumes were studied, including soybeans, split peas, blackeye peas, lentils, peanuts, lima beans, and several kinds of kidney beans (red and white kidney, pinto, pea, cranberry, pink and yelloweye, white marrow, Great Northern, black turtle soup, and Red Mexican). Two different methods were used to determine each vitamin in one sample of all legumes studied. Differences between methods averaged less than 5 percent in all cases. The routine methods finally adopted were the fluorometric method for riboflavin, the microbiological method for niacin, and the thiochrome method for thiamine.

Tabulated results show the average riboflavin content of legumes to be

rather constant, being highest in soybeans (average—3.3  $\mu\text{g./gm.}$ ) and ranging from 1.6 to 2.6  $\mu\text{g./gm.}$  in the other legumes studied. Little variation in niacin content was noted with the exception of peanuts, which average 136 and 157  $\mu\text{g./gm.}$  for the white Spanish and runner varieties, respectively. Other niacin values ranged from 18.1 for Red Mexican beans to 35.8 for green split peas. The average thiamine content ranged from 3.6 to 10.4  $\mu\text{g./gm.}$ , being lowest in lima beans and highest in soybeans.

Failure of succinylsulfathiazole to aggravate egg white induced biotin deficiency in rats, G. A. EMERSON and E. WURTZ (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 2, pp. 297–298).—Weanling male rats were fed biotin-deficient diets containing 15 percent egg white, certain groups receiving 2 percent dried beef liver and/or 0.75 percent succinylsulfathiazole in addition to the basal diet. In all cases, the addition of succinylsulfathiazole to these diets did not aggravate the signs of biotin depletion nor shorten the time required to produce the deficiency symptoms. When liver was contained in the diet, the addition of biotin was sufficient to produce normal growth. In the absence of liver in the diet, the addition of both biotin and a “folic acid” concentrate were necessary to produce good growth which was nearly equal to that obtained when liver was present in the ration.

Growth stimulants for microbiological biotin assay, V. R. WILLIAMS and E. A. FIEGER. (La. Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 2, pp. 127–130, illus. 3).—The *Lactobacillus casei* method of Shull et al. (E. S. R., 87, p. 626; 92, p. 8) for the assay of biotin was found to show a marked drift when used to assay certain rice products. Rice polish fractions, in particular, exerted considerable stimulatory action on the growth curve. By testing various extracts of rice polish treated by filtration, ether extraction, enzyme digestion, etc., the lipoidal nature of the stimulatory substance was established. Further studies with lecithin, mineral oil, oleic acid, and whole rice oil showed the latter two substances to be highly stimulatory. A less marked effect was noted with lecithin, while the results with mineral oil were uncertain. The use of these substances as supplements to the basal medium was not successful in improving the assay for biotin. No evidence of biotin synthesis could be found in tubes showing high acid and cell production in the presence of the basal medium and rice oil, but without added biotin.

The stimulatory effect of the rice polish could be obviated by filtration or ether extraction.

Growth stimulants in the *Lactobacillus arabinosus* biotin assay, V. R. WILLIAMS. (La. Expt. Sta.). (*Jour. Biol. Chem.*, 159 (1945), No. 1, pp. 237–238).—A brief note is presented to show that the same factors in rice polish which affect the *L. casei* assay for biotin (see above) also act as growth stimulants for *L. arabinosus*.

The microbiological determination of nicotinic acid, nicotinamide, and nicotinic acid, B. C. JOHNSON. (Univ. Ill.). (*Jour. Biol. Chem.*, 159 (1945), No. 1, pp. 227–230, illus. 1).—The medium of Gaines and Stahly (E. S. R., 90, p. 457) using *Leuconostoc mesenteroides* has been modified by the addition of purines, buffer, and glucose to give a maximum titration value of 12 to 15 cc. 0.1 N NaOH. *L. mesenteroides* has been considered to react specifically to nicotinic acid, as no response to nicotinamide or nicotinuric acid was noted in doses up to 10  $\mu\text{g./tube}$ . By using this organism as a test, parallel with the *Lactobacillus arabinosus* assay procedure of Krehl et al. (E. S. R., 90, p. 727), a differential determination of nicotinic acid and its derivatives could be made. Nicotinamide could be hydrolyzed to nicotinic acid by treatment with

0.6 N  $\text{H}_2\text{SO}_4$  for 1 hr. at 15-lb. pressure. Under these condition, nicotinuric acid remained unchanged.

The excretion of nicotinic acid, nicotinamide, nicotinuric acid, and N<sup>1</sup>-methylnicotinamide by normal individuals, B. C. JOHNSON, T. S. HAMILTON, and H. H. MITCHELL. (Univ. Ill.). (*Jour. Biol. Chem.*, 159 (1945), No. 1, pp. 231-236).<sup>9</sup>—A study of the metabolism of nicotinic acid and its metabolites was carried out by the procedures outlined above. N<sup>1</sup>-methylnicotinamide was assayed by the fluorometric method of Huff and Perlzweig. (*E. S. R.*, 92, p. 6). Four men subjected to a hot moist environment were fed a normal diet to which 50 mg. of nicotinamide were added at intervals over a 5-day period. Analyses were made for nicotinic acid, nicotinamide, nicotinuric acid, and N<sup>1</sup>-methylnicotinamide excreted in the urine and sweat.

Results showed that over 94 percent of the nicotinic acid and metabolites excreted in the urine was in the form of N<sup>1</sup>-methylnicotinamide, only 1-1.5 percent being excreted as free nicotinic acid, and 3.5-4.5 percent as nicotinamide. "No nicotinuric acid was found in either urine or sweat." The amounts of all these metabolites excreted in sweat were considered to be too small to be of significance in the nicotinuric acid requirement of man.

Fecal riboflavin of rats receiving varying intakes of riboflavin, H. G. OBERMEYER, E. WURTZ, and G. A. EMERSON (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 2, pp. 300-302).—A riboflavin-free purified diet was fed to weanling male rats, with daily supplements of 10  $\mu\text{g.}$  or 40  $\mu\text{g.}$  riboflavin fed by stomach tube to certain groups of animals. Those rats receiving the supplements were so subdivided that one group on each level of riboflavin was restricted to 50 percent of the caloric intake of the corresponding ad libitum group.

Fecal riboflavin was determined by the fluorometric method. Results showed that the concentration of riboflavin (as expressed in micrograms per gram of feces) was essentially the same for all groups. It more nearly followed the food consumption and seemed independent of the riboflavin intake.

"The total output of riboflavin was dependent upon the quantity of feces excreted. Rats receiving riboflavin but with the caloric intakes restricted to the extent of 50 percent excreted less total riboflavin than did their ad libitum controls."

A note on sterol production by *Aspergillus flavus-oryzae* with special reference to its anti-rachitic potency, W. J. ELLIS (*Jour. Council Sci. and Indus. Res. [Austral.]*, 18 (1945), No. 4, pp. 314-317, illus. 1).—The total sterol content of wheat bran mash was doubled by growing on it a mold of this group. The spectral absorption curves of alcoholic extracts of the moldy bran resembled those for ergosterol, and the antirachitic potency for rats observed after drying the bran in the sun was equivalent to approximately 1,800 International Units Vitamin D per 100 gm. of the water-extracted dry moldy bran.

Non-availability of fecal thiamine in thiamine deficiency, G. A. EMERSON and H. G. OBERMEYER (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 2, pp. 299-300).—Weanling male rats were fed a thiamine-low diet—technical casein, 16; cornstarch, 60; autoclaved brewers' yeast, 9; salt mix, 4; Crisco, 9; cod-liver oil, 2; and nonirradiated brewers' yeast, 0.2. The groups received either 0, 5  $\mu\text{g.}$ , or 50  $\mu\text{g.}$  of thiamine daily. Fecal thiamine excretion was measured by the thiochrome method. Results showed that "rats maintained on a thiamine-deficient diet excreted essentially the same concentration of thiamine in their stools as did animals receiving 5 or 50  $\mu\text{g.}$  of thiamine daily. The output of feces was greatly reduced in the thiamine low group. During the later stages of the depletion the thiamine was present largely in the form of cocarboxylase.

"The fecal thiamine of the deficient rats was not available when administered curatively by the oral route to animals which had plateaued in weight on a thiamine-low diet."

**Biological estimation of the thiazole and pyrimidine moieties of vitamin B<sub>1</sub>.** H. G. OBERMEYER and L. CHEN' (*Jour. Biol. Chem.*, 159 (1945), No. 1, pp. 117-122).—A differential procedure is described based upon the ability of bakers' yeast to synthesize thiamine from the active thiazole and pyrimidine moieties. In thiamine degradation products, these moieties can be estimated individually without interference from other fermentation-stimulating substances. Several derivatives of thiazole and pyrimidine were tested and their activity determined. Results indicate that a substantial amount of available thiazole and pyrimidine may remain in food products in which thiamine has undergone partial decomposition. The authors discuss these findings and their bearing upon the intestinal synthesis of thiamine in feeding experiments.

**Stability of thiamin chloride (vitamin B<sub>1</sub>) in mineral and vitamin-fortified cereal.** A. B. EKLUND and V. R. GODDARD. (Univ. Calif.). (*Food Res.*, 10 (1945), No. 5, pp. 365-372).—Eleven breakfast cereals showed a range of values from pH 5.1 to 7.5 in the raw state and from pH 5.5 to 7.3 when cooked. The cereal which tested to give the highest pH value was a product fortified with thiamine chloride and minerals. This cereal was assayed for thiamine by the biological (rat-growth) method of Booher and Hartzler (*E. S. R.*, 83, p. 131) both before and after quick cooking to determine the effect of the cooking process upon thiamine stability.

The thiamine value was found to be 3.2 for the raw cereal and 4.2  $\mu$ g. per gram for the cooked.

The authors conclude that quick cooking of this cereal caused no destruction of the added thiamine and possibly increased its availability to a slight extent.

**Further studies on factors that affect xanthurenic acid excretion.** E. C. MILLER and C. A. BAUMANN. (Wis. Expt. Sta.). (*Jour. Biol. Chem.*, 159 (1945), No. 1, pp. 173-183).—Xanthurenic acid metabolism was studied by the procedures previously reported (*E. S. R.*, 95, p. 128). Data are presented on the excretion of administered xanthurenic acid by normal and pyridoxine-deficient mice and rats. Studies were also made on the relative effectiveness of pyridoxal and pyridoxamine in promoting growth and preventing excretion of xanthurenic acid.

Mice fed 0.5 or 3.0 mg. of xanthurenic acid per gram of diet excreted about 16 percent in the urine. Rats fed single doses (12 to 20 mg.) excreted 10 to 30 percent in the urine in 3 to 7 days, while those injected intraperitoneally excreted 50 to 58 percent within 24 hr. The percentage of the doses that could be recovered was essentially the same whether pyridoxine was administered or not.

Pyridoxine-deficient rats excreted 12 to 16 percent of an intraperitoneal injection of 1-tryptophan, as xanthurenic acid in the urine, while only 1 percent was excreted by rats receiving pyridoxine in the diet.

Mice and rats fed xanthurenic acid in the diet excreted from 5 to 25 percent of the compound in the feces. No increased fecal excretion was observed after feeding diets high in casein to pyridoxine-deficient or control rats and mice, or after feeding single doses of tryptophan to pyridoxine-deficient rats.

The consumption of 3 mg. of xanthurenic acid per gram of diet for 31 days had no effect on the growth or survival of control or pyridoxine-deficient mice. These mice excreted as much xanthurenic acid in the urine as did deficient mice on 45 percent casein diets.

As judged by both growth and excretion of xanthurenic acid, pyridoxamine

and pyridoxal were less active for mice than pyridoxine. By growth tests these compounds also appeared to be less active for rats. A sample of the lactone of 2-methyl-3-hydroxy-4-hydroxymethyl-5-carboxypyridine was found to have only slight activity for mice.

**Retention of ascorbic acid in marmalade during preparation and storage.** R. LINCOLN and C. M. MCCAY. (Cornell Univ.). (*Food Res.*, 10 (1945), No. 4, pp. 357-363, *illus.* 1).—The preparation of a marmalade high in ascorbic acid was achieved by the use of orange and lemon peel or orange and grapefruit peel. The use of 1.2 parts fruit to 1 part sugar was satisfactory. The proportion of peel to fruit was 0.2 to 1.0. Commercial marmalades (stored for an indefinite period) gave ascorbic acid values ranging from 4 to 10 mg./100 gm., while the experimental samples (with orange and lemon peel) contained 28.6 mg./100 gm. This corresponded to a retention of 68 percent of the amount present before preparation. A marmalade containing 40 mg. percent ascorbic acid was prepared by using grapefruit and orange peel.

Ascorbic acid values for orange and lemon peel were found to average 115 and 178 mg. percent, respectively.

When marmalades prepared with or without the addition of citric acid were stored at 38°, 86°, and 100° F., the ascorbic acid losses increased with increase in storage temperature. However, over a 16-week period, samples prepared with citric acid showed very little loss of ascorbic acid (approximately 15 percent even at 100°). Practically no loss occurred at 38°.

Assays for ascorbic acid made by several methods—indophenol, phenylhydrazine, and the formaldehyde method of Mapson (*E. S. R.*, 93, p. 538)—indicated that in the marmalade samples stored at high temperatures (86° to 100°), a large percentage of the ascorbic acid values obtained by the first two methods were due to other reducing substances. When the ascorbic acid content was high, the nonspecific reducing substances were small (approximately 5 percent).

**Vitamin C changes occurring in tomatoes during home canning and subsequent storage.** M. B. PATTON (*Ohio Sta. Bimo. Bul.* 239 (1946), pp. 44-46, *illus.* 1).—Experimentally grown tomatoes of the Marosu variety were tested over a 3-yr. period. Ascorbic acid determinations were made on various samples—raw freshly harvested, after removal of skin and core, and after canning. No loss of ascorbic acid was observed when the tomatoes were allowed to stand 2 days before canning.

The ascorbic acid content of the freshly harvested tomatoes averaged 20.2, 25.2, and 26.0 mg./100 gm. wet weight for the 3 yr., respectively. Removal of core and skin resulted in an approximately 15 percent loss of ascorbic acid. The yearly averages of ascorbic acid retention in tomatoes analyzed within 24 hr. after canning by the hot pack method were 85, 88, and 76 percent, respectively.

Assays were made at intervals over a 12- to 16-mo. period in which the canned tomatoes were stored at room temperature. Results showed a progressive loss of ascorbic acid; the greatest rate of loss taking place during the first 3 mo. of storage. After 12 months' storage, the ascorbic acid content averaged slightly more than 50 percent of the amount originally present in the canned tomatoes.

**Inhibition of pigment deposition in incisor teeth of rats deficient in vitamin E from birth.** H. GRANADOS and H. DAM (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 2, pp. 295-296, *illus.* 1).—Normal female rats and their offspring were maintained for 60 days on the high- and low-fat vitamin E-deficient rations previously described (*E. S. R.*, 94, p. 279). An additional diet con-

sisting of vitamin E-deficient rations but containing 20 percent of lard was also tested. Production of normal pigment did not occur in the enamel of the incisor teeth of the young of those rats fed vitamin E-deficient high-fat rations (20 percent of cod liver oil or 20 percent of lard).

## TEXTILES AND CLOTHING

Selected references relating to the field of color science, D. NICKERSON. (U. S. D. A.). (*Textile Res. Jour.*, 16 (1946), No. 2, pp. 74-83).—This specialized bibliography lists books which are currently important to a technical worker in the science of color and its application. The list is prepared under these headings: General references; color standards and color charts; color tests; the eye; and periodical literature.

New test apparatus for measuring the coolness of textiles, R. H. ARMITAGE (*Rayon Textile Mo.*, 26 (1945), No. 11, pp. 77-78).—The apparatus described here measures the combined effect of air and moisture permeability, absorption, and evaporation of the fabrics. Operation and fabric testing procedures are outlined.

Physical properties of knitted fabrics made of natural and mercerized carded and combed cotton yarns, H. M. FLETCHER. (U. S. D. A.). (*Rayon Textile Mo.*, 26 (1945), No. 5, pp. 87-90, illus. 1).—"In the comparisons of carded and combed products the chief differences were found in the strength. In all cases the breaking strength of the combed yarns and the bursting strength of the fabrics knitted from these yarns were greater than the carded. The two groups showed no marked differences in other physical properties.

"In the comparisons of the natural and mercerized, the mercerized yarns were equal or greater in strength than the natural, but the mercerized yarns and also the fabrics had less elongation than the natural. The bursting strength of the fabrics knit of mercerized yarns was less in every case than those of natural yarns even though the mercerized yarns were equal or greater in breaking strength. The air permeability of the mercerized fabrics was greater than the natural. The two groups were similar in other characteristics."

A summary of the results of individual comparisons of the data on the various properties are tabulated.

Wool and its upkeep, L. LUND (*South Dakota Sta. Cir.* 63 (1946), pp. 4).—Wool properties which play an important part in its behavior are resilience, elasticity, and plasticity. Essential equipment for pressing wool materials efficiently include a well-padded board, heavy napped woolen pressing cloth, cotton cloths (cheesecloth or muslin, and heavy duck), sponge, padded roll for pressing seams, a tailor's cushion, and an ordinary or steam iron. Procedures for pressing wool and removing shine and baggy spots are given, and suggestions for care and storage are noted.

Mechanics of abrasion of textile materials, W. J. HAMBURGER (*Textile Res. Jour.*, 15 (1945), No. 5, pp. 169-177, illus. 6).—"A method is described for predicting the inherent abrasion resistance of textile materials substantively by the use of load-elongation diagrams of mechanically conditioned specimens. Immediate and delayed deflections are discussed as they affect energy coefficient E. This coefficient is shown to be a function of: (1) Low modulus of elasticity; (2) large immediate elastic deflection; (3) high ratio of primary to secondary creep; (4) high magnitude of primary creep; and (5) high rate of primary creep.

"Nylon shrunk, nylon unshrunk, acetate, and viscose yarns are evaluated

on the Taber Abraser, and from rate-of-destruction curves durability coefficients D are obtained. Correlation is shown to exist between durability coefficients and energy coefficients and energy coefficients for the four yarns."

**A study of lining fabric abrasion**, W. J. HAMBURGER and H. N. LEE (*Rayon Textile Mo.*, 26 (1945), Nos. 7, pp. 93-96, illus. 6; 8, pp. 61-64, illus. 14).—The problem of properly evaluating the abrasion resistance of viscose and Celanese lining fabrics was considered from the cause and effect point of view. The Taber Abraser was selected as the laboratory means of creating destruction by abrasion action, and a procedure standard was established. The effect of such abrasion was studied by examining microscopically the yarns and the fabric. From the data obtained on the physical properties governing repeated stress performance of textile materials, Celanese manifests a greater resistance to abrasion than does viscose for the materials investigated.

**Wear resistance of apparel textiles: A literature survey**, H. S. HALL and E. R. KASWELL (*Textile Res. Jour.*, 15 (1945), No. 5, pp. 178-189, illus. 2).—The scope of this survey covers abstracts and articles in periodicals which deal with textiles and related fields. The material included is confined to the subject of wear, with emphasis placed upon wear by abrasion. Also included are short descriptions of test machines and apparatus, methods, techniques, observations, and evaluations for measuring certain wear factors.

**Report of committee on flammability of consumer textiles**, H. E. HAGER (*Amer. Dyestuff Rptr.*, 34 (1945), No. 15, pp. P291-P292, illus. 1).—This paper reports a test method which distinguishes between dangerous fabrics and nondangerous fabrics and evaluates them for flammability characteristics by measuring their rate of burning. A description of the test apparatus and directions for its use in determining the flammability of test specimens are outlined. Using this test procedure, correlated test reports will serve as a basis for drawing up a tentative method which may be accepted as a commercial standard and serve as a basis for a Federal law.

**Inflammability of consumer textiles**, F. BONNET (*Rayon Textile Mo.*, 26 (1945), No. 7, pp. 62-64, illus. 1).—Legislation regarding the inflammability of garment fabrics is reviewed in this report. An account is given of the proposed tentative test method for evaluating textile materials and test apparatus noted above.

**Evaluation of fabrics as to their flammability** (*Amer. Dyestuff Rptr.*, 35 (1946), No. 1, pp. P20-P25, illus. 4).—In consideration of the above reports, this paper deals with difficulties encountered in arriving at a test method for evaluating textile flammability. As a result of correlated test reports from various laboratories, minor changes were suggested. These include conditioning the test specimens as a means of controlling burning time averages of the fabrics, and controlling the relative humidity of the fabric as well as drying temperatures. Revised instructions for operating the flammability tester and proposed testing procedures are given.

**Durable flameproofing suitable for cotton outer garments**, K. S. CAMPBELL and J. E. SANDS. (U. S. D. A.). (*Textile World*, 96 (1946), No. 4, pp. 118-119, 222, 226, illus. 1).—A flameproofing agent made with a resin of proper chlorine content was produced by employing an emulsion technic and by incorporating a water-soluble formaldehyde resin monomer. Mechanical application of the finish required passage through a two- or three-roll padder. Tests demonstrating the relative efficiency of the treatment showed that the proofed material increased in weight 30-60 percent, depending upon the type of fabric used. Fabrics so treated were found suitable for work uniforms, life-jacket vests, or coveralls. After 24 individual washings with soap and soda

ash at 160° to 170° F. in a commercial-type laundry machine, the fabric did not ignite with a lighted match.

**Evaluation of fabric pest deterrents** (*Amer. Dyestuff Rptr.*, 34 (1945), No. 21, pp. P400-P403, illus. 2).—This tentative method of test covers the biological procedure for determining the insect resistance of fabrics which contain wool or other susceptible fibers. The insect pests discussed here apply to webbing clothes moths and black carpet beetles larvae. The excrement weight method and the fabric loss method, previously noted (E. S. R., 92, p. 601), are discussed from the standpoints of test conditions, test insects (specific insects in each test given), and extent of damage. Visual examinations, based on visualometer readings, are described. The life cycle method is being considered as a final criterion on the efficiency of a moth-proofing compound. Tentative procedures for rearing and handling cultures of the black carpet beetle and webbing clothes moth for experimental purposes are noted.

**Evaluation of compounds designed to increase the resistance of fabrics and yarns to insect pests** (*Amer. Dyestuff Rptr.*, 34 (1945), No. 21, pp. P403-P404).—The procedure for the evaluation of compounds or treatments designed to protect textiles from damage by insect pests (moths and carpet beetles) is covered in this tentative method outlined here. It considers not only the initial protection furnished by the treatment in question, but also the permanency of this protection during ordinary conditions of use. The following conditions of use are noted: Duration, washing, cleaning, hot pressing, light, abrasion, sea water, and perspiration. The resistance of the treated fabric to insect pests is determined by the tentative method outlined above.

**Effects of mildew on vegetable tanned strap leather**, J. R. KANAGY, A. M. CHARLES, E. ABRAMS, and R. F. TENER (*Jour. Amer. Leather Chem. Assoc.*, 41 (1946), No. 5, pp. 198-213, illus. 7).—The action of mildew on vegetable-tanned leather produces changes in its physical properties. These changes were found due at least in part to removal of the grease, causing an increase in stiffness and a loss in both tensile strength and stretch at the breaking point; the grain was also weakened. Mildew caused no appreciable deterioration of hide substance in the leather.

**Hosiery size and fitting standards utilize new device**, W. P. SEEM (*Textile World*, 96 (1946), No. 3, pp. 125, 127, 240, illus. 3).—Newly developed hosiery fitting measure devices, providing a key to comprehensive size classification system, are now being perfected. These are designed to put hosiery knitting specifications and nylon preboarding on a wearing instead of a boarding length basis and to afford accurate testing for stretch and recoverability. It is estimated that 95 percent of women's leg sizes can be gaged by these devices, where at present 95 percent of the hosiery manufacturers produce only one length and one width size.

**Sewing for the home**, M. B. PICKEN (*New York and London: Harper & Bros.*, 1946, rev. and enl., pp. 211+, about 200 illus.).—This book deals in detail with the making of fabric furnishings for the home. Construction principles set forth here are illustrated by color pictures and by diagrammatical drawings.

## HOME MANAGEMENT AND EQUIPMENT

**Planning your house of the future**, H. GOLDSTEIN (*Minn. Farm and Home Sci. [Minnesota Station]*, 3 (1946), No. 2, pp. 8-9, illus. 4).—This is a discussion of methods for planning to build or remodel a house and install equipment.

## REPORTS AND PROCEEDINGS

Fifty-eighth Annual Report, Colorado Agricultural Experiment Station, 1944-45, H. J. HENNEY. (Partly coop. U. S. D. A.). (*Colorado Sta. Rpt. 1945*, pp. 52, illus. 4).—Results are briefly noted of progress in the division of agriculture, including tests of hybrid corn, a new barley, longevity of farm seeds, value of trashy fallow, and benefits from nitrogen fertilizers; animal investigations, including winter and summer feeding tests with cattle, ammoniated dried beet pulp and urea as protein sources, preservatives for alfalfa storage, nutrient utilization by steers of different body types, utilization of potatoes, alfalfa, and sweet clover as silage, beet pulp for fattening lambs, and pinto beans and potatoes for fattening pigs; plant pathology, including a new type of net necrosis, and control of pea diseases, *Verticillium albo-atrum* in sugar beets, and virus diseases of peaches; chemistry, including the relative absence of selenium and molybdenum under irrigation; entomology, including notes on the russet mite of tomatoes, control of the bean cutworm, Mexican bean beetle, codling moth, potato insects, aphid yellows of celery, and *Myzus persicae* Sulzer as a vector of peach mosaic; home economics, including vitamin losses in processing vegetables; horticulture, including effect of minor elements on potatoes, potato breeding, potato virus diseases, bacterial wilt, and ring rot, types of fertilizer and rate of application of sulfur for the San Luis Valley, breeding onions and peaches, fertilizers for peas, control of tomato fruit rot, and tests of tomato varieties and rust-resistant pinto beans; poultry, including notes on soybean products, laying houses for Colorado, and factors affecting the quality of eggs; range and pasture management, including revegetation studies of depleted range and crop lands, nutritive value of native forage plants, and improvement of sagebrush lands and other range practices to increase livestock production; rural economics, including notes on a two-edged potato seed cutter and marketing Colorado peaches; veterinary pathology, including notes on abscessed liver in cattle, overeating in feed-lot lambs and feed-lot gains as affected by drenching, rearing and diseases of foxes, nymphomania in cattle, and bovine mastitis; and engineering, including notes on the application of irrigation, notes on sugar beet machinery, and mechanical handling of cull potatoes.

Fifty-seventh Annual Report [of Georgia Station], 1945, H. P. STUCKEY. (Partly coop. U. S. D. A. et al.). (*Georgia Sta. Rpt. 1945*, pp. 91, illus. 4).—This report presents research findings in agricultural economics, including data on the wartime production capacity of Georgia farms in 1945, postwar adjustments in agricultural production, farm tenancy, Georgia farm prices, and a farm management analysis of dairying in Putnam County; agronomy, including yield tests with Empire and other cotton varieties, breeding cotton for wilt resistance, cotton defoliation and seed treatments, varieties of soybeans, sericea lespedeza, and kudzu, breeding corn, wheat, oats, barley, and rye, fertilizers for rye, oats, wheat, and barley, effect of fertilizers on *Sclerotium rolfsii* on Spanish peanuts, potash and borax for alfalfa, lime for cotton, silicate slag v. calcic limestone for corn and pimientos, liquid ammonia for sorghum, and sulfate of ammonia for corn; animal industry, including studies of home-grown roughages and sweetpotato meal for dairy cattle, supplementary concentrate feeding of dairy heifers and young beef cattle, wintering cattle on peanut hay and other feeds, comparison of cracked barley, wheat, and corn, and whole wheat for fattening beef cattle, creep feeding beef calves on pasture, sheep breeding, worm control in sheep, green grazing v. kudzu and pea-vine hay for swine, and control of the sheep tick and sheep

louse; pasture investigations, with beef cows and suckling calves, fertilizers and supplementary water, nitrogen sources for Bermuda grass, seeding winter grains for grazing, and alfalfa varieties; botany, including diseases of muscadine grapes, root rot of snap beans, peanut breeding, seed treatment, spacing, and leafspot control, breeding melons for wilt resistance, cantaloups for mildew resistance, tomatoes for disease resistance, and studies of diseases of field peas, vetch, soybeans, and lespedeza; chemistry, including studies of peanut byproducts for swine, sorghum sirup, peanut butter, and water-soluble N and moisture in peanuts; entomology, including studies of the cowpea curculio, stored peanut insects, the lesser cornstalk borer, lespedeza webworm, false chinch bug, and true chinch bug; food processing, including blanching of blueberries, apples, raspberries, blackberries, and various vegetables, and control of moisture in peanuts and peanut products; home economics, including studies of butter beans, sweetpotatoes, pimientos, turnip greens, asparagus, and snap beans; horticulture, including N fertilization of peach trees, peach varieties, breeding and culture of muscadine grapes, fertilizers for trees grown for posts, pimiento spacing, and sweetpotato breeding; results at the Mountain Experiment Station with grapes, vegetable varieties, irrigation, wheat, barley, corn, soybeans, and clover, and urea-treated bagasse v. bagasse and green soybeans for beef cattle.

**Annual Report of the Massachusetts Agricultural Experiment Station, 1945, [F. J. SIEVERS].** (Partly coop. U. S. D. A. et al.). (*Massachusetts Sta. Bul.* 428 (1945), pp. 71, illus. 2).—In addition to data noted elsewhere in this issue, this report gives results of progress in investigations in agricultural economics, including an analysis of milk trucking operations, farm real estate taxation, and land clearing and improvement; agronomy, including studies of brown and black root rots of tobacco, disinfection of tobacco seedlings, absorption by food plants of elements important in human nutrition, intake of elements applied in pairs v. singly, magnesium requirements of plants, long-time fertility tests, sunflowers and their possibilities, soil conservation with special reference to soil erosion, potato seed treatments and varieties, onion breeding, tests of hay and pasture seeding mixtures and oat varieties, *Bromus arvensis* for poultry ranges, and breeding of orchard grass; animal husbandry, including studies of legume and grass silage and the effect of feeding synthetic thyroprotein to milking cows; bacteriology, including studies of rural water supplies, milk supplies, and septic tank efficiency; botany, including work on the Dutch elm disease, hurricane and other damage of shade trees, damping-off and growth of seedlings and cuttings, control of diseases of plants caused by soil-infesting organisms, *Cladosporium fulvum* as the cause of tomato leaf mold and its control, control of squash decay in storage, interrelation of wettable sulfur, lead arsenate, and lime in apple spraying, effect of soil temperature on leaf shape of tobacco, toxic effect of creosote and other wood preservatives on plants, chlorine injury to plants, and resistance in carnations to *Fusarium dianthi*; chemistry, including notes on the ratio of various vitamins in late summer milk, effect of sunshine on ascorbic acid and riboflavin content of milk, vitamin content and other constituents of goat's milk, and influence of calcium and magnesium on lettuce; cranberry work, including notes on the hill fireworm (*Cirphis unipuncta*), Sabadilla and DDT as insecticides, winterkilling, and frost injury; dairy industry, including sterilizing agents, flavor improvement in milk and milk products, and packaged ice cream; economics, including farm adjustments; engineering, including poultry house construction and equipment; entomology, including studies of insecticidal materials for the European corn borer and other pests, potato spraying

for insects and diseases, control of onion thrips, the celery plant bug, red spider, plum curculio, cabbage mite, squash-vine borer, scolytids in elm log piles, and apple maggot emergence; floriculture, including the breeding of snapdragons and carnations, culture of *Anemone coronaria*, and effect of fungicidal hormones on carnation and geranium cuttings; food technology, including the nutritive value of mushrooms, glass container research, home freezing of fruit and vegetable varieties, utilization of the female sculpin, venting community cannery-type retorts, and fortifying red squill and vitamin D milk; home economics nutrition, including studies of the relationship between calcification of eggshell and carbonic anhydrase, and the requirement for calcium by children during growth; horticulture, including factors influencing the hardness of evergreens and the transplanting of evergreens, olericulture, including weed control for carrots and parsnips, the carotene content of carrots, breeding of sweet corn, peppers, tomatoes, cucumbers, rutabagas, lettuce, and butternut squash and the culture of asparagus; pomology, including the influence of various clonal rootstocks on apple varieties, bud sports of the McIntosh apple, tree characters of apples and peaches, winter hardiness in the raspberry, controlled-atmosphere storage of apples, cultivation v. sod for the bearing orchard, varieties of apples and peaches, blueberry culture, preharvest dropping of apples, magnesium deficiency in Massachusetts apple orchards, thinning apples with caustic sprays, and ammonium sulfamate for poison ivy and weed grasses; poultry husbandry, including broodiness in poultry selective breeding to reduce mortality, inheritance of higher fecundity, fertility cycles in males, a genetic analysis of Rhode Island Red color, egg characters in the domestic fowl, methods of feeding the laying flock, and poultry housing; and veterinary science, including notes on hemangioma tumors in poultry, protozoa in turkeys, flock mortality, and control of infectious bronchitis.

Fifty-second Annual Report [of Minnesota Station], 1945, C. H. BAILEY (*Minnesota Sta. Rpt. 1945, pp. 28*).—Among other administrative data, this report lists the station publications and other contributions of the year.

The [Missouri] Agricultural Experiment Station serves the farmer: Work of 2 years ending June 30, 1943, M. F. MILLER, S. B. SHIRKY, and H. J. L'HOTE. (Partly coop. U. S. D. A.). (*Missouri Sta. Bul. 490 (1945), pp. 132, illus. 26*).—Results are briefly noted of projects in agricultural chemistry, including notes on abnormal bleeding in swine, vitamins required by small animals, and chick nutrition on synthetic rations; agricultural economics, including land use studies, productive value of Missouri pastures, feed imports required in 1943, turkey production in Missouri, conservation of transportation facilities for farm products, land tenure in Missouri, farm land as an investment and the farm real estate situation, land values and rents in Atchison County, farming systems for small farms, influence of declining land productivity on land values, cooperative organizations in Missouri, farm construction needs, cost of producing cotton in southeast Missouri, and wartime utilization of farm labor and equipment; agricultural engineering, including use of a curved rafter type of construction in a machine shed, effect of ventilation on egg production, tillage methods for corn, cost of service for small tractors, hay harvesting costs, home-made electrical equipment, irrigation of corn in river bottoms, and use of straw in soil building; animal husbandry, including notes on the managed grazing of bluegrass, vitamin needs of swine, breeding systems for swine improvement, forage crops for swine, supplements to corn for fattening hogs, lespedeza seed as a protein supplement for lambs and fattening cattle, use of roughage in beef production, wintering yearling steers

on silage, physiology of reproduction in hogs, cattle, and sheep, black fibers, dwarfism, and turned-in-eyelids in sheep, and bleeder and other abnormalities in swine; botany, including studies of tomato resistance to *Fusarium* wilt and notes on other diseases; dairy husbandry, including studies of thyroprotein, the texture and structure of ice cream, sources of *Oospora lactis* on dairy farms, mold mycelia in ice cream and butter, artificial insemination of dairy cows, mechanization of milk secretion and mammary gland growth, the parathyroid gland and calcium metabolism, production of veal calves, rate of growth of dairy heifers, feeding value of lespedeza seed and hay, methods for lactose determination, heat-resistant bacteria in milk, lactose-fermenting yeasts in cream, metabolism in growth, construction of a straw loft calf barn, pasture studies, and tests of limited grain v. full grain rations, wave diathermy for mastitis, and value of condensed whey solids for butterfat production; entomology, including studies of ticks, chinch bug and codling moth control, insecticides, and control of the strawberry leaf roller and cucumber beetles; field crops, including breeding wheat, barley, and oats, improvement of pastures and soybeans, efficiency of grain-legume short rotations, cotton varieties, open-pollinated v. hybrid corn, control of seed corn diseases, comparison of X-ray and ultraviolet mutations, anthocyanin pigments in corn, and polyploidy in wheat and its relatives; home economics, including studies of the use of consumption credit by farm families, relation of the carotene and xanthophyll contents of the diet to the growth of young chicks, vitamin potency of pork as influenced by the rations, tests of flours for adaptiveness, and prices and qualities of towels and toweling; horticulture, including studies of biennial bearing of apples, effect of hormone sprays on tomatoes and peppers, nutrition of vegetables, adaptability of 64 kinds of flowers for outdoor planting, commercial production of various flowers, Christmas trees as a Missouri crop, inoculation of garden peas, soil management for young apple trees, value of stimulating substances for strawberry plants, soil fertility maintenance for tomatoes in glazed containers, value of heavy nitrogen applications for apple trees in sod, correctives for arsenical injury of apple foliage, and black rot control on grapes; poultry husbandry, including cleaning soiled shell eggs and stabilizing quality, effect of time of hatching White Leghorn chicks on egg production, normal growth rates for chickens, nutritional requirements of turkeys, protein supplements in poultry rations, feed purchasing power of eggs, and comparative values of various grains for egg production; rural sociology, including rural health facilities in Missouri and handicraft production in the Ozark region; soils, including studies of cationic activities, uptake of nutrient elements by plants, fine lime for legumes, relation of soil composition to nitrogen fixation and plant composition, function of the colloidal fraction of the soil, moisture movements in soils, rejuvenating eroded soils, use of cornstalks and straw in soil building, fertilizer tests with various crops and permanent pastures, function of acid clays in plant nutrition, and nitrogen and carbon accumulation in the soil; and veterinary science, including studies of blackhead in turkeys, leukosis and neuritis of fowls, worms in sheep, reactions to the Bang agglutination test in cattle and blood studies in Bang's disease, toxemia in sheep, and trichomoniasis in turkeys.

Investigations for the benefit of the Missouri farmer: Work of the [Missouri] Agricultural Experiment Station during the year ending June 30, 1944, M. F. MILLER, S. B. SHIRKY, H. J. L'HOTE, ET AL. (Coop. U. S. D. A. et al.). (*Missouri Sta. Bul.* 491 (1945), pp. 71, illus. 18).—In addition to reports on projects noted elsewhere in this issue or previously, progress results are pre-

sented in agricultural chemistry, including data on unrecognized vitamins required by livestock, vitamins and minerals required in lactation, nutritional requirements of poultry, and abnormal bleeding in swine; agricultural economics, including maximum wartime production possibilities in Missouri, trucking of livestock to Kansas City, variations in production per farm and per worker, and production adjustments tending to lower costs; agricultural engineering, including tests of a fertilizer drill for pastures and a contour furrowing plow with fertilizer attachment, a baffle to prevent drafts in open-front poultry houses, a portable farm elevator, utilizing straw in soil building, a metering device for compounding mixed feeds, and hay harvesting machinery; entomology, including control of ticks, chinch bugs, and codling moth, tests of DDT and other insecticides, and control of insect pests of melons and other cucurbits; animal husbandry, including pasture fertilization and winter feeds to increase gains of steers, swine breeding, inheritance in sheep, factors involved in muscular work in horses and mules, and semen investigations in boars, rams, and cocks; botany, including the development of wilt-resistant tomatoes, and control of seedling diseases of cereals; dairy husbandry, including studies of milk secretion, *Oospora lactis* in milk, cream, and butter, milking machine sanitation, mastitis treatment, artificial insemination of dairy cows, feeding tests with lowered grain rations for dairy cows and use of condensed whey and soybean meal for calves, composition of cheese and whey, energy efficiency of growth and work, and nutritional studies on growth and milk production, including work with Korean lespedeza, rye for silage, and use of thyroprotein during declining lactation; field crops, including development of corn hybrids, genetic studies with wheat and corn, improved oat, barley, wheat, cotton, and soybean varieties, and pasture improvement and management; home economics, including tests of soybean varieties and soya flower, and cotton and synthetic fabrics; horticulture, including control of spray injury to apples, tests of Fermate on various fruits, nitrogen fertilization of apple trees, regulating fruit set of apples with caustic sprays, subirrigation nutrient culture and hormone sprays for greenhouse crops, control of aster wilt, and relation of soil fertility to the vitamin and mineral content of vegetables; poultry husbandry, including reduction of egg spoilage in storage by thermostabilization, vegetable protein concentrates for egg production, soybean oil meal for young chicks, relative feed-purchasing power of eggs 1937-43, closed flock breeding, and protein needs of turkeys; soils, including erosion studies, nitrogen and carbon accumulation in soils, formation of clay soils from primary igneous rocks, properties of nontronite, attapulgite, and saponite, and the origin of heavy clay subsoils; and veterinary science, including control of internal parasites in sheep, studies of Bang's disease, the agglutination test, and vaccination, fowl paralysis, and pregnancy diseases of sheep.

Fifty-sixth Annual Report [of New Mexico Station, 1945], A. S. CURRY. (Partly coop. U. S. D. A.). (*New Mexico Sta. Rpt. 1945, pp. 58+, illus. 14*).—This report gives data from the departments of animal husbandry, including studies of the revegetation and carrying capacity of southwestern ranges, levels of nutrition for ewes, weights of range sheep, rations for fattening lambs, comparative physical characteristics of sheep and their offspring, relation of the carotene content of range forage to the vitamin A requirements of breeding cows, seasonal phosphorus supplements for range cattle, and low-protein roughage for range cattle; dairy husbandry, including notes on the use of a vitamin A supplement with a calf starter without animal protein, irrigated pastures for dairy cattle, and Johne's disease in goats; poultry

husbandry, including tests of dried buttermilk for laying hens, effectiveness of ferrous sulfate in preventing egg-yolk discoloration produced by cottonseed meal, and the inheritance of firm egg albumin; irrigation studies with cotton; agronomy, including notes on cotton varieties and cotton breeding, grade and staple estimates, and the effect of alfalfa, variety and fertilizer tests with alfalfa, grasses and legumes for pastures, varieties of barley, sugar beets, and sorghums, varieties and hybrids of corn and pinto beans, and effect of the preceding crop and of the fertilizer treatments on sugar-beet seed; dry farming investigations, including variety trials of sorghums, pinto beans, corn, millet, barley, wheat, alfalfa, potatoes, lettuce, tomatoes, sweet corn, permanent pastures, and sugar beets; horticulture, including fertilizer tests with potatoes, seed production of White Grano onions, variety tests with pecans, biennial bearing of apples, DDT for codling moth, corn earworm, and western flower thrips, and control of pink root of onions; home economics, including the carotene and ascorbic acid content of peppers and carrots and the ascorbic acid content of cantaloups; chemistry, including the content of NDGA (nordihydroguaiaretic acid) in creosote bush (*Larrea divaricata*); and agricultural economics, including the effect of wartime adjustments on the cost of cotton production, the economics of broomcorn production, and an analysis of sheep ranch organization.

In orme de la Estación Experimental Federal en Puerto Rico, 1944 [Report of the Puerto Rico Federal Station, 1944], [K. A. BARTLETT ET AL.]. (*Puerto Rico Fed. Sta. Rpt. 1944, Span. ed., pp. 55+*).—The English edition has been noted (E. S. R., 93, p. 668).

What's new in farm science; Annual report of the director [Wisconsin Station, 1944], I, compiled by N. CLARK and N. HOVELAND (*Wisconsin Sta. Bul. 468 (1945), pp. 72+, illus. 12*).—In addition to several items noted elsewhere in this issue, results are reported under soil conservation on the profitability of grassland farming, increase in wartime production by soil-conserving farms, costs of building terraces, and variation in farm incomes; farm business and rural welfare, showing a low school attendance of Wisconsin farm youth, farm earnings and debt reduction, relation of farm output to work capacity of family, dependency of profits in peas on yields, and need of planning for the rural-urban fringe around Madison; dairy products, including notes on types of cheese packages, gas in packaged cheese, seasonal variation in vitamin A content of cheese, and use of butter oil in vitamin D concentrate; farm animals, including notes on swine breeding, control of swine enteritis, trichomoniasis vaccination, and vitamin content of newborn lambs; feeding the family, including the value of skim-milk powder in cookery, buttermilk in biscuits, milk as a source of riboflavin, deflated soy flour in doughnuts, vitamins in fresh v. canned vegetables, quality of proteins in dehydrated meat, B-vitamin content of canned foods, and amino acid and folic acid content of meats; nutrition, including relation of corn to pellagra, relation of good nutrition and fluorine to dental health, butterfat as a preventive of vitamin B deficiency, high availability of iron in wheat bran, need of dogs for biotin, need of vitamin D to utilize phosphorus of cereals, importance of pyridoxine in protein metabolism, and development of abnormal blood vessels in swine on faulty rations; genetic limitations in mink breeding; and nutritional requirements of trout.

Fifty-fifth Annual Report [of Washington Station], 1945, E. C. JOHNSON ET AL. (Partly coop. U. S. D. A. et al.). (*Washington Sta. Bul. 470 (1945), pp. 167*).—Brief notes are given on progress results obtained in agricultural engineering, including temperature requirements of chicks during brooding,

livestock water heating, evaporative equipment for poultry house cooling, ultraviolet irradiation of turkey breeding flocks, insect electrocution, barn hay drying, and the jeep as a farm tractor; agronomy, including variety and breeding studies with wheat, barley, oats, and flax, improvement of peas, forage and pasture grasses, alfalfa, and sweetclover, crop rotations, control of bindweed, maintenance of fertility and organic matter in soils, and crop composition as influenced by soil types and fertilizers; animal husbandry, including vitamin, protein, and mineral requirements of the pig, nutritive adequacy of roughages and pea meal for fattening steers, adequacy of forages in vitamin A for sheep reproduction, progeny testing of rams, factors involved in the anestrus season of ewes, semen characteristics in rams, and development of a bacon-type hog; chemistry, including deficiencies in vegetable protein concentrates in poultry, availability for chicks of cystine and methionine in soybean oil meal, action of proteolytic enzymes on soybean oil meal proteins, tests of stationary spray systems, spray oils and ovicidal effectiveness, and spray residue analyses; dairy husbandry, including cheese making for vacuum canning, factors affecting the quality of dry milk solids, rations for dairy cattle, rotational v. continuous grazing of pastures, and oat gum and sodium alginate for stabilizing ice cream; entomology, including studies of potato flea beetles, increasing the efficiency of sulfur and lime-sulfur sprays, cryolite for codling moth, salts of dinitrophenol and dinitrocresol to control mites, control of the cherry maggot, bee poisoning in the Yakima Valley, control of crop pests by parasites, and the pear psylla survey; agricultural economics, including a comparison of farming systems in the State; home economics, including freezing of precooked foods, rancidity and thiamine retention in pork, and nutritive value of field peas; horticulture, including studies of orchard cover crops, vegetable seed production, fruit maturity, potato breeding, winter injury of fruits, factors affecting fruit set, spray injury, orchard fertilizers and irrigation, cork spot of pear quacy of cull peas for swine, grass-legume mixtures and grain feeding for trees, fertilizers for asparagus, breeding truck crops, variety studies of strawberries, raspberries, and apples, ornamentals for eastern Washington, fertilizers for grapes and cherries, freezing of vegetables, chlorosis of grapes, eradication of bindweed in orchards, and breeding of cranberries, blueberries, raspberries, and strawberries; plant pathology, including the plant disease survey, virus diseases of potatoes and stone fruits, control of alfalfa failures, influence of crop sequence on rhizoctonia infection in potatoes, yellows and root rot of strawberries, root rot of raspberries, black root of beets, smuts of wheat and oats, stem and root rots of peas, and smuts and rusts of grasses; poultry husbandry including calcium, phosphorus, and vitamin D in the chick ration, protein levels for egg production, silage v. pasture for turkeys, silage for laying hens, vitamin D for turkeys, nutritional factors and effect of inheritance on fertility and hatchability in turkeys, the B-complex vitamins for turkey poults, and the etiology of perosis; veterinary research, including mastitis in dairy herds and avian coccidiosis; and results at the branch stations, including at Lind variety tests with wheat, barley, and rye, weed control, organic matter maintenance, and tests of various grasses; at Prosser, variety tests with alfalfa, corn, wheat, and barley, fertilizers for alfalfa, corn, asparagus, lima beans, and cherries, variety tests of peas, sweet corn, lima beans, soybeans, strawberries, and grapes, irrigation methods, crop rotations, reclamation of alkali soil, soil erosion, and wireworm investigations; at Wenatchee studies of stationary spray systems, dormant sprays, DDT and

other sprays, sulfur and lime-sulfur sprays for orchard mites and scale, control of apple powdery mildew and codling moth, spray residues, toxicity of orchard soils, orchard cover crops, winter injury, pollination and fruit set, fertilizers, irrigation, weed control, cork spot of pears, fruit maturity, and effect of preharvest drop sprays on pears; at Long Beach, studies on cranberry dormant and summer sprays, weed control, fertilizers, and fungicides; at the soil conservation station on erodibility, cropping and tillage practices, and runoff measurements; at the nursery division, Soil Conservation Service, on observations of grasses, legumes, shrubs, and trees. alfalfa-grass and sweetclover-grass conservation mixtures, strain type comparisons, pasture trials, and culture and seed production of grasses and legumes; and at the U. S. Fruit and Vegetable Products Laboratory on the canning of peaches and the recovery of sugar from pear cannery waste.

From the Western Washington Station, division reports are made in agronomy and soils, including fertilizer placement with beets, sweet corn, peas, potatoes, swiss chard, and spinach, fertilizer rates and ratios with beets, sweet corn, peas, potatoes, spinach, beans, and broccoli, the role of minor elements in western Washington, comparative value of phosphate carriers, and green manure and cover crops; chemistry, including ground dehydrated flat pea forage for poultry, fluorine content of prune leaves, toxicity of flat peas forage and seed, management of poultry-house litter, and silage for poultry; entomology, including studies of the cherry fruit flies, bud and leaf nematode of Croft lilies, effect of chemical treatments on scale propagation, the seed corn maggot, the loganberry mite, and aphid resistance of red raspberry seedlings; grazing, including trials with cattle and sheep, the toxicity of the flat pea, and inoculants for flat peas; horticulture, including strawberry and raspberry breeding, peach varieties, root stimulants for evergreen cuttings, and variety tests of vegetables; plant pathology, including seed treatment of vegetable crops, Sudan grass, potatoes, and Douglas fir, foot rot of peas, leaf spot of spinach, bulb diseases of tulips, daffodils, lilies, and gladioli, control of leaf roll of peaches, brown rot of cherries, cane blights of blackberries yellows and root rot of strawberries and raspberries, and black root of beets; poultry husbandry, including changes in eggs from force molting yearling hens, eggshell quality as influenced by inheritance and prelaying calcium level, granulation of ingredients in poultry mashes, effect of season of hatch on albumin and shell quality, isolation v. nonisolation in brooding chickens, disease resistance, preserving grass and legume silage, and management of poultry house litter; veterinary science, including studies of avian leukosis, use of phenothiazine in control of enterohepatitis of turkeys, and erysipelas, paratyphoid infection, and hexamitiasis in turkeys; at Mt. Vernon, vegetable seed investigations on beets, potato breeding, control of the cabbage seed-pod weevil, maggot, and aphid, the pea moth, cabbage mosaic and other virus diseases, downy mildew, ring spot, and a *Phoma* leaf spot; and at Vancouver, variety tests of fruits, strawberry fertilizers, a prune disorder, boron for English walnuts, and variety tests with soybeans, sweet corn, potatoes, squash, muskmelons, and pumpkins.

*Acta final de la III Conferencia Interamericana de Agricultura* (Caracas, Venezuela: Litografia Com., 1945, pp. 98+).—This includes the programs and rules of procedure of the conference held in Caracas, Venezuela, from July 24 to August 7, 1945, a list of delegates, and the text of the 98 resolutions considered and recommendations adopted.

## MISCELLANEOUS

**Crofting agriculture—its practice in the West Highlands and Islands,** F. F. DARLING (*Edinburgh: Oliver and Boyd, 1945, pp. 163+, illus. 20*).—This book deals with the agriculture of the region, with chapters on the soil, plant foods, the management of grass, the conservation of winter fodder, weed control, planning for the spring work, growing early potatoes, the problem of shelter, the crofter's cow and sheep, the principles of animal feeding, and agricultural arithmetic.

**Colorado Farm Bulletin [January-February, March-April 1946]** (*Colo. Farm Bul. [Colorado Sta.]*, 8 (1946), Nos. 1, pp. 15, illus. 10; 2, pp. 15, illus. 11).—In addition to articles noted elsewhere in this issue, No. 1 contains **How About Commercial Fertilizer**, by R. S. Whitney (pp. 12-14), and **What the College is Doing with Artificial Insemination**, by H. R. Lascelles (p. 15); and No. 2, **What Is Artificial Insemination**, by V. D. Stauffer (pp. 12-13).

**Farm Research [April 1946]** (*Farm Res. [New York State and Cornell Stas.]*, 12 (1946), No. 2, pp. 20, illus. 11).—In addition to articles noted elsewhere in this issue, this number contains **Plan Better Houses for Rural Folk**, by G. Morin (pp. 3-4) ([N. Y.] Cornell Sta.); **More and Better Meat Possible for Farm Families**, by J. I. Miller (p. 7) ([N. Y.] Cornell Sta.); **Flavor Plays Major Role in Determining Food Quality**, by Z. I. Kertesz (p. 14) (N. Y. State Sta.); **New York Livestock Goes to Market**, by W. M. Curtiss (pp. 15-17) ([N. Y.] Cornell Sta.); and **Quality in Maple Products**, by C. S. Pederson and F. W. Hayward (p. 16) (N. Y. State Sta.).

**Bimonthly Bulletin [March-April 1946]** (*North Dakota Sta. Bimo. Bul.*, 8 (1946), No. 4, pp. 31, illus. 7).—In addition to articles noted elsewhere in this issue, a list of scientific papers of the staff, and miscellaneous notes, this number contains **It Pays to Brood Pigs with Electricity**, by W. J. Promersberger and R. Witz (pp. 12-14), in which a hover type brooder is described; **Experiment Station Had Six Hens Each with 300-Egg Record Last Year**, by J. E. Parker (p. 19); and **North Dakota Farm Prices**, by P. V. Hemphill (pp. 30-31).

**Farm and Home Science [March 1946]** (*Farm and Home Sci. [Utah Sta.]*, 7 (1946), No. 1, pp. 12, illus. 15).—In addition to several articles noted elsewhere in this issue, this number contains **The Economic Situation as It Relates to Utah's Agriculture**, by W. P. Thomas (pp. 3, 11, 12); **Ladybird Beetle Mistaken for Pest**, by G. F. Knowlton (p. 4); and **Retention of Ascorbic Acid in Cabbage Salad**, by E. B. Wilcox and A. Maughan (pp. 5, 11).

**Publications available from the [Kansas] Agricultural Experiment Station** (*Kansas Sta. Cir. 232 (1945), pp. [4]*).—This circular lists available publications on agricultural economics, agricultural production, and home economics.

**Farmer's guide to agricultural research in 1944** (*Jour. Roy. Agr. Soc. England*, 106 (1945), pp. 1-74).—Brief summaries are given as follows: **Crops and Plant Breeding**, by G. D. H. Bell (pp. 1-12); **Diseases of Animals—Prevention and Treatment**, by T. Dalling (pp. 13-29); **Farm Economics**, by C. S. Orwin (pp. 30-41); **The Feeding of Livestock**, by W. Godden (pp. 42-49); **Farm Implements and Machinery**, by S. J. Wright (pp. 50-60); and **Soils and Fertilizers**, by E. M. Crowther (pp. 61-74).

## NOTES

---

**Alabama College and Station.**—Dr. Charles F. Simmons has been appointed head of the department of agronomy and soils as of July 1. Dr. William E. Sewell, professor of animal husbandry and animal husbandman, has resigned to engage in commercial work.

**Colorado College and Station.**—Alvin Kezer, head of the department of agronomy, has retired after 37 years' service and was succeeded on July 1 by Dr. D. W. Robertson, station agronomist in cereal breeding.

**Kansas College and Station.**—L. E. Call, continuously associated with the institution since 1907, the first 18 years in agronomy work and subsequently as dean and director, has been given emeritus status following his appointment as chairman of the U. S. agricultural mission to the Philippines to co-operate with the Philippine Department of Agriculture in working out a national agricultural program. R. I. Throckmorton has been appointed dean and director and H. E. Myers head of the department of agronomy.

**Louisiana University and Station.**—Dr. A. H. Groth, associate professor of veterinary science and associate veterinarian, has been appointed director of the U. S. D. A. Animal Disease Regional Laboratory vice Dr. B. T. Simms, who several months ago became chief of the U. S. D. A. Bureau of Animal Industry.

**Massachusetts College and Station.**—An extension of the college to be known as the Massachusetts State College at Fort Devens has been established at the deactivated Army post at Ayer. This extension has been arranged to accommodate veterans qualified to undertake college training but who have been unable to gain college admission elsewhere because of limited quotas and facilities. Eligibility is restricted to male veterans who are residents of the State. Two years of accredited college work will be offered with privilege of transferring to the main campus in Amherst or to other institutions. Dr. Edward Hodnett has been appointed vice president in charge, with Dr. Wentworth Williams as dean of the faculty and Dr. Joseph Morgan Stokes as dean of men.

Philip H. Smith, associated with the station since his graduation in 1897, has retired as chief of the laboratory of feed and fertilizer control.

**Michigan College and Station.**—The pasture facilities of the institution, depleted by veterans' housing projects, have been increased by the purchase of 40 acres of land adjacent to the college farms.

Dr. Rufus H. Pettit, head of the department of entomology for 26 years prior to his retirement in 1933, died June 1 at the age of 77 years. A native of New York and a graduate of Cornell University in 1895, he spent a short time as assistant State entomologist in Minnesota, coming to Michigan in 1897.

**Nebraska University and Station.**—Dr. Raymond L. Borchers has been added to the staff in agricultural chemistry, chiefly for work in poultry nutrition.

**Nevada University and Station.**—Director S. B. Doten retired June 30, terminating a continuous service at the institution of 48 years, including instruction in history, mathematics, meteorology, and entomology, research as station entomologist from 1906 to 1913, and subsequently as director. He has been

succeeded by C. E. Fleming, previously in charge of range management investigations.

**Cornell University.**—An appropriation of approximately \$27,000 by the last Legislature is available for establishing two branch laboratories of the New York State Veterinary College for the diagnosis and study of poultry diseases. One laboratory is to be located at East Aurora to serve the western part of the State and the other at Kingston to serve the eastern area.

The first session of a new type of school was held at the College of Agriculture during the week of August 12. This was a bankers' school of agriculture which was sponsored by the State Bankers' Association.

Recent appointments include Dr. E. Lee Vincent as dean of the College of Home Economics, effective September 1; Vera Caulum as assistant State leader of home demonstration agents and assistant professor of home economics; and Arthur E. Durfee as assistant professor of extension teaching and information.

**New York State Station.**—Dr. Morrill T. Vittum has been appointed assistant professor of vegetable gardening.

**North Carolina College.**—Dr. Jane S. McKimmon, assistant director of extension since 1922, has retired. James T. Conner, Jr., has been appointed extension entomologist vice J. Myron Maxwell who is now in private business.

**Pennsylvania College and Station.**—The retirement on June 30 is noted of Dr. E. B. Forbes, head of the Institute of Animal Nutrition since 1922 and previously associated with entomological studies in Minnesota, animal husbandry work in Illinois and Missouri, and as chief of the department of nutrition in the Ohio Station; C. O. Cromer, professor of farm crops since 1920 and previously in similar work at the Purdue Station for 14 years; and F. W. Haller, assistant in horticulture since 1921.

G. W. Hedlund has resigned as the head of the department of agricultural economics to accept a professorship at the Cornell University and Station, and LeRoy Voris as assistant professor of animal nutrition to remain in the armed forces. Recent appointments include M. E. John as head of the newly established department of agricultural economics and rural sociology, and R. W. Swift as acting head of the department (formerly the institute) of animal nutrition.

**Tennessee University and Station.**—Director C. A. Mooers, continuously associated with the station since his graduation from the university in 1893 except for about a year as chemist in the Louisiana Station, retired on June 30. He had been director since 1923. Dean C. E. Brehm has been appointed director, with Frank S. Chance, the assistant director, becoming vice director.

**Texas Station.**—Dr. R. D. Lewis, chairman of the department of agronomy in the Ohio State University, has been appointed director, effective September 1.

**Utah College.**—At the recent commencement the honorary D. Sc. degree was conferred on Dr. William Peterson '99, extension director emeritus, and in absentia on Dr. James T. Jardine '05, chief of the U. S. D. A. Office of Experiment Stations.

**Vermont Station.**—C. H. Jones and L. S. Walker, chemists since 1896 and 1927, respectively, have been retired with emeritus status.

**Washington Station.**—George A. Olson, associated with the chemical work of the station from 1911 to 1921, the last 10 years as head of the division of agricultural chemistry, died July 29. He had also served on the chemical staff of the Wisconsin University and Station and from 1921 to 1928 was agricultural director of Gypsum Industries.

**Office of Experiment Stations.**—Dr. James T. Jardine, chief since 1931, retired on July 31, terminating a notable career in the Department of Agriculture of nearly 30 years in several capacities, including that of director of research from 1936 to 1941. In addition, he had served over 10 years as director of the Oregon Experiment Station. On August 1 he was succeeded by the assistant chief, Dr. Robert W. Trullinger, and he in turn by Erwin C. Elting, previously principal experiment station administrator (animal husbandry).

The recent retirement after long service of two members of the staff of *Experiment Station Record* is also noted. Fred G. Harden, principally engaged in recent months in abstracting the literature on agricultural economics, ended on July 31 a service which began with the Division of Irrigation Investigations in 1908 and had included an unusual range of duties. Dr. George Haines, in charge of the sections on animal genetics, animal husbandry, and dairying, retired on August 23 after nearly 25 years of continuous service.

Dr. Floyd Andre, principal experiment station administrator (entomology), has resigned to become assistant director of the Wisconsin Station.

**U. S. Department of Agriculture.**—R. H. Allee, assistant chief of the technical collaboration branch, U. S. D. A. Office of Foreign Agricultural Relations, has been appointed director of the Inter-American Institute of Agricultural Sciences in Costa Rica, vice Dr. E. N. Bressman.

W. A. Wheeler, chief of the seed marketing division of the Production and Marketing Administration, retired June 30 after 30 years of service, largely with hay, feeds, and seeds. Before coming to the Department he had been associated with the University of Minnesota and the South Dakota College and Station.

W. A. Lloyd, from 1913 to 1940 a member of the Extension Service staff and previously agriculturist for 4 years with the Ohio Station, died in Washington, D. C., July 10 in his seventy-sixth year. Since his retirement from the Department, he had been Washington representative of the Association of Land-Grant Colleges and Universities.

**Flannagan-Hope Act for Agricultural Research.**—This act, signed by President Truman on August 14, authorizes a much broadened agricultural research program. While no funds were appropriated prior to the adjournment of Congress, a total of \$9,500,000 is authorized to be appropriated in the 1947 fiscal year for agricultural research and marketing services, with special emphasis on the utilization of farm products, the marketing, handling, storage, processing, transportation, and distribution of these products, and cooperative production research. The principal objective, as stated by its authors and sponsors, is to give agriculture parity with industry in the field of research.

As brought out in a recent explanatory statement by the U. S. D. A. Office of Information, basic agricultural research, now carried out under various grants by Congress, is greatly expanded by the terms of the new measure. Title I of the act broadens the authority of the Bankhead-Jones Act of 1935 and provides for payments to the States for additional research on farm problems, particularly those of recent origin and any that may develop later. The fields of research include improved methods of production, problems of human nutrition, discovery of new and useful crops, expanded uses for farm products, and conservation and development of land, forest, and water resources for agricultural purposes.

A major share of the expanded research work will be done by State agricultural experiment stations. An equal allotment of 20 percent of the funds

to each State and Territory and Puerto Rico is provided, with additional allotments on the basis of rural and farm population ratios and the need for cooperative research on regional problems. The initial appropriation is \$2,500,000, which may be increased annually until it totals \$20,000,000 by the fifth year, but a condition for receiving 72 percent of the funds for this type of research is that the several States must match the Federal funds with State appropriations. A fifth of the funds allocated to the States must be earmarked for research in marketing.

A separate provision of \$1,500,000 in 1947 is authorized for cooperative agricultural research conducted by the Department, the State stations, and other appropriate agencies. This may be increased by \$1,500,000 annually until it totals \$6,000,000.

The act permits the Secretary of Agriculture to contract for the service of public or private organizations in carrying out utilization research if it promises more effective or economical results. However, the utilization research is to be conducted so far as practicable in the Department's laboratories. An initial appropriation of \$3,000,000 is authorized to be made for 1947, which may rise to \$15,000,000 in 1951.

Aiming at a reduction in the spread between farm prices and costs to consumers, title II of the legislation, citable as the Agricultural Marketing Act of 1946, provides funds and authority to expand research and service in the marketing, transportation, and distribution of agricultural commodities. In this field, too, the Secretary of Agriculture may contract with outside agencies for research services. Authorization is also given for making allotments of funds to State departments of agriculture, State bureaus and departments of markets, State agricultural experiment stations, and other agencies for cooperative research projects. An appropriation of \$2,500,000 is authorized to be made for 1947 to conduct this research and service, and annual increases may raise this amount to \$20,000,000 in 1951. These funds would be in addition to all other funds available for marketing activities.

In title III the establishment by the Secretary of Agriculture of a National Advisory Committee of 11 members, 6 of whom are to be producer representatives, is provided. This committee must meet at least quarterly and will make recommendations regarding the research and service work and assist in obtaining cooperation of affected groups and Federal and State agencies. Other committees may also be set up by the Secretary to assist in effectuating specific research and service programs.

## RECENT WORK IN AGRICULTURAL SCIENCE<sup>1</sup>

### AGRICULTURAL AND BIOLOGICAL CHEMISTRY

Some correlations of growth-promoting powers of proteins with their strepogerin content, D. W. WOOLLEY (*Jour. Biol. Chem.*, 162 (1946), No. 2, pp. 383-388).—When mice were fed a highly purified ration in which casein hydrolysate plus tryptophan and cystine was the nitrogen source, they grew at a submaximal rate. Small proportions of proteins rich in "strepogenin" (a name tentatively assigned to "a factor (or factors) which stimulates the growth of *Lactobacillus casei*, some hemolytic streptococci, and certain other micro-organisms") were effective growth promoters, while proteins low in this peptidlike growth factor were not. Concentrates of strepogenin prepared from tryptic digests of casein were as active as the intact protein. When the strepogenin was destroyed in such concentrates, the growth-promoting powers for mice were lost. When egg white, a protein low in strepogenin but otherwise nutritionally adequate, was used as the source of nitrogenous matter in a highly purified ration, a slow rate of growth was observed. The growth rate produced by this diet was accelerated by administration of small proportions of proteins rich in strepogenin but not by those poor in this factor. Some implications of these findings with respect to current theories of protein nutrition are indicated. A stimulation of growth caused by the addition of heated starch to highly purified rations is described.

The effect of proteolytic enzymes on raw and heated casein, N. R. ELDRÉD and G. RODNEY (*Jour. Biol. Chem.*, 162 (1946), No. 2, pp. 261-265).—The combined action of crystalline pepsin, trypsin, and chymotrypsin on raw and heated casein was studied. Digestion of the heated substrate did not differ greatly from that of raw casein, but the available lysine, as determined by the specific enzyme lysine decarboxylase, was appreciably less. Similar results were obtained with crude pancreas as the source of proteolytic enzymes.

The effect of certain experimental conditions on the formation of thyroxine from diiodotyrosine, E. P. REINKE and C. W. TURNER. (Mo. Expt. Sta.). (*Jour. Biol. Chem.*, 162 (1946), No. 2, pp. 369-375 illus. 1).—Diiodotyrosine dissolved in 0.116 N sodium hydroxide (pH 9.4 to 9.6) was incubated with vigorous stirring for 18 to 20 hr. under various conditions,

<sup>1</sup> The publications abstracted in these columns are seldom available for distribution by the Office of Experiment Stations. In general, application should be made to the Office of Information of the U. S. Department of Agriculture, Washington 25, D. C., for publications of the Department; to the directors of the State agricultural experiment stations, as listed on page 3 of the cover of this issue, for publications of the several experiment stations; and to publishers of books and journals for material issued by them. Microfilms and photostatic copies, the latter legible without magnifying equipment, may be purchased from the Library, U. S. Department of Agriculture, Washington 25, D. C. Rates and other details will be supplied by the Library on request.

and the quantity of thyroxine formed was determined by isolation of the crystalline product. It was found that a definite temperature optimum for the formation of thyroxine under these conditions occurs at 60°C. Thyroxine formation during the incubation was greatly accelerated by atmospheric oxygen, whether incorporated by stirring or by direct aeration. Only traces of thyroxine were formed in solutions that were neither stirred nor aerated. Manganese oxide was shown to catalyze the reaction in the presence of atmospheric oxygen. With all of the known conditions at the optimum, a yield of thyroxine equivalent to 0.85 percent of the diiodotyrosine taken initially was obtained. When allowance was made for the recovery of unaltered diiodotyrosine, this was equivalent to a net yield of 2.8 percent. The identity of the thyroxine was verified by its iodine content of 65.2 percent and melting point of 230°-231°. The thyroxine was optically inactive, apparently because of racemization under the conditions of incubation employed.

The biological conversion of *l*-serine to glycine, D. SHEMIN (*Jour. Biol. Chem.*, 162 (1946), No. 2, pp. 297-307).—Amino acids, labeled with  $N^{15}$ , together with benzoic acid were injected into rats and guinea pigs and the isolated hippuric acid was analyzed for its  $N^{15}$  concentration. By comparison of the dilution factor  $C_0/C$  ( $C_0 = N^{15}$  concentration of administered compound,  $C = N^{15}$  concentration of hippuric acid) of several amino acids with that found for glycerine and ammonia, it was found that only *l*-serine is directly converted, with utilization of carbon and nitrogen, into glycine in the rat and guinea pig. It appeared from the data that a considerable fraction of *l*-serine was converted to glycine. The mechanism of this conversion was established by employing serine labeled with  $N^{15}$  in the amino group and with  $C^{13}$  in the carboxyl group. It was found that *l*-serine is converted into glycine by the splitting off of the  $\beta$ -carbon atom. It was also found that the  $N^{15} : C^{13}$  ratios of the administered serine and of the glycine of the excreted hippuric acid are essentially the same. The formation of some of the amino acids is discussed.

The structure of an egg albumin-detergent complex, K. J. PALMER. (U. S. D. A.) (*Jour. Phys. Chem.*, 48 (1944), No. 1, pp. 12-21, illus. 5).—The author postulates a structure for a denatured egg albumin-detergent complex which appears to be in agreement with the results of an electrophoretic investigation of this system. It consists of a polar protein monolayer with the detergent molecules absorbed on one side only and with the long axes of the detergent molecules perpendicular to the protein layer. On the basis of this structure it is suggested that the polar amino acids probably alternate along the peptide chain in egg albumin. From this hypothesis it follows that if the layer structure for native egg albumin postulated by Pauling is acceptable, the layers in the native configuration are polar. By use of this model a plausible structure for the complex which forms between native egg albumin and detergent is postulated. This structure is considered to account for the observed facts that the complex formed from native egg albumin never contains less than 25 percent of the commercial detergent used (whereas that formed from denatured egg albumin does), and that the complex containing 75 percent "native" egg albumin and 25 percent detergent can exist in equilibrium with free native protein.

Pea starch, a starch of high amylose content, G. E. HILBERT and M. M. MACMASTERS. (U. S. D. A.). (*Jour. Biol. Chem.*, 162 (1946), No. 2, pp. 229-238, illus. 5).—Starch belonging to an entirely new class was found to occur in three varieties of garden type, wrinkled seeded peas. The granules

did not gelatinize completely even after prolonged heating in a boiling water bath. The pea starch-water systems heated to 97°C. resemble suspensions rather than pastes, and a paste is not formed even after heating the system to 120° for 1 hr. Iodine-sorptive capacity and fractionation of the starch show the amylose content to be 60 to 70 percent, depending upon the variety of peas. No starch with so high an amylose content or such unusual physical characteristics has hitherto been reported.

Dough development and mechanical gluten dispersion in relation to amount of mixing and to the flour-water ratio, C. O. SWANSON and A. C. ANDREWS. (Kans. Expt. Sta.). (*Cereal Chem.*, 22 (1945), No. 1, pp. 60-75, illus. 3).—The authors found that in dough made slack by extended treatment with the pull-fold-repull action of the mixograph or dough mixer used in making baking tests, gluten was finely dispersed among the starch granules. Such gluten was not readily separated by the process of washing in water. It had suffered no apparent change in constitution and could be separated as a rubbery wad by appropriate methods. The use of the Waring blender together with the centrifuge was the best method for separating the gluten from the most severely treated doughs. By this method most of the starch was separated and then excess water in the foam was removed. Gluten from doughs mixed as long as 36 min. in the mixograph or to a paste in a high-speed baking-test mixer was successfully separated. Dispersion of gluten which produced the difficulty in separation by washing took place much more slowly in slack or very soft doughs than in stiff doughs. Gluten was readily separated from batters made stiff by the addition of starch. Very soft doughs, 90 percent absorption, when mixed a long time stiffened into a soft dough from which gluten was readily washed. The rate at which a dough developed from a very soft dough of Tenmarq was much slower than for Chiefkan. Greater differences in mixogram patterns of Tenmarq and Chiefkan were obtained by using soft doughs than by using stiff doughs.

The composition of the "amylodextrin" fraction of wheat flour, M. M. MACMASTERS and G. E. HILBERT. (U. S. D. A.). (*Cereal Chem.*, 21 (1944), No. 6, pp. 548-555, illus. 2).—The so-called amylodextrin, small-granule or tailings fraction separated by centrifuging crude wheat starch after the removal of the bran and gluten, was found to be composed of very small starch granules, proportions of damaged large granules varying with the severity of the milling, and smaller quantities of protein, fatty acids, ash, and pentosans, and cellulose in the cell wall debris. The damaged granules gelatinized in cold water. There was evidence of relatively little degradation of the starch. Large sorptive surfaces of the small granules, together with high ash content, suggested that the semi-fluid consistency of the fraction was due at least in part to an electroviscous effect.

Effect of the sulfurous acid steep in corn wet milling, M. J. COX, M. M. MACMASTERS, and G. E. HILBERT. (U. S. D. A.). (*Cereal Chem.*, 21 (1944), No. 6, pp. 447-465, illus. 10).—The authors describe a microscopic technic for the study in situ of the changes which occur in structural protein when corn kernels are subjected to various conditions. It was found that sulfurous acid in the steep used in the wet-milling process for cornstarch extraction had a specific effect in facilitating the separation of starch from protein. A technic was developed whereby the starch granules could be removed from a section of the kernel, leaving the protein network clearly visible. Birefringence of this network indicated that the molecules in it were largely oriented. Considerable peptization of the protein was effected when corn kernels were subjected to a sulfurous acid steep. At 38° to 43°C., a 0.2-per-

cent sulfur dioxide steep left much of the protein in globules or in strands ending in globules. At 49° to 55°, greater dispersion of the protein resulted from steeping, and globules were found only in the cells just under the aleurone, where protein packing was most dense. The steep caused more complete protein dispersion, the higher the temperature (38° to 55°) and the greater the sulfur dioxide content (0 to 0.4 percent). Sulfurous acid appeared to effect disintegration and dispersal of the protein matrix more by its reducing action than by its acidity. It could not be successfully substituted by lactic, acetic, or hydrochloric acid in equivalent concentration or by acetic or hydrochloric acid at the same pH. Addition of lactic acid to a sulfurous acid steep increased softening of the kernel. Both glutinous and nonglutinous cornstarch contained more nitrogen and phosphorus and had lower paste viscosity the higher the sulfur dioxide content of the steep used prior to extraction (from 0 to 0.4 percent). In glutinous cornstarch, the ash content also was greater. The fat content of the starch was not affected by the steep. It was difficult or impossible to separate prime-quality starch from corn dried artificially at high temperatures, because the protein adhered to the starch granules with unusual tenacity. The difficulty was greater the higher the temperature at which the corn had been dried. The specific action of sulfurous acid in the steep was to disintegrate the protein matrix throughout the kernel, and, in consequence, to facilitate complete hydration with consequent softening of the kernel. This action is suggested to be due mainly to the reducing action of the sulfurous acid. Bleaching of the starch by the sulfurous acid during steeping was apparently negligible.

The pigments of cottonseed, C. H. BOATNER. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 1, pp. 10-15, illus. 8).—A method for the purification of gossypol which yields material differing in optical properties from those previously reported for gossypol preparations is described, together with a colorimetric test for extractable gossypol. It was shown that cottonseed contains at least three pigments in addition to gossypol. Some of the properties of the three pigments are reported. One of these newly detected pigments, here designated "gossypurpurin," was found to be the substance which, mixed with gossypol, constitutes the so-called "red gossypol." The water-dispersable blue pigment of cottonseed appeared to be either a complex of gossypol, gossypurpurin and protein, or a mixture of two protein-pigment complexes. The blue substance was separated into two pigments and a protein component.

Dilatometric investigations of fats, I, II. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 9, pp. 251-256, illus. 7).—Of these two papers, the first emphasizes especially some of the less obvious sources of technical error while the second reports results of measurements upon various individual fats.

I. *Apparatus and techniques for fat dilatometry*, A. E. Bailey and E. A. Kreamer (pp. 251-253).—The authors here discuss volume changes associated with phase transformations in fats and the general procedure applicable in dilatometric measurement; describe forms both of volumetric and of gravimetric dilatometer found to be suitable for work with fats; discuss certain precautions necessary to the accurate computation of volume changes in the fat; and detail the procedure adopted for the measurements.

II. *Dilatometric behavior of some plastic fats between 0°C. and their melting points*, E. A. Kreamer and A. E. Bailey (pp. 254-256).—The fats here reported upon are: Lard, butterfat, cottonseed oil, peanut oil, a commercial margarine oil, a commercial all-hydrogenated vegetable shortening, three samples of soybean oil hydrogenated to different degrees, a hard butter

fractionally crystallized from hydrogenated peanut oil, a mixture of tristearin and soybean oil, and a synthetic fat containing equal molar proportions of stearic and oleic acids.

The dilatometric curves of volume change in the fat against temperature were in every instance composed of a series of straight lines, separated by sharp break or transition points. The number of linear sections in the dilatometric curves corresponded generally with the known degree of complexity in the glycerides of the fats and varied from two in the case of the relatively simple stearic-oleic glyceride mixture, to at least seven in the case of the all-hydrogenated shortening. Since each break in the curve must correspond to the disappearance of a distinct class of solid glycerides or glyceride complexes, the application of dilatometry to the qualitative and quantitative determination of glyceride composition in fats as suggested. Only two of the fats examined, a mixture of tristearin and soybean oil and a synthetic stearic-oleic glyceride mixture, exhibited polymorphism, even after rapid solidification in ice water.

**Stability values of fats by the active oxygen method and by storage in glass vials.** R. W. FULMINSCHNEIDER and R. M. SPECK. (U. S. D. A.) (*Oil & Soap*, 22 (1945), No. 1, pp. 23-25).—The stability of lards containing various antioxidants was determined by the active oxygen method and by storage in glass vials at 21°C. In many instances there was general agreement in the results, but no constant relationship was found. The difference between the results of the rapid test and those of the storage tests seemed to be greatest when tocopherol concentrate and lecithin were added to lard. In most instances in which antioxidants were used, the protection indicated by the rapid stability test was higher than that found in the storage test.

**The fluorescence of chlorophyll in fats in relation to rancidity.** C. S. FRENCH and W. O. LUNBERG. (*Oil & Soap*, 21 (1944), No. 1, pp. 23-27, illus. 2).—The disappearance of chlorophyll fluorescence in ultraviolet light caused by the addition of cottonseed oil appeared to be due to the absorption of the light by the cottonseed oil and to the intense white fluorescence of the oil itself rather than to a chemical reaction of some constituent of the oil with the excited chlorophyll. There was no evidence of a stoichiometric quenching reaction between the chlorophyll and acceptor substances in the fats used in this study, and, in consequence, no "endpoint" was observed in any of the titrations. A lack of correlation between either the peroxide value or the stabilities measured in conventional ways and the amount of chlorophyll fluorescence of several fats made the "chlorophyll value" test appear to have doubtful value as a generally applicable test for fat rancidity or stability. The crude absorption curves suggested that the greater absorption of near ultraviolet light by oxidized fats may be related to their content of fat peroxides.

**The fats and phosphatides in grass.** B. REWALD (*Oil & Soap*, 21 (1944), No. 2, pp. 50-52).—Analyses of dried grass [species or varieties not specified] showed the total of fats and fat-like substances, phosphatides, and waxes to amount to somewhat more than 7 percent. Most of the phosphatides could be extracted only with a solvent mixture including alcohol. The author holds that true phosphatides can without doubt be separated, but that other phosphorus-containing ones are present in small quantities. The total phosphatide content of dry grass was found at least 0.5 percent.

**Notes on the stabilization of oxidized fats by steam deodorization with phosphoric acid or commercial lecithin.** A. E. BILEY and R. O. FEUGE. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 10, pp. 286-288, illus. 2).—When a

normal fat containing tocopherols was to be stabilized by the addition of lecithin or phosphoric acid, these substances were as effective if added before deodorization as if added afterwards. When such a fat was oxidized until nearly rancid, these antioxidants were much more effective if added before the fat was deodorized. Lecithin and phosphoric acid were equally effective for the treatment of oxidized fats in the deodorizer. There was an optimum proportion of each to be used; the most effective stabilization was obtained with about 0.1 percent lecithin and 0.001 percent phosphoric acid. The optimum percentages of the two were approximately equal, on the basis of the phosphorus content of the materials. Oils deodorized with the optimum quantity of lecithin (0.1 percent) darkened in color in the deodorizer, although there was no darkening when 0.02 percent lecithin was used. The optimum quantity of phosphoric acid (0.001 percent) had no adverse effect on the color. Little phosphorus, either as lecithin or as phosphoric acid, was removed by steam deodorization. In spite of the fact that lecithin and phosphoric acid had a superior stabilizing effect when added to oxidized fats before deodorization, there was no evidence of any regeneration of tocopherols from tocoquinone in the deodorizer. On the contrary, deodorization with these materials appeared to convert tocopherols partially to tocoquinones or other nonreducing chromans.

**Comparison of fat-splitting reagents in the Twitchell process.** A. J. STIRTON, E. M. HAMMAKER, S. F. HARR, and E. T. ROE. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 5, pp. 148-151, illus. 1).—Commercial petroleum sulfonic acid reagents were compared with Twitchell reagents, alkylaryl-sulfonic acids, and sulfoarylsulfonic acids as fat-splitting reagents in the hydrolysis of lard oil, tallow, cottonseed oil, garbage grease, and inedible grease. The best reagents were made from commercial wetting agents of the alkylarylsulfonate type. Sulfoxylyl-stearic acid, seven petroleum sulfonic acids, and four Twitchell reagents followed in order of decreasing effectiveness. Observations were made on the distribution of the fat-splitting reagent between phases, the necessity of removing the sweet water [aqueous glycerin solution] before completion of hydrolysis, and the effect of the fat-splitting reagent upon the color of the crude fat acids.

**Spectrophotometric determination of small proportions of polyunsaturated constituents in fatty materials.** B. A. BRICE, M. L. SWAIN, B. B. SCHAEFFER, and W. C. AULT. (U. S. D. A.). (*Oil & Soap*, 22 (1945), No. 9, pp. 219-224).—Ultraviolet spectrophotometric methods were modified for application primarily to the detection and estimation of low proportions of conjugated and nonconjugated unsaturated constituents in fats, oils, and soaps. The method was found applicable also to fatty materials having high proportions of these constituents. Modifications included corrections for absorption by interfering substances, use of alkaline glycerol as an isomerization medium in the analytical procedure, and correction of absorption data on the isomerized product for absorption by conjugated constituents in the material before isomerization.

The presence of small proportions of highly unsaturated conjugated and nonconjugated compounds in lards, tallows, tallow soaps, and highly purified esters and acids was established. Fatty acids of tall oil were shown to contain approximately 10 percent of conjugated diene acids and a small amount of linolenic acid.

**The effect of fat on the utilization of galactose by the albino rat.** R. P. GEYER, R. K. BOUTWELL, C. A. ELVEHJEM, and E. B. HART. (Wis. Expt. Sta.). (*Jour. Biol. Chem.*, 162 (1946), No. 2, pp. 251-259).—Fat increased the utili-

zation of galactose by the rat when either lactose or galactose was ingested. This phenomenon occurred on milk or synthetic type rations. The percent of the ingested galactose lost in the urine was independent of the actual amount of galactose ingested, but was dependent on the percent of galactose in the ration.

**Measurement of the consistency of plastic vegetable fats:** A standard micro-penetration technic, R. O. FEUGE and A. E. BAILEY. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 3, pp. 78-84, illus. 10).—The authors describe an improved micropenetrometer by means of which it is possible to measure the consistency of fats with a high degree of precision. Since "the intelligent use of a micropenetration method requires some consideration of the theory of plasticity in fats, this theory is briefly discussed." The influence of various factors on the consistency of solidified fats was investigated, and a standard technic for making micropenetration tests is proposed. Micropenetration data on cottonseed, peanut, and soybean oils hydrogenated to different degrees, on cottonseed oil blended with various proportions of highly hydrogenated oil, and on various commercial samples of shortening and margarine are recorded. A quick micropenetration method, applicable as a control in the hydrogenation of fat products, is described.

**Thermal properties of fats and oils, I-V.** (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 10, pp. 293-302, illus. 1; 22 (1945), Nos. 1, pp. 10-13, illus. 1; 2, pp. 39-41, illus. 2).—These five papers deal with the setting up of suitable calorimetric equipment and measurements of some properties of cottonseed oil, its hydrogenation products, and other fatty substances.

I. *Apparatus and techniques for low temperature calorimetry*, A. E. Bailey, S. S. Todd, W. S. Singleton, and G. D. Oliver (pp. 293-297).—A low-temperature calorimeter suitable for the examination of fatty materials with moderate accuracy is described and its method of use outlined. The applications of calorimetry in the examination of fats and fatty materials are discussed.

II. *Heat capacity and latent heat of cottonseed oil*, G. D. Oliver, W. S. Singleton, S. S. Todd, and A. E. Bailey (pp. 297-300).—The heat contents of cottonseed oil, a hydrogenated cottonseed oil, and a mixture of cottonseed oil and petroleum naphtha were measured over ranges of temperature within which there is transformation of the glycerides of the oils from a completely solid to a completely liquid form. From the heat content data, determinations of the heats of fusion of the oils and of the specific heats of the oils in both solid and liquid states were made. Equations for expressing the best capacities of the oils and the oil-solvent mixture with the oil in either the liquid or solid form were derived. Values found for the specific heat of the liquid oils were in general agreement with values found by previous investigators. The values calculated for the heat of fusion of the oils were much lower than values reported by other workers for highly saturated glycerides. It is pointed out, however, that a low value for mixed glycerides of saturated and unsaturated fatty acids was to be expected from considerations of molecular structure.

III. *Calorimetric estimation of solid and liquid glycerides in cottonseed oil and hydrogenated cottonseed oil*, A. E. Bailey and G. D. Oliver (pp. 300-302).—The relative quantities of solid and liquid glycerides in cottonseed oil and a hydrogenated cottonseed oil were estimated calorimetrically at different temperatures over the melting ranges of the oils. A correlation between the content of solids in hydrogenated cottonseed oil and the consistency of the oil, as measured by micropenetrations, was established. From previous

micropenetration data on commercial fat products, it was established that such fats were plastic and easily worked only at solids contents between about 15 and 35 percent. Differences in the content of solids of as little as 1 percent were sufficient to cause noticeable differences in the consistency of plastic fats. Within the ranges of temperature and iodine value at which hydrogenated cottonseed oil was plastic, it was estimated that each decrease in iodine value of 1 unit caused the solid glyceride content of the oil to increase approximately 1 percent.

IV. *Some observations on the polymorphism and X-ray diffraction characteristics of tristearin and a highly hydrogenated cottonseed oil*, A. E. Bailey, M. E. Jefferson, F. B. Kreeger, and S. T. Bauer (pp. 10-13).—Melting points and X-ray diffraction patterns of cottonseed oil hydrogenated to an iodine value of less than 1 and of a very pure sample of tristearin were determined. Contrary to the observations of previous investigators, the X-ray patterns indicate a well-defined crystal structure with a sharp long spacing and a single sharp short spacing in the lowest-melting form of tristearin. A new pattern, with two short spacings and a long spacing, was observed in tristearin of intermediate melting point. Four polymorphic forms of the hydrogenated cottonseed oil were detected. The X-ray pattern of the lowest-melting form of the hydrogenated oil was similar to that of the corresponding form of tristearin. The pattern of the highest-melting form of the hydrogenated oil differed from that of either tristearin or  $\beta$ -palmitodistearin, the major components of the oil. Distinctive patterns for the intermediate forms of the hydrogenated oil could not be obtained, presumably because of the instability of the lower melting forms at room temperature.

V. *The heat capacity and heat of fusion of highly hydrogenated cottonseed oil*, G. D. Oliver and A. E. Bailey (pp. 39-41).—The heat content of a quickly chilled sample, and that of a slowly chilled and tempered sample, of almost completely hydrogenated cottonseed oil, was measured over a temperature range within which there was in each case complete transformation of the oil from a solid to a liquid form. Heat capacity data were calculated for the liquid oil and for the quickly chilled and the tempered solid oil. Equations expressing the changes in heat capacity with temperature were derived. A correlation of the heat capacity data on highly hydrogenated cottonseed oil and similar data previously obtained on unhydrogenated cottonseed oil, and on partially hydrogenated oil, in both liquid and solid states, is presented. The heat of fusion calculated for the quickly chilled and for the tempered solid oil is given.

*Effect of deodorization and antioxidants on the stability of lard*, R. W. RIEMENSCHNEIDER, S. F. HERB, E. M. HAMMAKER, and F. E. LUDDY. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 10, pp. 307-309, illus. 1).—Deodorization produced no appreciable increase in the stability of steam-rendered lard but significantly increased the stability of kettle-rendered lard. A substantial increase in the stability of lard was produced by tocopherol, regardless of whether it was added as a pure compound, as a concentrate, or as a tocopherol-bearing oil. Accelerated tests showed that this increase was more than doubled when small amounts of synergists also were added. Deodorization of the lard prior to addition of the synergistic antioxidant compositions produced even greater stability. Nordihydroguaiaretic acid was more effective than tocopherol as an antioxidant for lard, as determined by both the active oxygen and the oxygen-absorption methods. Deodorization of the lard prior to addition of this antioxidant and synergists did not effect further increase in stability over that obtained by the addition of these materials

to undeodorized lard. In most instances, deodorization after the addition of synergistic compositions resulted in some decreases in stability, as compared with similar additions to the lard without deodorization.

**Improvement produced in the stability of lard by the addition of vegetable oils.** R. W. RIEMENSCHNEIDER, J. TURER, and W. C. AULT. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 4, pp. 98-100).—As measured by an active oxygen method, the stability of lard could be increased appreciably by the addition of from 1 to 10 percent of any one of several vegetable oils. The increased stability thus obtained appeared to be closely related to the tocopherol content of the added oils. It is pointed out that since the tocopherols function most efficiently at lower levels and with decreasing efficiency at each successively higher level, it would seem possible to take advantage of a considerable part of the stabilizing action of these compounds without adding the vegetable oils or fats in excessively large quantities. Tocopherol thus added appeared to be capable of acting synergistically with certain other known antioxidants, such as *D*-isoascorbyl palmitate and commercial lecithin. At the same time, choice between the use of liquid fats or oils hydrogenated to various degrees of hardness appeared to allow a considerable measure of control over the hardness and plasticity of the finished product.

**The fractionation of milk fat from a solvent at low temperatures.** J. L. HENDERSON and E. I. JACK. (Univ. Calif.). (*Oil & Soap*, 21 (1944), No. 3, pp. 90-92, illus. 3).—A procedure for fractioning milk fat from a solvent at low temperature consists in freezing out fractions of the fat from solvent (a specified brand of petroleum spirit) at progressively lower temperatures  $-7^{\circ}$ ,  $-13^{\circ}$ ,  $-23^{\circ}$ , and  $-53^{\circ}\text{C.}$ , the remaining filtrate being taken as a final fraction. In physical appearance these fractions varied from a dry white powder to a reddish-yellow oil; in melting point from  $53^{\circ}$  to  $-10.6^{\circ}$ ; in iodine number from 8.29 to 58.37; and in saponification equivalent from 262.8 to 235.2. The saponification equivalents did not change in the same order as the other properties mentioned. This fat fractionation effected a simplification of milk fat and made available less complex portions of the natural glyceride mixtures for detailed study of the composition, configuration, and other properties.

**A bibliography on the solvent extraction of vegetable oils from raw materials, with special attention to soybeans.** A. C. BECKEL. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 9, pp. 264-270).—Groups of reference numbers referring to a following alphabetical author list are classified under the captions and subcaptions: Apparatus (continuous and batch); process (continuous and batch); reviews; principles, effects on oil and meal; hazards; byproducts; costs; and solvents (general; and ethyl alcohol, methyl alcohol, hexane, benzene, propane, trichlorethylene, ethylene dichloride, carbon dioxide, sulfur dioxide, butane, and carbon tetrachloride).

**Effect of metallic salts on the stability of palm and hydrogenated cottonseed oils.** S. T. BAUER and V. GASTINEL, JR. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 2, pp. 36-42, illus. 5).—It was found that when palm and hydrogenated cottonseed oils were heated in the presence of tin to temperatures comparable with those obtaining during the hot dipping of tin, palm oil showed a slightly lower rate of increase in viscosity compared to hydrogenated cottonseed oil. When zinc and ferric salts were added to the otherwise similarly treated oils, hydrogenated cottonseed oil was found to be more stable than palm oil. Metallic contaminants such as ferric oxide, which had a marked effect on the rate of viscosity increase of palm oil, produced no change in the rate of increase in viscosity in the case of hydro-

genated cottonseed oil. The addition of zinc stearate, of zinc chloride alone, or of zinc chloride and ferric salt retarded polymerization of both oils, as measured by the rate of increase in viscosity. The addition of either ferric oxide or ferric stearate accelerated the rate of viscosity increase of the heated oils. It was concluded that the inorganic salts are partly converted to ferric and zinc soaps in situ by reaction with free fatty acids already present or formed in the heated oils. When palm oil was heated with various metallic compounds, it lost free fatty acids rapidly during the early stages of heating until the concentration attained a definite value, at which it remained during further heating. The concentration at which the free fatty acids in the palm oil became constant was directly affected by the specific nature of the added metallic compound. When hydrogenated cottonseed oil, having a lower initial content of free fatty acids than the palm oil was treated in the same manner, there was an accumulation of free fatty acids during heating until the concentration attained a definite value, after which it remained constant on further heating. The concentration at which the free fatty acids of any sample of oil became constant was found to be dependent on the specific nature of the added metallic compound.

Molecular distillation of a hydrogenated cottonseed oil and certain characteristics of the distilled fractions, W. S. SINGLETON and A. E. BAILEY. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 6, pp. 157-159).—Fractionation of a hydrogenated cottonseed oil in a molecular distillation followed the course to be expected on the basis of differences between the glycerides in molecular weight, the composition of cottonseed oil permitting a considerable separation of glycerides in accordance with degree of unsaturation. Fractionation of a molecularly distilled oil occurred, as is to be expected, on the basis of variations in molecular weight of the glycerides. The composition of cottonseed oil was such that there was a considerable separation of the glycerides according to their degree of unsaturation. The composition of peanut oil was such that similar separation can only be slight. Soybean oil was in this respect intermediate between cottonseed oil and peanut oil. Molecular distillation of hydrogenated cottonseed oil caused a segregation of tocopherols and related compounds similar to that observed in peanut oil. However, the fractions first distilled from the oil were relatively weak in antioxygenic properties. It appeared probable that their lack of effectiveness was due to the presence of unknown substances capable of inhibiting or counteracting the action of tocopherols, but the presence of substances other than tocopherols which responded to or interfered with the Emmeric-Engel test could not be excluded. The tocopherols in the potent fractions were more effective than  $\alpha$ -tocopherol, but less effective than  $\gamma$ -tocopherol.

Tocopherol concentrates by the fractional crystallization of cottonseed oil from solvents, W. S. SINGLETON and A. E. BAILEY. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 8, pp. 224-226, illus. 2).—Tocopherol concentrates equivalent in tocopherol content and antioxygenic activity to molecularly distilled concentrates were obtained from cottonseed oil by hydrogenating the oil and removing the bulk of the glycerides and sterols by low temperature crystallization from acetone. Concentrates of high tocopherol content could be obtained only from hydrogenated oils. Completely hydrogenated oils were the best source of concentrates at crystallization temperatures down to  $-60^{\circ}\text{C}$ . Below this temperature partially hydrogenated oils were equally good. A solvent : oil ratio of 8 : 1 by weight appeared to be about the optimum. At this ratio, crystallization from acetone at the temperature of dry ice ( $-78^{\circ}\text{C}$ .) yielded a concentrate containing 34 percent tocopherols

from an oil originally containing 0.05 percent tocopherols. The direct addition of dry ice to the solvent and oil was to be avoided, since this lowered the recovery of tocopherols. Petroleum naphtha and methyl ethyl ketone were less suitable solvents than acetone because of their greater capacity for dissolving glycerides at low temperatures.

Gamma-tocopherol as a precursor of a red quinoid substance developed in cottonseed oil during oxidation, C. E. SWIFT, G. E. MANN, and G. S. FISHER. (U. S. D. A.) (*Oil & Soap*, 21 (1944), No. 11, pp. 317-320, illus. 5).—On the basis of spectrophotometric data showing the characteristic spectral absorptions observed in oxidizing substrates with and without added  $\gamma$ -tocopherol, it was concluded that the red color which develops on accelerated oxidation of fat substrates containing this tocopherol results from its conversion to chroman-5,6-quinone. The chroman-5,6-quinone thus produced showed relatively little antioxidant activity.

Oil from tumbling mustard seed, W. H. GOSS and J. E. RUCKMAN. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 8, pp. 234-236).—A sample of the seed of *Sisymbrium altissimum* was obtained from wheat screenings and found to contain 5.46 percent moisture and 32.6 percent of an oil having a Wijs iodine number of 151.0. The oil-free residue of the seed contained 7.22 percent of nitrogen. By fractionation of the methyl esters of the fatty acids, the oil was shown to contain linolenic acid, 34.9 percent; erucic acid, 25.3 percent; linoleic acid, 19.0 percent; palmitic acid, 14.1 percent; palmitoleic acid, 1.0 percent, and 0.5 percent of unsaponifiable matter. The oil is compared, in a table showing the known fatty acid components, with other oils having important proportions of erucic acid. Although the tumbling mustard seed oil was found to fall far short, with respect to erucic acid content, of being an adequate replacement for rapeseed oil (of which the erucic acid content is given as 50.0 percent), it is noted that "the present trend in the oil and synthetic chemical industries is to consider the component fatty acids of an oil as potential raw materials for industrial products, and means for fractionating the oils and their acids to obtain technically pure materials are now being made available. In view of these developments, it will be of interest, and of considerable value to the oil trade, to procure information on the compositions of the oils in the several other types of weed seeds available as waste products of the grain-processing industries."

Valencia orange-seed oil, G. R. VAN ATTA and W. C. DIETRICH. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 1, pp. 19-22, illus. 2).—On the basis of dry substance of the uncleaned seed, the oil content of the seed examined was 34.2 percent; of the clean, dry kernels, 55 percent. Processing data and observations from experiments on hydraulic and continuous pressing and solvent extraction and on refining, bleaching, and deodorizing are recorded. The characteristics and composition of the oil were investigated, individual saturated fatty acids having been determined by the method of fractionation of the methyl esters. On the basis of the total mixed acids, 20.7 percent of palmitic acid is reported, 4.7 percent of stearic acid, and 0.9 percent of arachidic acid.

With regard to possible uses, it was concluded that when refined, bleached, and deodorized the oil would be quite acceptable as a food oil.

Analyses of peanut kernels with relation to U. S. standards for farmers' stock peanuts, M. F. STANSBURY, J. D. GUTHRIE, and T. H. HOPPER. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 8, pp. 239-247, illus. 3).—Average data for the oil and nitrogen content and for the iodine number of the oil, as determined by the authors for Spanish and for runner peanuts, were found to

agree fairly well with the values previously obtained by others. Statistical consideration of the figures indicated that probably two-thirds of all graded samples of Spanish and runner peanut kernels will have oil contents between 48.9 and 52.3 percent and nitrogen contents between 4.64 and 5.14 percent on the moisture-free basis. Similarly, two-thirds of all graded samples of Virginia peanut kernels should have oil contents between 4.64 and 50.4 percent and nitrogen contents between 4.46 and 5.08 percent.

Viscosities and densities of hydrogenated peanut oils, F. C. MAGNE and H. WAKEHAM. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 13, pp. 347-349, illus. 2).—The viscosity and density data reported include those of oils from several varieties of peanuts grown at a number of experiment stations, the samples having been selected to cover as wide a range of iodine number as possible, together with measurements of the same properties of a group of hydrogenated oils prepared from a commercial alkali-refined and bleached peanut oil.

Molecularly distilled peanut oil antioxidants and pure  $\alpha$ -tocopherol as stabilizing agents for fats of poor keeping quality, G. D. OLIVER, W. S. SINGLETON, and A. E. BAILEY. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 7, pp. 188-193, illus. 10).—Molecularly distilled concentrates of peanut oil antioxidants and pure  $\alpha$ -tocopherol were tested at 110°C. as agents for the stabilization of lard and abnormal peanut oil products of poor stability.

Neither the peanut oil concentrates nor  $\alpha$ -tocopherol were effective in improving the stability of either raw or hydrogenated peanut oils. The addition of these substances materially reduced the stability of some of the oils. The results indicated that poor keeping quality in hydrogenated peanut oils is not in general due to a deficiency in tocopherols or related antioxidants alone. Both  $\alpha$ -tocopherol and peanut oil antioxidants were effective stabilizers for lard in concentrations up to approximately 0.06 percent. Above this concentration, the addition of  $\alpha$ -tocopherol did not materially extend the keeping time of the lard, and the addition of peanut oil antioxidants decreased the keeping time. Essentially similar relationships between antioxidant concentrations and effectiveness were observed at the lower levels of concentration of the two antioxidants. In an investigation of the kinetics of peroxide formation in lard containing various percentages of  $\alpha$ -tocopherol, with increasing tocopherol concentration, the peroxide level at which rapid oxidation begins was found to increase constantly, whereas the initial rate of peroxide formation passed through a minimum. This is held to account for the antioxidant effect of low concentrations of  $\alpha$ -tocopherol. At higher tocopherol levels the rate at which the peroxide level rose was balanced by the rate at which peroxide formation was accelerated, and there was consequently no stabilizing effect. No correlation between the rate of tocopherol disappearance and either peroxide concentration or rate of peroxide formation in accelerated tests of lard containing 0.5 percent peanut oil tocopherols or 0.5 percent  $\alpha$ -tocopherol was observed. In these tests there was a considerable residue of unoxidized tocopherols remaining after the fat had become strongly rancid. The experimental results are considered strongly to suggest the presence of distillable substances in vegetable oils which are capable of inhibiting the action of tocopherols, or otherwise acting as pro-oxidants. The possibility that such substances are developed by oxidation but do not consist of peroxides is noted.

Relation between the fatty acid composition and the iodine number of soybean oil, C. R. SCHOLFIELD and W. C. BULL. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 3, pp. 87-89, illus. 1).—It was found that over the entire

range of iodine numbers the percentages of total saturated and individual unsaturated fatty acids in soybean oil extracted in the manner described vary in a regular manner, within reasonable limits, according to the iodine numbers. Similar relations were observed whether the variables considered were the percentages of individual fatty acids and iodine numbers of the mixed acids, or the percentages of individual fatty acids in the mixed acids and iodine numbers of the oils. The proportions of individual fatty acids in the mixed fatty acids also represented the proportions of individual fatty acids as glycerides in the oil. The principal variation in fatty acid composition was the large decrease in oleic acid and the large increase in linoleic acid with increasing iodine number. Linolenic acid increased slightly with increasing iodine number, while the proportion of saturated acids was relatively constant for the entire range of iodine numbers.

**Analysis and fatty acid composition of tobacco seed oils, R. W. RIEMENSCHNEIDER, R. M. SPECK, and E. G. BEINHART. (U. S. D. A.)** (*Oil & Soap*, 22 (1945), No. 5, pp. 120-122).—The fatty acid composition of 12 samples of oil representing a number of different types and varieties of tobacco were determined by the thiocyanometric method. The samples were remarkably uniform in composition, containing on the average 75 percent linoleic, 15 percent oleic, and 10 percent saturated acids. Spectrophotometric determination of the linoleic acid content of two samples of oil gave values 3.0 and 5.4 percent higher than those indicated by the thiocyanometric method. A more complete investigation of the fatty acid constituents of one sample of flue-cured tobacco seed oil was carried out by analysis of fractions obtained by distillation of the methyl esters and by low-temperature crystallization of the distilled ester fractions. The composition calculated from these analyses agreed well with that determined from analysis directly on the oil. The saturated acids consisted of palmitic and stearic acids, the proportions being about 7 and 3 percent, respectively, of the total fatty acids. This sample of oil contained 0.043 percent of tocopherol.

On the basis of the composition determined in the investigation here noted, tobacco seed oil seemed particularly suitable for the manufacture of nonyellowing alkyds or for the preparation of technical linoleic acid.

**Studies in the expression of oil from tung fruit, R. S. MCKINNEY, N. J. HALBROOK, and R. E. OGLESBEE. (U. S. D. A.).** (*Oil & Soap*, 21 (1944). No. 12, pp. 353-357).—Best results in yield of crude and filtered oil by an expression procedure were obtained with a tung meal containing 4.2 percent moisture and 20 percent shell. The drying of tung meal with an initial air temperature of 320°F. appeared to affect adversely the yield of filtered oil from the expeller process. A filtration test was developed for determining the amount of foots in a crude tung oil. It was found difficult to obtain efficient oil expression from tung meals containing filter cake; in one test with this material the resulting press cake was high in oil content, while in another test the crude tung oil contained about twice as much foots material as was present in crude tung oil from tung meal containing no filter cake. The expression of tung oil from a tung meal consisting of ground old tung kernels and tung shell was found difficult if not impossible. This difficulty appeared to be due, at least partly, to the fact that the meal from old kernels would not plasticize when subjected to heat and pressure. When these kernels were mixed with new kernels no difficulty was experienced in expressing the tung oil from the meal. Tests indicated that hulling the moist tung fruit in the grove did not interfere with the expression of the oil if the moist dehulled tung fruits were properly dried before pressing. A process

for producing a clear tung oil by treating the crude oil with a chemical agent to precipitate certain nonoil constituents in the crude tung oil, followed by either pressure filtration or centrifugation, was developed. When tung oil filter cake was mixed with an equal amount of tung press cake, over 98 percent of the oil could be extracted by petroleum solvents.

Effect of moisture on grinding of tung kernels and solvent extraction of meal, A. F. FREEMAN, F. C. PACK, and R. S. MCKINNEY. (U. S. D. A.), (*Oil & Soap*, 21 (1944), No. 11, pp. 328-330).—Data showing the effects of moisture on grinding of tung kernels and no solvent extraction of oil from the resulting meal indicated that the efficiency of oil extraction can be materially increased by vacuum drying ground kernels before extraction. The state of comminution obtainable on grinding tung kernels was dependent upon moisture content; above 9 percent moisture content the efficiency of grinding, and consequently the efficiency of extraction, decreased progressively with increase of moisture content; the most efficient grinding was obtained with material of moisture content in the range of 6 to 9 percent; and, in general, progressively poorer grinding of tung kernels with moisture contents ranging downward from 6 percent was obtained.

A note on the composition of wheat-germ oil, S. B. RADLOVE. (U. S. D. A.), (*Oil & Soap*, 22 (1945), No. 7, pp. 183-184).—As a preliminary to an investigation of the possibilities for the increased industrial utilization of wheat oils, the proximate analysis of a commercially available wheat-germ oil was repeated "in the light of present conceptions of the significance of the analytical constants of the unsaturated fatty acids."

Fatty acid monoesters of l-ascorbic and d-isoascorbic acids as antioxidants for fats and oils, R. W. RIEMENSCHNEIDER, J. TURER, P. A. WELLS, and W. C. AULT. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 2, pp. 47-50).—The fatty acid monoesters of l-ascorbic and d-isoascorbic acids were tested for antioxygenic activity in different fats and oils under various conditions and in combination with other inhibitors. Traces of soap were found to have a deleterious effect on the stability of fats. This deleterious effect could be counteracted by the use of fat-soluble ascorbyl monoesters. The ascorbyl monoesters used in combination with either  $\alpha$ -tocopherol or phospholipids, or both, showed a marked synergistic antioxidant effect. Possible explanations are given for certain synergistic phenomena that have been observed.

Formation and decomposition of peroxides of unsaturated fat esters, R. F. PASCHKE and D. H. WHEELER. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 2, pp. 52-57, illus. 12).—Distilled methyl esters of soybean fat acids were used because they were easy to prepare and could be readily purified by distillation. The difficulty involved in the preparation of the pure esters in quantities sufficient for exploratory work made their use in the experiments here dealt with impracticable. A study of reaction time and the effect of oxygen on determination of peroxide by acetic acid-potassium iodide method showed that a 1-hr. reaction time in the absence of oxygen was necessary, especially on samples of high peroxide. The peroxide-formation curves at 100°, 75°, 55°, 35°, and 15° [C.], showed a progressive increase in maximum peroxide value reached as the temperature was lowered to 35°. At 15°, the maximum was the same as 35°; this value was over 30 percent of what it would be if all the double bonds were converted to peroxide. The agreement between actual peroxide and "theoretical peroxide" calculated from decrease in iodine number extended to higher values as the temperature was decreased. The rate of decomposition or disappearance of peroxide at 100°, 75°, 55°, and 35° agreed best with that of a bimolecular reaction, but

definite exceptions existed. The speed of decomposition of peroxide became progressively greater as the degree of oxidation was increased. The changes in unsaturation, OH number, and acid number were small compared to the decrease in peroxide value as the peroxide decomposed. The formation of volatile and inflammable products was qualitatively observed in the decomposition of highly oxidized esters.

Some relationships between fat acid composition and the iodine number of linseed oil, E. P. PAINTER. (N. Dak. Expt. Sta.). (*Oil & Soap*, 21 (1944), No. 12, pp. 543-546, illus. 4).—Results of analysis of 148 linseed oil samples are summarized. When the constituent fat acid glycerides were plotted against the iodine number the points fell close to a straight line in the cases of saturated acids, oleic acid, and linolenic acid. Of the data for linoleic acid, however, the points were so dispersed that no significant relationship to the iodine number was apparent. Correlation coefficients between iodine number and the fat acids were: Linolenic, +0.97; oleic, -0.94; saturated, -0.80; and linoleic, -0.27. It was possible to estimate within limits the contents of linolenic, oleic, and saturated acids in linseed oil by applying equations where the iodine number was the only variable. For linoleic acid, however, the standard deviation along the regression line was almost equal to the standard deviation from the mean, although real differences in composition which were independent of the iodine number existed. The dispersion of the points along the regression lines was greater than would result from errors of precision in the analyses.

Purification of oleic acid, methyl oleate, and oleyl alcohol for use as chemical intermediates, D. SWERN, H. B. KNIGHT, and T. W. FINDLEY. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 5, pp. 133-139).—Oleic acid, methyl oleate, and oleyl alcohol of high purity (93 to 96 percent) were prepared from readily available and inexpensive commercial materials in 65 to 70 percent yields by fractional distillation and a single low-temperature fractional crystallization. The starting material for the preparation of the purified oleic acid and methyl oleate was commercial red oil. The oleyl alcohol preparation was made from a commercial grade containing a little more than 70 percent of the desired compound. In the fractional distillation of red oil and its methyl esters, lower fractions amounting to about 20 percent of the starting material were obtained. These are suggested for use in soap manufacture. A fraction containing more than 50 percent linoleic acid was obtained from the C-18 fraction of red oil by fractional crystallization. This fraction amounted to about 20 percent of the total starting material and had approximately the same percentage composition with respect to fatty acids as several important semi-drying oils.

Solidification points of binary mixtures of caprylic and capric acids, H. A. SCHUETTE and H. A. VOGEL. (Univ. Wis.). (*Oil & Soap*, 22 (1945), No. 9, pp. 238-240, illus. 1).—Clearly defined inflections were shown to characterize the solidification point diagram of binary mixtures of caprylic and capric acids. These diagrams are presented, together with pertinent data and a description of attested procedure for preparing the acids from readily available raw material.

Polyamides from polymeric fat acids, L. B. FALKENBURG, H. M. TEETER, P. S. SKELL, and J. C. COWAN. (U. S. D. A.). (*Oil & Soap*, 22 (1945), No. 6, pp. 143-148, illus. 1).—The preparation and properties of various polyamides, copolyamides, and modified polyamides of polymeric fat acids are described. These polymers are shown to be of interest because of their unusual properties and because of the unsaturation and relatively high molecular weight

of the polybasic acids involved. Despite the presence of tribasic acids in polymeric fat acids, ungelled polymers having molecular weights of 3,000 to 5,000 are obtainable. The application of theoretical principles of polymerization to the preparation of these polymers is briefly discussed. Possible industrial uses for the polyamides are indicated.

Allylic esters of polymeric fat acids, II. M. TEETER and J. C. COWAN. (U. S. D. A.). (*Oil & Soap*, 22 (1945), No. 7, pp. 177-180, illus. 2).—Allyl,  $\beta$ -methallyl, and  $\beta$ -chlorallyl esters were prepared from polymeric soybean fat acids by direct esterification and from dilinoleic acid by transesterification of methyl dilinoleate. The method of polymerizing the esters and the properties of the polymers are described. The properties observed were considered to indicate the possibility of the use of these polymers as modifiers and softening agents in the production of various other polymers, as tackifiers and softening agents for elastomers, and as components of surface coatings for special purposes.

Oxygen absorption of methyl esters of fat acids, and the effect of antioxidants, A. J. STIRTON, J. TURER, and R. W. RIEMENSCHNEIDER. (U. S. D. A.). (*Oil & Soap*, 22 (1945), No. 4, pp. 81-83, illus. 2).—The oxygen absorption of methyl linolenate, methyl linoleate, methyl oleate, methyl stearate, the distilled methyl esters of lard, and various mixtures of the four individual methyl esters were measured at 100°C. in the Barcroft-Warburg apparatus. Mixtures of methyl esters absorbed oxygen at a rate which could be approximately predicted from the rate of oxygen absorption of each component and the percentage of each present. The antioxidants nordihydroguaiaretic acid, propyl gallate, benzylhydroquinone,  $\alpha$ -tocopherol, and their synergistic combinations with citric acid, *d*-isascorbyl palmitate, and lecithin were tested with the substrates methyl linoleate, methyl oleate, methyl stearate, and the distilled methyl esters of lard. Citric acid showed marked synergism with each antioxidant. The two most effective were the combinations of citric acid with nordihydroguaiaretic acid and with propyl gallate.

The synthesis and properties of the acyl phosphates of some higher fatty acids, A. L. LEHNINGER (*Jour. Biol. Chem.*, 162 (1946), No. 2, pp. 333-342).—Monopalmitylphosphoric acid and monooctanoylphosphoric acid (mixed anhydrides of phosphoric acid and the fatty acid) were synthesized by the reaction of the proper acyl chloride with monosilver phosphate. It is pointed out that the methods developed could be used in the synthesis of other higher fatty acid phosphates. Silver, calcium, barium, and strychnine salts of these compounds were obtained. The introduction of the phosphate group into the fatty acid molecule gave it the properties of a much more soluble, more hydrophilic substance. The compounds were relatively unstable in aqueous solution, but showed themselves to be more stable than either acetyl phosphate or 1,3-diphosphoglyceric acid. It was found that the phosphatases present in mammalian tissues quickly hydrolyze the fatty acid phosphates, and that the adenylic acid system is not an obligatory phosphate acceptor in the dephosphorylation of the fatty acid phosphates.

Oxidation of acetyl phosphate and other substrates by *Micrococcus lysodeikticus*, M. F. UTTER, L. O. KRAMPTZ, and C. H. WERKMAN. (Iowa State Col.). (*Arch. Biochem.*, 9 (1946), No. 2, pp. 285-300, illus. 1).—Addition of NaCl to lysed preparations of *M. lysodeikticus* greatly increased respiration on several substrates and permitted oxidation of substances which were otherwise not utilized by lysed cells. Lysed cells in the presence of NaCl were able to metabolize acetyl phosphate. Phosphate was transferred from acetyl phosphate to adenylic acid and there was an increased rate of  $O_2$ -uptake and

an accompanying decrease in volatile acid. Comparison of the range of NaCl concentrations at which acetate and acetyl phosphate oxidation were stimulated suggested an oxidation path for acetyl phosphate which did not involve acetate as an intermediate. A discussion of the possible routes for the oxidation of acetyl phosphate is presented.

The component fatty acids of soybean lecithin, M. H. THORNTON, C. S. JOHNSON, and M. A. EWAN. (Ind. Expt. Sta.). (*Oil & Soap*, 21 (1944), No. 3, pp. 85-87).—Lecithin was prepared from crude soybean phosphatides by a form of the cadmium chloride method. Results of analysis indicated that of this preparation 97 percent was lecithin and 3 percent cephalin. Its fatty acid composition was as follows: Palmitic—15.77 percent, stearic—6.30 percent, oleic—12.98 percent, linoleic—62.92 percent, and linolenic—2.02 percent.

Foaming properties of soap solutions, R. C. MERRILL, JR., and F. T. MOFFETT. (U. S. D. A.) (*Oil & Soap*, 21 (1944), No. 6, pp. 170-175, illus. 3).—Results of tests of the stability of foams prepared from solutions of soaps and detergents by a "liquid drainage" method and a modified "foam time" method were qualitatively equivalent. Rates of drainage of liquid from soap and detergent foams were not proportional to the volumes of liquid in the foam. The stabilities of foams from 0.1 percent solutions of soaps of most of the natural fats and oils tested were much greater than those of foams from single soaps that were sufficiently soluble to form solutions of this concentration. The foam time of a mixture of equal volumes of two 0.1 percent solutions was not equal to the average of the foam times of the separate solutions. A number of electrolytes, organic liquids, pectic materials, and vegetable gums greatly increased foam stability. Data on 0.03 percent sodium tallow and palm-oil soap solutions indicated a maximum foam time at a pH of about 10.6. Increasing the concentrations of 10 soaps from 0.05 to 0.1 percent more than doubled the foam time.

The antioxidant properties of nordihydroguaiaretic acid, W. O. LUNDBERG, H. O. HALVORSON, and G. O. BURR. (*Oil & Soap*, 21 (1944), No. 2, pp. 33-35, illus. 4).—The authors report upon the antioxidant properties of nordihydroguaiaretic acid. This substance is described as readily obtained in substantial yields from a common plant (*Larrea divaricata*) and comparing favorably with other highly effective inhibitors of the phenolic type. It was found more soluble in fats than hydroquinone but not as soluble as the tocopherols. Within the limits of these experiments, and at optimal concentration, it appeared to have no deleterious effects on the qualities of lards. Its effectiveness in stabilizing fats was to some extent carried over into baked products. Ascorbic acid enhances its effectiveness.

Effect of antioxidants, individually and in combination, on stability of carotene in cottonseed oil, K. T. WILLIAMS, E. BICKOFF, and B. LOWRIMORE. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 6, pp. 161-164, illus. 3).—By an accelerated test, *l*-ascorbyl palmitate, alpha-tocopherol, hydroquinone, and phospholipids from cottonseed and soybean oil were evaluated singly and in combinations for their antioxidant effect on carotene in mineral oil and cottonseed oil solutions. Their effects in retarding the formation of peroxides in the refined cottonseed oil were also determined, and similar studies were made on cottonseed oil after the addition of 1.2 mg. of carotene per gram of oil. In the refined cottonseed oil the formation of peroxides occurred concurrently with the destruction of carotene and was greatly accelerated as the carotene disappeared. In mineral oil solutions, no peroxides were found until after the carotene had become completely decolorized. Although

alpha-tocopherol was very effective in stabilizing carotene when added to mineral oil solutions, neither the naturally present nor added tocopherol was effective in a more unstable solvent such as refined cottonseed oil. To make the tocopherol effective in such a solvent it was necessary first to stabilize the solvent. When the combination of phospholipid and hydroquinone was added to the refined cottonseed oil, the oil was stabilized and a very marked increase in carotene stability was obtained.

**Stabilization of carotene with nordihydroguaiaretic acid and other antioxidants.** E. BICKOFF, K. T. WILLIAMS, and M. SPARKS. (U. S. D. A.). (*Oil & Soap*, 22 (1945), No. 5, pp. 128-131, illus. 1).—Relative values for the carotene-stabilizing effects in edible oil solutions of a number of antioxidants, alone and in various combinations, were determined. One of the more promising for this purpose was nordihydroguaiaretic acid. When this antioxidant was used together with phospholipid or citric acid, its effectiveness was enhanced. Addition of  $\alpha$ -tocopherol to oils containing only traces of this antioxidant caused a significant increase in carotene stability. Its sparing effect on carotene in vivo would further add to the desirability of its use in such oil solutions of carotene. In refined cottonseed oil, carotene destruction occurred concurrently with the accumulation of peroxides. In the more saturated oils, carotene destruction occurred before much peroxide was detected in the oils.

**Identity of some electrodialyzable constituents of cotton root bark.** D. R. EGGLE, L. E. HESSLER, and J. E. ADAMS. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 68 (1946), No. 1, pp. 48-49).—The authors report upon a "systematic attempt," with reference to the relation of the chemical composition of the cotton root to the incidence of phymatoulichum root rot, to isolate quantitatively and to identify "definite organic compounds, principally nitrogenous, from the dialyzates of cotton root bark." Electrodialysis was used to separate the nitrogen that was subsequently determined as ammonia, amide, amino, and basic nitrogen. Although the experiments "were not completed with respect to determining the relationship to root rot resistance of these organic constituents," arginine, asparagine, betaine, and oxalic acid were isolated in significant quantities from the electrodialyzates of extracts from cotton root bark. Approximately half of the total organic nitrogen content of the catholyte was accounted for as definite compounds of which asparagine was predominant.

**Norelac—a proposed new synthetic coating material.** J. C. COWAN, A. J. LEWIS, and L. B. FALKENBURG. (U. S. D. A.). (*Oil & Soap*, 21 (1944), No. 4, pp. 101-107, illus. 4).—A new protective coating material, Norelac (NORthern REgional LACquer), the ethylene diamine polyamide of polymeric fat acids, is described. A preliminary report on its properties indicates that it may prove to be a superior protective coating for wood, metal, and other materials, and an adhesive for heat-sealing and laminating of paper, cellophane, glassine, and other packaging materials. The solubility characteristics of Norelac show that solvation probably occurs in compounds containing electron-acceptor groups, such as alcohols, amines, acids, and chloroform.

**Bromine analogs of DDT.** S. J. CRISTOL and H. L. HALLER. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 68 (1946), No. 1, pp. 140-141).—The authors here report upon the preparation of 1-tribromo-2,2-bis(4-chlorophenyl)-ethane and of 1-tribromo-2,2-bis-(4-bromophenyl)-ethane. These compounds were obtained, although in poor yields, by condensing bromal with chlorobenzene and with bromobenzene, respectively, in reactions catalyzed by sulfuric acid.

The first of these analogs was found fairly stable. It could be recrystallized from 95 percent ethanol, and melted, when pure, at 146°–147°C. The second (pentabromo-) analog proved very unstable. It melted at 173°–174° when pure. Dinitro derivatives of both of these DDT analogs were prepared.

Stability of DDT and related compounds, E. E. FLECK and H. L. HALLER. (U. S. D. A.). (*Jour. Amer. Chem. Soc.*, 68 (1946), No. 1, pp. 142–143).—Despite the recognized actions of iron chromium, ferric and aluminum chlorides, etc., in catalyzing a reaction resulting in the loss of hydrogen chloride from the DDT molecule and of certain solvents tending to inhibit this catalytic decomposition, the authors find to be prevalent a belief that pure 1,1,1-trichloro-2,2-bis-(4-chlorophenyl)-ethane is less heat stable than is technical DDT.

Experimentally, they found that a technical DDT sample having a setting point of 91.4°C. could be heated in chemically clean glass dried at 110° for 4 hr. at from 115° to 120° with the loss of only 0.02 mole of hydrogen chloride. Twice recrystallized from alcohol, air-dried, and handled with stainless steel spatulas, this material melted at 108°–109°, but lost 0.45 mole of HCl on being heated as above specified. Again purified, but handled with a nickel spatula and dried in a vacuum at room temperature, the preparation had the same melting point (108°–109°) but lost no HCl when heated for 4 hr. at 115°–120° as above specified. It is concluded that small traces of catalytic substances are readily taken in the handling of the pure compound with iron or stainless steel instruments. "While it is probable that catalytic materials may exist in the technical grade, other impurities such as polymers of chloral and 2-trichloro-1-*p*-chlorophenylethanol inhibit their action to a certain extent. When these inhibitors are removed without taking safeguards against removal of catalytic substances, an apparent instability of DDT is produced." Further experiments showed a marked catalytic action of 0.01 percent of ferric chloride, causing somewhat larger losses of HCl from pure than from crude DDT.

Electrokinetics.—XXVI, The electroviscous effect, III, in  $\beta$ -lactoglobulin systems: An interpretation of the meaning of  $K\phi$  values obtained from electroviscosity data, D. R. BRIGGS and M. HANIG. (Minn. Expt. Sta.). (*Jour. Phys. Chem.*, 48 (1944), No. 1, pp. 1–12, illus. 1).—Tested quantitatively by means of the data obtained in the first two studies of this subseries (E. S. R., 86, p. 724), the Krasny-Ergen theoretical equation for the electroviscosity effect was found not to describe the observed phenomena accurately. The equation was so modified as to express correctly the experimentally measured relationship between the viscometrically effective volume and the unsolvated volume of the dispersed phase of colloid electrolyte, to illustrate the dependence of the equation upon the particular colloid electrolyte system to which it is applied, and to eliminate the conversion of the experimental terms of the equation E. S. U. Experimental data for the electrokinetic potentials ( $\zeta$ ), the specific conductivities ( $\lambda$ ), and the viscosity increments ( $\eta_s - \eta_0$ ) of the systems  $\beta$ -lactoglobulin-sodium chloride and sodium gum arabate-sodium chloride were applied to the modified equation.

It was found for  $\beta$ -lactoglobulin, as the salt content was increased with an ion common to the gegenion, that the entire change in viscosity is due to the electroviscosity effect and that this change is independent of the pH of the solution and of increased salt concentrations to higher ionic strengths. Under these conditions, therefore, the values for the degree of hydration, or of asymmetry, for the protein in aqueous solution, as calculated from the values of  $K\phi/C$ , agree with those calculated from viscosity, diffusion, and

ultracentrifugal measurements at high salt concentrations. For the system sodium gum arabate-sodium chloride, it was found that as the ionic strength was increased above 0.01, the straight line of the plot of  $1/\eta_{sp}$  against

$\frac{m^2}{\lambda(\eta_s - \eta_0)}$  departs from linearity, the rise in the curve being interpreted as a decrease in the viscometrically effective volume of the colloid. The  $K\eta/C$  value for the two systems  $\beta$ -lactoglobulin and sodium gum arabate are compared. Those for  $\beta$ -lactoglobulin were found to be constant throughout the range of ionic strengths, protein concentration, and pH employed; those for sodium gum arabate were found to decrease with high ionic strengths. A theory to explain the differences between these two systems as representative of two distinct classes of colloids is proposed.

" $\beta$ -Lactoglobulin is pictured as a strong, internally well knit micelle, incapable of changing either in size, or shape, under the relatively weak, osmotic forces of its gegenions; sodium gum arabate is pictured as an internally weakly knit colloid, fully capable of undergoing large changes in size, or shape, under the relatively weak osmotic influence of its gegenions."

The uses and limitations of membrane electrodes, C. E. MARSHALL. (Mo. Expt. Sta.). (*Jour. Phys. Chem.*, 48 (1944), No. 2, pp. 67-75, illus. 1).—"An examination of assumptions made and errors encountered in the use of membrane electrodes leads to the conclusion that single cationic activities are determined with an uncertainty not exceeding 4 percent at ionic strengths around  $M/10$  and 2 percent at and below  $M/100$ ."

The special characteristics of clay membranes prepared by preheating films of montmorillonite and beidellite are described. By determining the mobility ratio of two cations within a given membrane, mixtures may be analyzed. Such determinations are facilitated by the use of membranes sensitive to monovalent but not to divalent cations.

Electron micrographs of crystalline plant viruses, W. C. PRICE, R. C. WILLIAMS, and R. W. G. WYCKOFF. (*Arch. Biochem.*, 9 (1946), No. 2, pp. 175-185, illus. 8).—Air-dried films of the diluted virus suspension on the usual collodion-covered metal screens were subjected to a high-vacuum gold evaporation deposit, the filament so placed that objects on the collodion substrate shielded areas about five times their height from the depositing gold; the weight of gold was chosen so that its average calculated thickness over the surface of the preparation was 8 a. u. The resulting shadowed electron micrographs show that the elementary particles of the tomato bushy stunt and of the southern bean mosaic viruses are essentially spherical bodies of about the same size. The measured diameter of the bushy stunt particle on these photographs is 255 a. u. The micrographs also provide evidence of the regular way in which the particles arrange themselves when forming crystalline aggregates.

A modified Kreis test suitable for photocolorimetry, M. F. POOL and A. N. PRATER. (U. S. D. A.) (*Oil & Soap*, 22 (1945), No. 9, pp. 215-216).—A form of the Kreis test described as sensitive, convenient, rapid, and yielding reproducible results was developed for a single-phase reaction system suitable for direct photometric measurement.

The acid reagent consisting of trichloroacetic acid diluted with amyl acetate proved to be unstable and unpleasant to use, and to produce large and variable blank values which could not be reduced by purification of the reagents. It was found, however, that the color could be developed equally well in glacial acetic acid solution of trichloroacetic acid containing enough chloroform to dissolve the fat. A sample of the fat weighing 1.5 gm. or less

is introduced into an 18- by 250-mm. test tube and diluted to 5.0 cc. with chloroform. To this mixture, 5.0 cc. of a solution of 1.0 gm. of trichloroacetic acid in 500 cc. of glacial acetic acid and 1.0 cc. of a solution of 1.0 gm. of phloroglucinol in 100 cc. of glacial acetic acid are added. The resultant mixture is stirred by a bubbling stream of air for 2 or 3 sec. The test tube is then placed in a water bath at 45°C. After exactly 15 min., the tube is removed and 4 cc. of 95-percent alcohol is added. The photometric measurement is made on this solution within a few minutes. The comparison solution for adjustment of the colorimeter is prepared like the test solution with the exceptions that the phloroglucinol is omitted and 1 cc. of glacial acetic acid is used. The colorimeter should be equipped with a yellow-green filter, preferably having its maximum transmission near 545 m $\mu$ .

Sampling soybeans for analysis, O. A. KROEBER, F. I. COLLINS, and M. J. DEMLOW. (U. S. D. A. coop. 24 expt. stas.). (*Oil & Soap*, 22 (1945), No. 8, pp. 194-196, illus. 4).—Under the conditions of this study, 30-gm. samplings of mixtures of soybeans were found to differ significantly in oil and nitrogen content, indicating the desirability of larger samples. The use of 120- to 240-gm. aliquots from mixtures of soybeans which vary widely in chemical composition is suggested as likely to reduce differences due to sampling to a reasonable minimum. Differences among 30-gm. samplings of highly uniform soybean seed of a single variety appeared to be of slight significance. It is emphasized that the limitations of present sampling methods should be recognized in any comparison or interpretation of chemical analyses of soybean seed.

Effect of relative humidity on the determination of oil in soybeans, O. A. KROEBER and F. I. COLLINS. (U. S. D. A. coop. 12 expt. stas.). (*Oil & Soap*, 21 (1944), No. 1, pp. 1-5, illus. 5).—Experiments upon the petroleum spirit extraction of samples adjusted to various moisture percentages in atmospheres of three different ranges of relative humidity led to the conclusion that the percentage of extractable material which is obtained is highly dependent upon the atmospheric conditions under which the sample is analyzed. When soybean meals with moisture content from 4.35 to 16.8 percent were analyzed for oil content at 75-80 percent relative humidity, the percentage of extractable material was not dependent upon the original moisture level. At lower moisture percentages or in lower ranges of relative humidity, this independence was not observed, however. Under conditions of relatively high humidity with meals of high moisture content, the short (2-hr.) extraction gave results which checked satisfactorily with the results obtained by the official 4-hr. method under like conditions. The data emphasize the fact that the determination of oil in soybeans was empirical, and that any analysis did not necessarily represent the total lipides present in the sample. The data are held to have shown the necessity of control of moisture conditions under which seed is stored and under which it is analyzed if reproducible results are to be obtained.

Micromethod for the determination of urea, V. E. KINSEY and P. ROBISON (*Jour. Biol. Chem.*, 162 (1946), No. 2, pp. 325-331, illus. 3).—A micromethod of estimating urea in plasma or other body fluids in quantities as small as 4 mm.<sup>3</sup> containing 1 $\gamma$  of urea, with an accuracy of  $\pm$  5 percent, consists in direct conversion of urea into ammonia by means of urease, distillation into a hanging drop of glycerol containing boric acid, and titration with dilute acid or, alternatively, with a colorimetric procedure in place of the acid titration. Average recoveries of urea from 0.01 to 0.02 cc. of plasma or aqueous humor were 97.8 percent with a variation from 94 to 101 percent.

The quantity of urea in rabbit plasma and aqueous humor averaged 306 $\gamma$  and 270 $\gamma$  per cubic centimeter of water, respectively, with an average ratio of 0.88.

**Detection and estimation of steam-distilled wood turpentine in gum spirits of turpentine,** S. R. SNIDER. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 2, pp. 107-109).—It is noted that steam-distilled turpentine has been used as an adulterant for the gum spirit, and that, of the four types of turpentine (gum spirit, steam-distilled wood, sulfate wood, and destructively distilled wood turpentine) only the steam-distilled wood product has been found to contain benzaldehyde. It is proposed to oxidize the aldehyde to benzoic acid and to nitrate under carefully specified conditions leading to the formation of 3,5-dinitrobenzoic acid, the reduction of which by hydroxylamine in ammonia solution to the 3,5-diamino acid (the ammonium salt of which gives a characteristic red color to the solution in which it is formed), completes the test. A qualitative test and an approximate quantitative determination for steam-distilled wood turpentine in the gum spirit are based upon this color reaction.

**Standards in vitamin A assays:** U. S. P. reference cod liver oil vs. beta-carotene, E. C. CALLISON and E. ORENT-KEILES. (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 6, pp. 378-379).—Evidence both from biological and from spectrophotometric data showed that U. S. P. reference cod-liver oil No. 2 contains less than 1,700 International Units of vitamin A per gram, and therefore assays of vitamin A value performed by bioassay using U. S. P. reference cod-liver oil No. 2 as the standard and expressed in terms of International Units may be from 30 to 44 percent higher than the actual value. Data showing the instability of vitamin A as it occurs in U. S. P. reference cod liver oil No. 2 are also presented. Pure  $\beta$ -carotene may be used as a standard for the bioassay of vitamin A until a more stable and satisfactory standard is developed.

**Frozen vitamin standards,** O. E. STAMBERG and D. W. BOLIN. (Idaho Expt. Sta.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 10, p. 673).—Thiamine and riboflavin standards were prepared in 2 percent acetic acid and 5 cc. aliquots were pipetted in 15 cc. vials. These were placed in a refrigerator at  $-15^{\circ}\text{C}$ . at a  $45^{\circ}$  angle for freezing and storage. Using the fluorometric method of assay, comparisons were made with fresh standards, and indicated that the frozen standards stored up to 6 mo. were still satisfactory. The method is recommended as being accurate and time-saving.

**A rapid method for the combined determination of thiamine and riboflavin in cereal products,** A. HOFFER and A. W. ALCOCK (*Cereal Chem.*, 22 (1945), No. 3, pp. 271-272).—The method of Hoffer et al. (E. S. R., 92, p. 616) has been simplified to permit simultaneous assay of both thiamine and riboflavin. Aliquots of the same extract from a 0.5-gm. sample are used, and the permanganate decolorization step in the riboflavin determination is omitted.

Duplicate 1-gm. and 0.5-gm. samples from 87 enriched flours were tested. Slightly higher results were found with the 0.5-gm. samples (4.63 v. 4.57), but the standard error was smaller.

**A simple fluorometric method for thiamin in milk,** A. Z. HODSON (*Food Res.*, 10 (1945), No. 4, pp. 351-356).—A simplification in the thiochrome method of Hennessey and Cerecedo (E. S. R., 82, p. 588) is presented for the assay of milk products. Briefly, the milk is digested with takadiastase at pH 4.0 to 4.5 for 3 hr. at  $50^{\circ}\text{C}$ ., diluted with 2 percent trichloroacetic acid, and filtered. The filtrate, if reasonably clear, is then treated with the same reagents as in the original method, but without passing through the base-

exchange step. Three aliquots are used—one serving as sample, the second containing 1 mg. added thiamine, and the third serving as the blank.

Recovery of thiamine, added to the original fresh or evaporated milk samples, ranged from 94 to 107 percent. The use of takadiastase was necessary for best results.

The results are in good agreement with duplicates run by microbiological methods.

**Simplified colorimetric determination of thiamine in cereal products**, M. HOCHBERG, D. MELNICK, and B. L. OSER. (*Cereal Chem.*, 22 (1945), No. 2, pp. 83-90, illus. 1).—The method previously described by Melnick and Field (E. S. R., 83, p. 11) has been modified for use with cereal products. A 10- to 20-gm. sample is refluxed in 0.05 N H<sub>2</sub>SO<sub>4</sub>, cooled, adjusted to pH 4.5, treated with takadiastase, and a clear extract prepared by centrifugation or filtration. A special apparatus is described for the adsorption and elution of the thiamine from a zeolite column. After elution, the concentrated thiamine extract is then treated with diazotized *p*-aminoacetophenone; the red pigment formed is extracted with xylene, and colorimetric comparisons are made with thiamine standards similarly treated. The method is considered applicable to low potency material if it is not rich in protein. Large quantities of adsorbable amino acids interfere with the retention of thiamine on the zeolite column.

**Methods for determination of thiamine in blood and tissues with observations on relative contents**, L. D. GREENBERG and J. F. RINEHART (*Soc. Expt. Biol. and Med. Proc.*, 59 (1945), No. 1, pp. 9-13).—A simplified procedure is described based on the methods of Friedemann and Kmieciak (E. S. R., 91, p. 638) and Harris and Wang (E. S. R., 87, p. 762). As little as 1 cc. of blood or 0.3 to 1.0 gm. of tissue can be used.

In general, the sample is heated with 5 percent metaphosphoric acid, cooled, adjusted to pH 4.5, and centrifuged. The supernatant fluid is incubated with takadiastase, the extract absorbed on Decalco, and the usual thiochrome procedure carried out. Experiments on thiamine-deficient and control rats have shown that the thiamine concentration in the blood parallels that in the tissue, and that both reflect the thiamine intake.

**Note on Antonoff's so-called rule**, H. L. CUPPLES. (U. S. D. A.). (*Jour. Phys. Chem.*, 48 (1944), No. 2, pp. 75-76).—The author points out sources of error in a recent discussion of this subject.

**Wax pencils for writing on cold wet glassware**, J. E. LOVELOCK (*Nature [London]*, 155 (1945), No. 3941, p. 581).—Pencils which will write satisfactorily on cold glass covered with a moisture film can be made by adding from 5 to 10 percent of "a detergent, preferably cationic," to the wax mixture. Of "many possible formulae," the following is recommended as easily made up: Paraffin wax, m. p. 65°C., 100 gm.; beeswax, 20 gm.; vaseline, 20 gm.; cetyltrimethylammonium bromide, 10 gm.; a fat-soluble dye (e. g., Sudan III), 0.5 to 1 gm.; and 20 gm. of titanium dioxide or other white pigment, to be stirred in after the waxes have been melted together and the dye and "detergent" [wetting agent?] dissolved. The author completed his pencils by casting the mixture in the form of sticks about 6 in. long by 1/8 in. in diameter and wrapping these with paper.

**Stability values obtained by different rapid methods as a means of evaluating antioxidants for fats and oils**, R. W. RIEMENSCHNEIDER, F. E. LUDDY, S. F. HERR, and J. TURER. (U. S. D. A.). (*Oil & Soap*, 22 (1945), No. 7, pp. 174-177).—The authors compared stability values and protection factors as determined by three widely used rapid methods, the active-oxygen,

oxygen-absorption, and the oven-test methods. In most instances there was fair agreement between the results by the active-oxygen and oxygen-absorption methods, as indicated by protection factors. In general, use of dry air instead of moist air in the active-oxygen method resulted in little significant difference in the stability values, although in some preparations differences which may be significant were observed. Use of dry oxygen in the active-oxygen method gave results comparable with those obtained by the oxygen-absorption method. In experiments in which an oven test was also used, the protection factors in most cases were in general agreement with those obtained by the other two methods. The synergistic antioxidant effect of acidic compounds with phenolic antioxidants was most pronounced with lard of low stability. Likewise, the protection factors were disproportionately greater when antioxidants were added to lard of low stability than when these compounds were added to lard of good stability. The results indicated that comparison of antioxidants by means of protection factors is valid only when the same substrate is used. Protection factors so obtained were found to help in the evaluation of the order of effectiveness of various antioxidants, but not to yield a strict quantitative comparison of the protective power of the antioxidants when applied to other substrates.

**Modified thiocyanogen reagent and method, M. G. LAMBOU and F. G. DOLLEAR.** (U. S. D. A.). (*Oil & Soap*, 22 (1945), No. 9, pp. 226-232, illus. 2).—The authors report upon a general reagent applicable to a wide range of thiocyanogen values and capable of reacting with practically all types of fats and oils. Modifications include rigorous purification of all reagents; replacement of 25 percent of the volume of glacial acetic acid normally used in preparing the thiocyanogen reagent with an equal volume of carbon tetrachloride; use of finely powdered, dry potassium iodide; increase in the quantity of potassium iodide added prior to titration from 1.0 gm. to twice the equivalent weight calculated for the volume of standard reagent used; and complete exclusion of water from all reagents and glassware. Data indicating the stability, accuracy of determination of pure unsaturated acids, and the general applicability of the reagent are given.

**Determination of the saturation water content of protein plastics, E. F. MELLON.** (U. S. D. A.). (*Indus. and Engin. Chem., Analyt. Ed.*, 17 (1945), No. 11, pp. 743, illus. 1).—The A. S. T. M. standard disk, 0.125-in. thick and 2 in. in diameter, did not reach saturation after several weeks of immersion in water. Disks of one-half the standard thickness approached an equilibrium moisture content during both water absorption and drying much more rapidly than did disks of the standard thickness. Both absorption and drying became essentially asymptotic with approach to completion. Numerous experiments led to the conclusion, however, that a value between 95 and 100 percent of the long-period immersion water content of hot-molded protein plastics could be thus measured: "When the gain in weight in a 24-hr. period is less than 20 mg., or less than 10 percent of the gain in weight in the first 24 hr. if the first 24-hr. gain is less than 200 mg., the specimens are removed from the water and dried."

**Improvements in the determination of starch in corn and wheat, F. R. EARLE and R. T. MILNER.** (U. S. D. A.). (*Cereal Chem.*, 21 (1946), No. 6, pp. 567-575).—Samples of starch, comprising two from corn, two from wheat, and one each from waxy corn, tapioca, and potato, were analyzed for non-starch constituents. The specific rotation  $[\alpha]_D$ , of all these starches was found to be 208°C. in calcium chloride dispersion, when corrected for the non-

starchy material. Modifications of the polarimetric method for starch in corn and wheat were studied and procedures devised which, for these two grains, gave results agreeing closely with those obtained by the diastase acid hydrolysis method. These improved polarimetric procedures are described.

Method for the direct determination of diacetyl in tissue and bacterial filtrates, A. G. C. WHITE, L. O. KRAMPITZ, and C. H. WERKMAN. (Iowa State Col.). (*Arch. Biochem.*, 9 (1946), No. 2, pp. 229-234, illus. 2).—The authors have developed a sensitive and fairly rapid method for the determination both of diacetyl and of acetoin, their procedure being based upon the condensation of diacetyl-oxime with urea. They found it possible to determine diacetyl in tissues and in bacterial filtrates directly and without previous distillation. Acetoin was determined by oxidation to diacetyl by ferric chloride in acid solution followed by distillation. The method appeared to be sensitive for diacetyl and acetoin in concentrations at least as low as 25% with an accuracy of  $\pm 10$  percent.

A modification of the Kneen and Sandstedt methods for the determination of alpha- and beta-amylases in barley malt, W. J. OLSON, R. EVANS, and A. D. DICKSON. (Univ. Wis. and U. S. D. A.). (*Cereal Chem.*, 21 (1944), No. 6, pp. 532-539, illus. 1).—The original method of Sandstedt, Kneen, and Blish (E. S. R., 83, p. 440) for  $\alpha$ -amylase was modified to make it more applicable to routine determinations in barley malt laboratories. The dextrinization was measured at 20°C. instead of 30°, and the American Association of Cereal Chemists diastatic power procedure was substituted for the malt saccharifying activity determination of Kneen and Sandstedt (E. S. R., 89, p. 8). The relation between  $\alpha$ -amylase saccharifying and  $\alpha$ -amylase dextrinizing activity was established under these modified experimental conditions. By the use of the values so obtained, suitable corrections for  $\alpha$ -amylase saccharifying activity could be made and a valid measure of  $\beta$ -amylase activity secured. Two methods of preparation of enzymatically pure  $\beta$ -amylase were tested, and a simple method for ascertaining the presence of  $\alpha$ -amylase is described.

## · AGRICULTURAL METEOROLOGY

Relations between solar activity and the lower atmosphere, B. HAURWITZ (*Amer. Geophys. Union Trans.*, 27 (1946), No. 2, pp. 161-163).—The existence of close connections between solar activity and physical processes in the upper atmosphere is well established; whether similar relations exist between solar activity and the state of the lower atmosphere is an open and sometimes hotly debated question. It would seem that if a plausible mechanism were suggested for interaction between the sun and the lower atmosphere, progress in this field would be greatly enhanced. The purpose of this note is to start discussion of the subject and to show what kind of investigations are required to check the hypothesis presented with respect to the effects of solar flares. It is believed that the hypothesis outlined will have some value even if proved untenable by further study, since in that case it is difficult to see how any causal relationship between solar activity and the weather can exist. On the other hand, it is well to remember that the establishment of relations between solar activity and the lower atmosphere on a firm physical basis cannot be expected to bring about a complete solution of the problem of weather forecasting. The solar flares would be only one of the factors influencing the atmosphere and, moreover, the atmosphere will re-

spond differently to the same impulse, depending on its initial state. Nevertheless, considerable progress in understanding atmospheric developments can be expected if one more of the causes of changes therein is found.

**Single-radiosonde analysis in local 8-hour forecasting of precipitation,** I. I. SCHELL. (*Amer. Met. Soc. Bul.*, 27 (1946), No. 4, pp. 164-168, illus. 2).—A simple and rapid analysis of a radiosonde ascent may indicate to a high degree of probability whether or not precipitation will occur at the station within 8 hr. The procedure consists in determining for each significant point below the 600-mb level the ratio of the mixing ratio to the lift (pressure drop required to bring about condensation), from which ratios is derived a "precipitation index." Since the method is applicable without synoptic charts, it could be of most value for forecasts covering areas near radiosonde ascents made where preparation of charts or their proper use is impractical or delayed. The method is described in detail.

**A simple theory of the electric hygrometer,** W. SCHAFER (*Amer. Met. Soc. Bul.*, 27 (1946), No. 4, pp. 147-151, illus. 5).—The electrical resistance hygrometer has assumed great importance to all meteorologists using upper air data based on the American radiosondes. Unfortunately no previous account of the theory of the instrument appears to have been published, though greatly needed to clarify the working of the instrument, its possibilities, and—more particularly—its limitations. This paper attempts to give a simplified theory satisfying these requirements. Besides presenting the theory, the instrument is described, its operation and limitations are discussed, and the effects of temperature are shown.

**Anemometer slowage indicators,** R. L. IVES (*Amer. Met. Soc. Bul.*, 27 (1946), No. 4, pp. 173-177, illus. 4).—Experience with these and related slowage-indicating devices is said to indicate that those embodying condenser-resistor timers are not suited to use with standard anemometers, though they have proved satisfactory with those having very short contacting intervals, and that those using electric clocks, stepping switches, and similar rugged electromechanical devices are highly satisfactory for continuous operation under favorable environmental conditions.

**Climatology,** A. A. MILLER (*London: Methuen & Co., 1946, 4. ed., pp. 325+, illus. 82*).—"The object of this book is to provide advanced students, and especially students of geography, with a reasoned account of the world's climatic types."

**Climatic divisions of Maine,** C. B. FOBES (*Maine Technol. Expt. Sta. Bul.* 40 (1946), pp. 44+, illus. 14).—The multiplicity of weather observations recorded in many different publications gives a particularly good basis for research in climatology; the very nature of the sources of these data and the forms in which they are recorded tend, however, to obscure regional climatic types and inter-regional variations. Until statistical data are spread on maps, thus bringing out areal relationships and differences, geographical significance is at best difficult to deduce. According to J. M. Trefethen in the foreword, the author here "assembles pertinent data and makes their significance readily comprehensible by means of maps and discussions. . . . By the text and accompanying maps, this paper shows what can be expected in the various parts of Maine during the year."

**Agricultural climatology in Australia,** H. C. TRUMBLE (*Jour. Austral. Inst. Agr. Sci.*, 11 (1945), No. 3, pp. 115-119).—The author reviews the recent developments of agroclimatological methods in relation to an improved understanding of the Australian environment, discussing world classifications of climate, Australia in relation to other regions and climatic indexes developed

there, evaporation from water and the soil, duration of periods relating to growth, climatic variability, and the relationship of climatic indexes to land use and production in Australia. There are 24 references.

Microclimatic differences in minimum temperature and variations in frost injury to hillculture plants, J. M. AIKMAN and G. L. BRACKETT. (Iowa Expt. Sta. and U. S. D. A.). (*Iowa Acad. Sci. Proc.*, 51 (1944), pp. 147-156, illus. 1).—Of the climatic factors influencing the growth and yield of fruit trees and other hillculture plants in southeastern Iowa—with the possible exception of excessive drying on southwest-facing slopes—the most important is said to be low temperature. Records are presented of the occurrence of definite frost injury to grapes in microclimatic areas much later in spring and earlier in fall than seemed possible from examination of U. S. Weather Bureau records—possible because the weather stations are located in sites giving average over-all climatological records in spite of variations within small areas. It is also shown that even in special studies of microclimatic areas, climatological determinations may be inadequate, and in order to supplement the thermograph data use of minimum thermometers is advised on the basis of experimental tests. The information presented on variations in temperature between two seasons (1942 and 1943) indicated that seasonal variations and their effects on plant growth must be considered in a study of microclimates. The ranking of the sites on a farm on the basis of adequacy of cold air drainage, length of growing season, and other temperature values may easily be done with the use of three to four minimum thermometers. In measuring cold air drainage, the readings should be taken after the cold air has moved in and the cold air drainage down the slope is well established. Comparisons are made of minimum temperatures during winter storm periods at three elevations on a south slope and at the two nearest Weather Bureau stations (1943-44); the results seem to indicate that evaluation of sites on a winter temperature basis for fruit trees, vines, and other woody plants by means of minimum temperature readings would be advisable to prevent possible winterkilling. It would also seem desirable to designate the elevation of the site in making recommendations on the adaptation of plants to different regions or zones. There are 12 references.

Evaporation regions in the United States, S. S. VISHNER (*Sci. Mo.*, 62 (1946), No. 5, pp. 453-457, illus. 11).—The rate of evaporation of water is a highly important environal influence meriting continued study. Several prolonged investigations of local and regional differences in evaporation have been made by biologists; the accompanying 11 maps present some recent data—chiefly by nonbiologists—which supplement earlier studies in significant ways.

Notable local floods of 1939.—I, Floods of September 1939 in Colorado River Basin below Boulder Dam, J. S. GATEWOOD. II, Flood of July 5, 1939, in eastern Kentucky, F. F. SCHRADER. III, Flood of August 21, 1939, in town of Palawin, Maine, M. R. STACKPOLE (*U. S. Geol. Survey, Water-Supply Papers* 967-A (1945), pp. 39+, illus. 13; 967-B (1945), pp. 41-59+, illus. 11; 967-C (1946), pp. 61-68+, illus. 7).—Of the three floods in widely separated areas noted in these papers, those in Maine and Kentucky were caused by single local storms of brief duration and cloudburst intensity. The Maine storm lasted about 3 hr., covered an area of about 100 sq. miles, had an intense rainfall area (6 in. to more than 12 in.) of about 30 sq. miles, and produced a flood discharge of 340 sec.-ft. per square mile in a brook draining a 4.7-sq.-mile area. The Kentucky storm was of about the same duration, included about 443 sq. mile within the 8-in. isohyetal, and had a maximum

intensity of more than 12 in. Probable rates of flow include a maximum of 2,000 sec.-ft. per square mile or more from an area of from 5 to 10 sq. miles. The Colorado River Basin floods were caused by three successive tropical storms occurring between September 3 and 26, the mean annual precipitation being exceeded at many points by that for September 1939. Flood peaks in Colorado River were greatly reduced by storage. Between September 5 and 20 Lake Mead stored 330,000 acre-ft. of water. Between September 4 and 7 Havasu Lake stored 135,000 acre-ft., and the channel storage between Topock and Yuma, exclusive of Havasu Lake, accounted for about 110,000 acre-ft. at the peak.

Notes on the three cyclones in Mauritius in 1945: Their effect on exotic plantations, indigenous forest, and on some timber buildings, H. C. KING (*Empire Forestry Jour.* [London], 24 (1945), No. 2, pp. 192-195).

## SOILS—FERTILIZERS

Some soil properties which influence the use of land in West Virginia, R. M. SMITH, G. G. POHLMAN, and D. R. BROWNING. (Coop. U. S. D. A.). (*West Virginia Sta. Bul.* 321 (1945), pp. 71, illus. 14).—Soil profile samples selected to be typical of the soils mapped in the State were examined, with laboratory determinations of texture, structure, organic matter, pH, buffer curves, exchange capacity, exchangeable bases, and acid-soluble phosphorus. Color was defined by field observation and by comparison with color charts.

Most of the surface soils were loams or silt loams with clay or clay-loam subsoils. Structural profiles are shown for certain groups of series, and the relationship of structure to movement of air and water, to soil erosion, and also to root penetration is pointed out. The distribution of organic matter in the soil profile in a number of series is given, and the effect of climate and past treatment on organic matter content is discussed.

The relationship between pH, percentage of saturation, and total bases in the major series is given. This shows considerable variation within series as well as between series. Within the soil profiles certain series (particularly Hagerstown and Frederick) increase in base content and percentage of saturation, others show little change, and some show increased acidity and decreased saturation with increasing depth. The relationship of this to growth of certain crops is discussed. The relationship between exchange capacity and organic matter and clay content is shown, and a general guide for evaluating this relationship is given.

The available phosphorus content was generally low, but a few subsoil samples showed high contents of acid-soluble phosphorus. These did not seem necessarily to indicate high available phosphorus contents, as some of these soils showed marked responses to phosphate fertilizers. Exchangeable potash values ranged from low to high, with an average of 0.256 milliequivalent of potassium per 100 gm. of soil. Low potash values occurred, especially in highly leached terrace soils, in sandy soils, in the silty limestone soils, and in old ridgetop soils. Surface soils were usually higher in exchangeable potash than subsoils. High potash content was usually associated with high organic matter in the soil or with high clay content, but the reverse was not always true. The relationship of the various factors to land use is discussed.

Management of soils in the Lower Rio Grande Valley, B. S. PICKETT (*Texas Sta. Cir.* 110 (1946), pp. 13).—Conclusions and recommendations based both on local experiments and on observations of successful practice include the following: Light soils, because of their faster percolation rates,

are easier to handle under irrigation than heavy soils. Light soils can be wet to a considerable depth with a normal irrigation, but heavy soils are wet to only a shallow depth. Because of the difference in depth to which water may penetrate in sandy and heavy soils, it is occasionally desirable to irrigate heavy soils much more heavily than is the ordinary practice in order to allow some leaching to remove some of the excess soluble salts. Although light soils can withstand considerably deeper cultivation than heavy soils, it would be better to use shallow cultivation on all soils in orchards. The vegetable farmer or the farm crops farmer will also find shallow cultivation more satisfactory than deep cultivation. There is less damage done by soil cracking than by deep cultivation. Crops on heavy soils respond more slowly to fertilization than crops on light soils. Nitrogen, alone and in combination with phosphorus, was found to be effective for both citrus and vegetables. No response was obtained from applications of potash on Lower Valley soils.

Some improvements in tensiometer design, E. A. COLMAN, W. B. HANAWALT, and C. R. BURCK. (U. S. D. A. et al.). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 5, pp. 455-458, illus. 1).—In elaborating an improved tensiometer design, the authors have "drawn liberally upon that of Richards" (E. S. R., 87, p. 186), but have lessened the difficulties and inconveniences involved in the insertion and removal of the porous cup, reduced the fluctuations of the manometer readings caused by the change with temperature of the volume of the water in the column above the cup, and provided for the removal of air trapped in the porous cup.

Easier placement of the instrument in the soil was attained by placing a 1-in., thin-walled brass tube in a 2-in. auger hole, the top of the brass tube about 6 in. below the soil surface and the space about it back-filled for support. Before the tensiometer was lowered into the brass jacket, a steel gad having a conical shape the same as that of the porous cup and mounted on a suitable length of brass pipe was pressed into the soil at the bottom of the tube. The gad was then removed from the brass pipe, the tensiometer unit attached in its place, a rubber stopper fitted about the copper tubing of the tensiometer and into the top of the brass pipe, and the assembly lowered into working position. The part of the auger hole above the brass jacket was then refilled with soil. Two lengths of  $\frac{1}{8}$ -in. copper tubing extending from the porous cup to the above-ground part of the apparatus were used. One tube left the uppermost point within the porous cup and was connected to the U-tube above by a short piece of synthetic rubber tubing. The other extended from the bottom of the cup and was connected at its upper end by a longer piece of synthetic tubing. This double-tube construction accomplished two purposes. It provided, first, a minimum volume of water subject to volume changes in response to temperature. Second, it provided a circulating system by which air coming out of solution within the porous cup could be brought to the U-tube and removed from the instrument. Constructional detail is shown in a dimensioned drawing, and the manner of operating the instrument is briefly indicated.

The laws of soil colloidal behavior.—XXIV, Donnan equilibria in soil formation, S. MATTSUN and K. G. LARSSON (*Soil Sci.*, 61 (1946), No. 4, pp. 313-330, illus. 4).—This paper continues a series of theoretical and experimental studies (E. S. R., 86, p. 593) begun by Mattson at the New Jersey Experiment Stations. The Donnan equilibrium theory applied to soils led the authors to the following conclusions: (1) Soils having a low cation-exchange capacity, that is soils which are weak acidoids, such as Red earths

and Laterites, should, other things being equal, contain a higher proportion of exchangeable monovalent cations (Na and K as compared to Ca and Mg) than soils having a high exchange capacity. The former soils possess a lower micellar-ion concentration (a more dilute "inside" solution) and should adsorb the monovalent ions relatively better than the latter. (2) The more unsaturated a soil, the greater should be the proportion of exchangeable monovalent cations. The undissociated acidoid does not participate in the Donnan equilibrium. A highly unsaturated soil has, therefore, a greatly reduced micellar-ion concentration and should adsorb the monovalent cations relatively better than the saturated soils. (3) Among the leached soils the proportion of alkali cations should therefore be greatest in the highly unsaturated soils possessing weak acidoid properties, whereas the proportion of the alkaline-earth cations should be greatest in the slightly leached, saturated soils possessing a high exchange capacity.

As experimental evidence supporting the conclusions above stated, the authors cite the observations (1) that kaolin and a Laterite were found to adsorb relatively more of the ammonium ion from solutions of ammonium and calcium chlorides than did bentonite; (2) that the more unsaturated a bentonite becomes, the more it adsorbs of the monovalent ions; and (3) that analytical data from various sources support the conclusions stated.

A critique of estimating soil solution concentration from the electrical conductivity of saturated soils, R. F. REITEMEIER and L. V. WILCOX. (U. S. D. A. coop. 11 western States et al.). (*Soil Sci.*, 61 (1946), No. 4, pp. 281-293, illus. 8).—The variability of the ratio between the conductivity of the saturation extract ( $K_e$ ) and that of the saturated soil ( $K_s$ ) was found to be of a magnitude such as to render the soil conductivity unreliable as an index of soil solution concentration. The extract conductivity was better correlated with crop response than was the soil conductivity. It was shown that the  $K_e : K_s$  ratio increases with a decrease in saturation percentage and with an increase in extract concentration. These two relationships appeared to account for the greater part of the variation of this ratio. Factors contributing to the inaccuracies of this method were found to include the lack of a cell constant for some soil cups, variations in saturation percentage, variations in soil salinity, and the conductivity of soil minerals. When a reasonable degree of accuracy is desired, the solution should be extracted from the saturated soil and the conductivity of the solution measured.

Relation of soil reaction to toxicity and persistence of some herbicides in greenhouse plots, A. M. HURD-KARRER (U. S. Dept. Agr., *Tech. Bul.* 911 (1946), pp. 31, illus. 9).—Tested under greenhouse conditions and not subjected to leaching, all of the herbicides studied (sodium chlorate, ammonium and sodium thiocyanates, sodium arsenite, ammonium sulfamate, and borax) showed a toxicity toward plants which was maximal in highly acid soils and diminished with rising pH to a minimum value in alkaline soils. Persistence of toxicity was longest in the acid soils with the exception of that of sodium chlorate, most persistent in the limed soils. Sodium and calcium carbonates reduced borax injury similarly. Sodium chlorate and the thiocyanates were most toxic, 5 gm. in 200 lb. of soil generally being lethal or nearly so. Borax toxicity showed no significant change after 36 mo. in the soil. Thiocyanates disappeared from all the plots within 3 mo. and from nonacid ones in half this time or less. Admixture of sulfur markedly increased borax toxicity. Sodium nitrate mixed into chlorate-containing soil reduced the toxicity at all soil reactions tested from pH 4.3 to 7.9. Ammonium sulfate reduced chlorate toxicity as promptly as did nitrates in slightly acid and in alkaline

soils, but in strongly acid soils, below pH 5.0, its effect was delayed. Cyanamid generally reduced chlorate toxicity fairly promptly in slightly acid and alkaline soils, but it had no effect in the strongly acid plots, even after several months. The reduction of chlorate toxicity by the nitrogen fertilizers, though unmistakable, was not great enough to be significant in a fertile soil. The experimental results were such as to "suggest that the degree to which the various nitrogen fertilizers can inhibit chlorate toxicity depends on their ability to supply nitrogen as nitrate in the particular soil. Comparative effects of these materials at the different soil reactions were in accord with anticipated effects of soil reaction on nitrification."

**Dynamics of wind erosion.**—VI, *Sorting of soil material by the wind*, W. S. CHEPIL (*Soil Sci.*, 61 (1946), No. 4, pp. 331-340, illus. 2).—This is a continuation of a series previously noted (E. S. R., 95, p. 172).

It is shown that although the wind tends to remove large quantities of fine dust from cultivated fields, the less mobile grains, none of which exceed 2 mm. in diameter, pile up into dunes or remain in a more or less uniform layer in the vicinity of the eroded area. The size distribution of particles contained in the dunes was found to conform to a definite logarithmic relationship first observed in desert sand. For soils deposited in dunes under apparently the same wind force, the actual peak diameter varied from 0.18 mm. for Hatton fine sandy loam to 0.59 mm. for Sceptre clay. The equivalent peak diameter varied only from 0.13 to 0.28 mm., for the same soils. Average drift soils were considerably more sandy than the corresponding cultivated soils, indicating that much of the fine material in the form of silt and clay was blown away. The greatest sorting of the mechanical fractions was on fine sandy loam, the least, if any, on fine clay. Except in Hatton fine sandy loam, the quantity of organic matter and nitrogen was found to be about the same in the drifted as in the corresponding residual soil material.

**Losses of nitrous nitrogen from soils on desiccation**, M. R. MADHOK and F. UDDIN (*Soil Sci.*, 61 (1946), No. 4, pp. 275-280).—Of four 50-gm. portions of a sieved sandy loam soil two were treated with sodium nitrate equivalent to 5 mg. of nitrogen per 100 gm., the moisture content was adjusted to 10 percent, and the samples were exposed to the sun for 1 day. Determinations of nitrite, nitrate, and ammoniacal nitrogen showed that the greater part of the added nitrate had disappeared from the treated soil during desiccation, and that it had not been converted either into nitrates or into ammonia. In a clay loam to which 10 mg. of nitrogen as nitrate was added, a like experiment showed about 5 percent of the added nitrate to have been oxidized. The work was repeated with the last-named soil and at 90°C., "a temperature at which little bacterial action could take place," and the same loss of nitrogen was observed. The soils used in these and other experiments had a pH value of 8.7. Ammoniacal nitrogen was present only in traces. A sample of the nitrate-treated soil to which 10 mg. of nitrous nitrogen per 100 gm. had been added was found to give off oxides of nitrogen during desiccation in quantities sufficient not only to be detected by a test paper containing Griess' reagent but also in a concentration such that the odor of nitrogen peroxide could be noted. At a temperature of 80°, similar decomposition of nitrite was obtained in purified sand and after partial removal of air (filter pump vacuum). Such losses of nitrite nitrogen were found to take place in some soils having a pH value as high as 10.7. Atmospheric ammonia and carbon dioxide were both found to accelerate the nitrogen loss, as did exchangeable soil hydrogen and, apparently, the catalytic action of some soil component or components not present in the purified sand.

The nitrogen requirement in the utilization of carbonaceous residues in soil, L. A. PINCK, F. E. ALLISON, and V. L. GADDY. (U. S. D. A.). (*Jour. Amer. Soc. Agron.*, 38 (1946), No. 5, pp. 410-420, illus. 2.—This paper records two greenhouse experiments, one carried out during the winter with wheat as indicator, the other during the spring and summer with Sudan grass as the test crop. The work was designed to show (1) the quantity of nitrogen which must be applied to the growing crop to counteract the effect of a unit of carbon applied as straw, and (2) the extent delayed planting following the turning under of straw and nitrogen will decrease or increase the harmful effect of the straw.

It was found necessary to add, under winter greenhouse conditions, enough nitrogen to make the carbon : nitrogen ratio of a straw-urea mixture about 35 in order to avoid injury by the straw, this addition being equivalent to a nitrogen content of 1.2 percent of the dry organic matter. Under spring and summer conditions, the corresponding values were 27 to 31 for the carbon : nitrogen ratio and 1.56 to 1.37 for the nitrogen percentage. There was no evidence of any injury due to straw other than its effect on nitrogen availability. Additions of nitrogen above that required to meet the needs of the soil flora produced essentially a linear effect on the total nitrogen content of the harvested crops; the increase in yields of dry matter, however, decreased with successive increments of added nitrogen. A 6 weeks' delay in the planting of the crop resulted in a slightly lower recovery of the added nitrogen, but essentially none of this effect could be attributed to the straw. The residual crops of Sudan grass removed only small quantities of nitrogen, even though the highest percentages of the added nitrogen removed by the first crop in the two experiments were only 47 and 55, respectively.

The experiments are held to indicate that by using adequate quantities of commercial nitrogen, undecomposed carbonaceous crop residues can be utilized advantageously for soil organic matter maintenance without injury to crops.

Variance in the carbonatation of certain "glassy" and crystalline calcium silicate materials in soils, W. H. MACINTIRE, S. H. WINTERBERG, II. W. DUNHAM, and L. B. CLEMENTS. (Tenn. Expt. Sta. et al.). (*Soil Sci.*, 61 (1946), No. 4, pp. 295-311, illus. 1).—The reactivity in soils of the relatively new glassy (quenched) calcium silicate slag from electrical phosphate reduction, as distinct from that of the crystalline silicate, was investigated.

Nearly all of the Ca of a 5-ton incorporation of quenched slag was sorbed by a Montevallo silt loam, without appreciable accumulation of  $\text{CaCO}_3$  during the growth of nine successive crops. With increase in rate and with decrease in particle size, substantial accumulations of carbonate came from heavier incorporations and from the fines of quenched slag; but, invariably the accumulations were less than the residues of limestone in the controls. At a 39-ton rate, neither wollastonite nor its calcines underwent conversion to carbonate in cropped Hartsells fine sandy loam, whereas corresponding incorporation of quenched slag caused a 15-ton gain in  $\text{CaCO}_3$ . Substantial and proportional accumulations of  $\text{CaCO}_3$  came from three quenched slags, under three crops, in two soils that were slagged at rates beyond sorptive capacity, the carbonatation having occurred chiefly during the growth of the initial crop, whereas no increase in carbonate content came from the parallel incorporations of wollastonite. The accumulations of  $\text{CaCO}_3$  from quenched glassy slag were far more extensive than those from crystalline slag, under five successive crops in each of two soils. A similar disparity in carbonate accumulations was shown by the quenched and unquenched portions of a

laboratory melt of wollastonite. Carbonate accumulations from incorporations of a quenched experimental slag that contained the calcium fluoride complex ( $\text{CaO-Al}_2\text{O}_3\text{-F}_2\text{O}_3\text{-SiO}_2\text{-CaF}_2$ ) were twice as great as the accumulations from incorporations of a slag devoid of that fluoride.

The processes responsible for the silicate transitions are discussed, in accounting for the disparate reactivities of the glassy and crystalline forms in the soils. "When the foregoing observations are integrated with the results obtained when slagged soils were aerated with normal air and with  $\text{CO}_2$ -free atmosphere, it appears that the  $\text{CO}_2$  of the carbonate accumulations in the slagged soils is attributable to bacterial activations in the soil rather than to influent atmosphere."

Soil studies for 1945: Nebraska outstate crops and soils tests, J. W. FITTS, J. R. MCHENRY, and W. H. ALLAWAY (*Nebraska Sta. Bul. 382 (1946)*, pp. 22, illus. 4).—Of experiments on various crops and fertilizers, the following are a part of the numerous results recorded:

Nitrogen fertilizers increased the yield of corn significantly in six of the eight tests on irrigated land and in three of the eight tests on nonirrigated land. Uniformity and thickness of stand greatly influenced the results obtained from application of fertilizers. In general, increases in yield from the use of fertilizers were obtained only where the plants were spaced on an average of 20 in. or less in rows 40 in. apart. Ammonium nitrate applied at the last cultivation was more effective than when applied at the time of planting. In all the tests a 40-lb. rate of nitrogen application gave the largest increase per unit of fertilizer added. However, in several tests an 80-lb. rate increased the yield sufficiently over the 40-lb. rate to make such an application profitable.

Phosphorus and potassium fertilizers did not increase the yield of corn significantly in any of the tests. In a test in an irrigated area, sweetclover plowed under when 12 in. tall, 10 tons of manure, and ammonium nitrate applied at the last cultivation, increased the yield of corn markedly over untreated plots. The largest increases were obtained on the corn growing on the sweetclover ground and the corn which received an application of 80 lb. of nitrogen.

Nitrogen was found to be the most effective fertilizer in increasing the yield of forage of bromegrass, western wheatgrass, blue grama, and big bluestem. Nitrogen, phosphorus, and potash when applied in combination increased the yield and protein content of forage produced on native wet-hay meadows, but the increase was not sufficiently large to be profitable.

In irrigation experiments, the relative rates and depths of moisture penetration were found to be influenced greatly by small differences in the slope of the irrigation furrow. The rate of entry and depth of penetration of the added irrigation water was greater on the alfalfa and bromegrass fields than on adjacent cornfields. No correlation between the distance from the field lateral and the intake of water into the soil was observed. The data indicated that the rate of entry and the depth of penetration of water generally decrease with successive irrigations.

Chemical composition of hay and forage crops as affected by various soil treatments, H. J. SNIDER (*Illinois Sta. Bul. 518 (1946)*, pp. 259-292+, illus. 1).—In protein and mineral content, alfalfa had a feeding value higher than that of any other important Illinois hay crop. The protein content of alfalfa hay did not change with soil productivity levels, and only slightly from one cutting to another through the season. Red clover hay averaged slightly lower than alfalfa in nitrogen, protein, and minerals. Various soil

treatments increased the yields of red clover hay and on some soils increased the amount of protein in the hay. When phosphorus was included in the treatment the hay generally had a higher phosphorus content. Korean lespedeza averaged considerably lower than alfalfa in nitrogen and minerals and was somewhat lower in these constituents than were most of the other legumes. It was especially low in calcium and magnesium. Lespedeza responded to various soil treatments with larger yields of hay and with higher percentages of phosphorus and potassium when these elements were included in the soil treatment.

Alfalfa at the hay stage was superior to soybeans in pounds of nitrogen an acre. Of the four crops compared—alfalfa, sweetclover, lespedeza, and soybeans—sweetclover in the spring yielded the least dry matter to the acre. Among the nonlegumes, Kentucky bluegrass and bromegrass had the highest feeding values as judged by protein and mineral content. Both grasses responded to various soil treatments with larger yields of dry matter and usually with a higher content of nitrogen, phosphorus, and potassium, depending on the nature of the treatment. Redtop was slightly higher in protein than either timothy or orchard grass, although there was not a great difference in the average composition of the three grasses at hay stage. All three grasses responded to soil treatment by producing larger yields and yields with higher percentages of the elements considered in this study. Bromegrass appeared to give larger response in nitrogen content when grown in association with legumes. All the grasses, however, responded to legume association. Cornstalks—including the main stalk, blades, sheath, and husk—had very low percentages of protein and phosphorus. They had a slightly higher content of calcium and magnesium than had the other nonlegumes. The chemical composition was increased by various soil treatments, but even under the best treatment the feeding quality of cornstalks was low.

In general, the percentages of phosphorus and potassium in both the legumes and the nonlegumes varied with the amounts of these elements available in the soils. When phosphorus and potassium were applied to the land, there was as a rule an increase of each element in the hay. The calcium and magnesium content of legume hays was relatively high, and the amounts of these two elements were rather closely related to the potassium content of the hay.

Values of the legumes as plow-under crops for soil improvement on the light and the dark Illinois soils are briefly noted. It was further found that a number of soils in Illinois produce legume and nonlegume hay and forage that contain less than 3 lb. of phosphorus per ton of dry weight. Three lb. is considered the least amount that will make these hays nutritionally safe for livestock feeding.

**Prewar world production and consumption of plant foods in fertilizers,** K. G. CLARK and M. S. SHERMAN (*U. S. Dept. Agr., Misc. Pub. 593 (1946), pp. 56 +, illus. 8*).—Brief introductory statements call attention to the importance of collected information concerning prewar world production of the three major plant foods and of phosphate rock for the solution of supply and requirement problems in areas needing postwar relief and rehabilitation, note sources of information, and give general statements concerning the plant food content of fertilizers. The major part of the publication, plant-food statistics by geographic divisions and units, groups the available data by continents and their respective national subdivisions. A list of the reference material and an appendix containing supplementary tabulated statistics conclude the publication.

## AGRICULTURAL BOTANY

La naturaleza de los virus [The nature of the virus], E. ALCARAZ MIRA (*Euchdis*, 6 (1946), No. 59, pp. 64-73).—A general review (12 references) and discussion of the nature of plant and animal viruses and bacteriophages.

Carbon dioxide as an essential factor in the bacterial decomposition of cellulose, A. S. PERLIN and M. MICHAELIS (*Science*, 103 (1946), No. 2683, p. 673).—On the basis of tests with *Vibrio parvum* and an unidentified bacterium, the authors claim to have established that CO<sub>2</sub> is essential for the aerobic decomposition of cellulose by bacteria.

Production of antibiotics by fungi, A. H. COOK and M. S. LACEY (*Brit. Jour. Expt. Pathol.*, 26 (1945), No. 6, pp. 404-409).—Inhibitory actions—often of varying kind and degree of permanence—toward a range of gram-positive and gram-negative bacteria including several plant parasites were found in cultures of *Aspergillus*, *Fusarium*, *Chaetomium*, *Trichoderma*, and other minor fungus species. Differential estimates of antibiotic effectiveness showed *A. parasiticus* able to produce at least four antibiotics, including kojic acid and a penicillinlike material. Several *Fusariums* produced solutions active against *Mycobacterium phlei*, as well as other organisms.

Sur l'élaboration et la libération de la pénicilline par le *Penicillium notatum*, P. HEITZMANN and N. GRELET (*Compt. Rend. Acad. Sci. [Paris]*, 222 (1946), No. 13, pp. 762-763).—The authors report the separation of penicillin production by a mycelium during growth on a nutritive medium and its final liberation in a reduced volume of medium in process of exhaustion or in a buffer containing no nutritive elements. The hypothesis is presented that elaboration and liberation of penicillin are partially independent processes.

Influence of the proportions of KH<sub>2</sub>PO<sub>4</sub>, MgSO<sub>4</sub>, and NaNO<sub>3</sub> in the nutrient solution on the production of penicillin in submerged cultures, R. PRATT and K. A. HOK. (*Amer. Jour. Bot.*, 33 (1946), No. 3, pp. 149-156, illus. 5).—The authors studied the accumulation of penicillin in cultures of *Penicillium* strains grown in 65 nutrient solutions containing KH<sub>2</sub>PO<sub>4</sub>, MgSO<sub>4</sub>, and NaNO<sub>3</sub> in different proportions but all with a total molar concentration (of these three salts) of 0.04 M. In addition, the solutions contained lactose and corn steep liquor. The results emphasize the importance of obtaining a proper balance among the concentrations of KH<sub>2</sub>PO<sub>4</sub>, MgSO<sub>4</sub>, and NaNO<sub>3</sub> in the solutions in order to obtain maximum penicillin yields. Pronounced differences in the responsiveness of several strains to changes in the relative concentrations of the three salts were observed.

Antibiotic activity of extract of western red cedar heartwood, C. M. SOUTHAM. (*Soc. Expt. Biol. and Med. Proc.*, 61 (1946), No. 4, pp. 391-396, illus. 1).—Water extracts of *Thuja plicata* heartwood inhibited the growth of a wide variety of bacteria and fungi, due to stasis rather than death of the organisms. The susceptibility of the organisms was unrelated to the gram stain reaction or to morphology. The extract did not lose its antibiotic activity on boiling, on considerable changes in pH, or by treatment with urine or gastric juice; it was, however, inactivated by blood, serum, and cysteine. Large doses of the extract failed to cause death or illness in mice and rabbits. No in vivo activity against infections has as yet been demonstrated.

An antibiotic from *Spiraea aruncus* L., E. P. ABRAHAM, N. G. HEATLEY, R. BOLT, and E. M. OSBORN. (*Nature [London]*, 157 (1946), No. 3990, p. 511).—Some of the properties of an antibiotic isolated from *S. aruncus* suggest that an  $\alpha$ - $\beta$  unsaturated lactone ring may be present in the molecule.

A contribution to our knowledge of the wild and cultivated flora of Pennsylvania, I. H. N. MOLDENKE, (*Amer. Midland Nat.*, 35 (1946), No. 2, pp. 289-396).—The author presents an annotated catalog of 4,321 collections of Pennsylvania plants, representing some 2,185 species, subspecies, varieties, forms, and hybrids in 977 genera and 267 families, as one of a series of papers on the flora of each of the States of the United States and several foreign countries.

Flora of Alaska and adjacent parts of Canada: An illustrated and descriptive text of all vascular plants known to occur within the region covered.—Part V, Cabombaceae to Droseraceae, J. P. ANDERSON (*Iowa State Col. Jour. Sci.*, 20 (1946), No. 3, pp. 297-347, illus. 120).—A continuation (E. S. R., 95, p. 83).

Fruit key to the Umbelliferae in Iowa, with plant distribution records, M. R. MURLEY. (Iowa Expt. Sta.). (*Iowa State Col. Jour. Sci.*, 20 (1946), No. 3, pp. 349-364, illus. 47).

New and noteworthy Asiatic species of Lespedeza, P. L. RICKER. (U. S. D. A.). (*Amer. Jour. Bot.*, 33 (1946), No. 4, pp. 256-258).—Five new species and one new variety are included.

The Mammillaria handbook, with descriptions, illustrations, and key to the species of the genus Mammillaria of the Cactaceae, R. T. CRAIG (*Pasadena, Calif.: Abbey Garden Press*, 1945, pp. 390+, illus. 304).

Physiological studies on some members of the family Saprolegniaceae.—V, Growth substances, K. S. BHARGAVA (*Lloydia*, 9 (1946), No. 1, pp. 13-23, illus. 8).—In further studies of this fungus group (E. S. R., 93, p. 557), *Achlya* sp., *Brevilegnia gracilis*, *Isoachlya anisospora* var. *indica*, and *Saprolegnia monoica* were found capable of unlimited growth on a nutrient medium containing no appreciable amount of thiamine; they synthesize their own from the ingredients of the solution, and some of the thiamine thus elaborated is also given off by the mycelium into the medium. The amount manufactured was greater in cultures kept in darkness than in those exposed to constant light. Addition of vitamins B<sub>1</sub>, B<sub>2</sub>, C, thyroxine, and  $\beta$ -indolyl 3-acetic acid in low concentrations had no marked effect on the growth of these organisms; higher concentrations of vitamin B<sub>2</sub>, C, thyroxine, and  $\beta$ -indolyl-acetic acid retarded their growth. The findings indicate that "*Achlya* sp., *I. anisospora* var. *indica*, and *S. monoica* may be biotin-deficient organisms whereas *B. gracilis* does not require an external supply of biotin."

The vitamin requirements of *Memnoniella* and *Stachybotrys*, P. B. MARSH and K. BOLLENBACHER. (U. S. D. A.). (*Amer. Jour. Bot.*, 33 (1946), No. 4, pp. 245-249, illus. 3).—In studies of the vitamin needs of six isolates of the cellulose-decomposing fungus *Memnoniella* and five isolates of the closely related genus *Stachybotrys*, all were found to require biotin for their growth; the amounts required were, however, very low and of the same order of magnitude as has been found effective by previous workers for several other microorganisms. On the other hand, experiments with 15 other vitamins and similar materials failed to reveal any influence on growth. Abundant sporulation occurred on a synthetic liquid medium containing biotin as the only vitamin, provided a suitable physical substrate for sporulating growth was used. A medium containing mineral salts, agar, and brown sugar proved satisfactory in routine culture procedures for obtaining good growth and sporulation, as also have yeast extract and corn meal agar media. The two fungus groups grew readily on unbleached cotton duck, indicating the presence of biotin in the fabric.

Experiments showing the action of thiamin (vitamin B<sub>1</sub>) on the germination and development of orchid seeds in asymbiotic media, J. R. MEYER (*Amer. Orchid Soc. Bul.*, 14 (1946), No. 12, pp. 505-509, illus. 3).—Plants raised from seeds germinated in Knudson's or a modified Sladen's solution in test tubes made much better growth with than without added thiamine. The observation is made that perhaps this vitamin may be one of the factors of interchange in the symbiosis between orchid plants and certain fungi. There are 18 references.

The influence of kernel size, age, location in panicle, and variety of oat, on the variability of the *Avena* test, W. P. JUDKINS. (Ohio Expt. Sta.) (*Amer. Jour. Bot.*, 33 (1946), No. 3, pp. 181-184, illus. 1).—No factors were discovered in this investigation which would account for the marked variations in curvature, but the following conclusions—all applying specifically to the Skoog "deseeded" method (E. S. R., 78, p. 26)—are considered of interest and have at least a minor influence on the uniformity of the *Avena* test results. Coleoptiles growing from small-sized kernels of Victory oats were somewhat more sensitive to the unilateral application of auxin than were the coleoptiles from large kernels. Coleoptiles from comparable kernels of spikelets from different parts of the panicle exhibit similar sensitivity in the test; those from the small apical kernels of the spikelet make greater curvatures in the test than those from the large basal grains. This substantiates the data secured from the mechanical sorting of a random sample of oats. The age of oats seed (from 9 to 24 mo.) had no significant influence on sensitivity to auxin of coleoptiles produced from such kernels. Coleoptiles of early-maturing oats varieties were less sensitive in the hormone test than were those of late varieties. The Victory oats—commonly used in plant hormone work—is a late-maturing variety.

Experiments on the effects of animal sex hormones on dioecious plants, A. and D. LÖVE. (*Arkiv Bot.*, 32 (1945), No. 3-4, [Sect. A, Art. 13], pp. 60, illus. 38).—In a 4-yr. study of the effects of animal sex hormones on dioecious plants, they were found to stimulate cell divisions; it is suggested that they belong to the bios group of phytohormones. These hormones affected sexual development in the plants studied. In *Rumex* only a very weak positive influence was noted, but in *Melandrium* a clear positive effect in the ♀ direction was observed in the series treated with estrone, estradiol, and estradiolbenzoate, and in the ♂ direction in the series treated with testosterone and testosteronepropionate. No such effect was observed after treatment with heteroauxin, aneurin, and cholesterolin. When series of *Melandrium* plants were treated with water solutions of the hormones no effect was noted; all positive results were obtained in series treated with the hormones in lanolin paste applied to the young stems before flowering. A poisonous effect of the hormones directly proportional to their concentration was clearly observable in all the series. No sex reversal was found after grafting the different sexes on each other.

Auxin-protein complexes of the wheat grain, S. A. GORDON (*Amer. Jour. Bot.*, 33 (1946), No. 3, pp. 160-169, illus. 1).—Auxin was found associated with each of the five major proteins isolated from the wheat grain; considerably more was obtained from the albumin, globulin, and proteose of the embryo than from the prolamine and glutelin of the endosperm by tryptic digestion. Auxin was secured only from the  $\alpha$ -fraction when the  $\alpha$ - and  $\beta$ -components of the glutelin were enzymatically hydrolyzed. Auxin was obtained from the globulin and proteose by enzymatic digestion but not by alkaline treatment; with prolamine, glutelin, and albumin, either method yielded

auxin. Two types of auxin—(1) acid-stable alkali-labile and (2) acid-labile alkali-stable (indoleacetic acid type)—were found. Both types were in the free auxin of the grain. By tryptic digestion, type (2) was obtained from the globulin and proteose; type (1) and possibly type (2) were secured from the prolamine, glutelin, and albumin. Only type (2) was obtained by alkaline treatment of the latter proteins and by alkaline treatment of the whole grain. Electrolysis experiments indicated auxin to be associated with the proteins as an adsorbed or unstably bound electrolyte. Though digestion of the various proteins was necessary to obtain specific types of auxin, there was no correspondence between the rates of protein hydrolysis and of auxin formation. The implications of these findings to methods of auxin extraction and to some concepts of auxin origin are discussed.

The construction and installation of thermocouples for biological research, R. EGGERT. (N. H. Expt. Sta.) (*Jour. Agr. Res. [U. S.]*, 72 (1946), No. 11, pp. 341-355, illus. 4).—The potentiometer-thermocouple method of measuring internal temperatures in plants is said to be accurate if the thermocouples are properly installed. Within working limitations, the size of the hole in which a couple is placed is less important than other factors of installation; from the standpoint of injury to plants, however, the smallest hole in which a junction can be inserted is best. In order to obtain an accurate reading of temperature in live wood tissue during rapidly rising or falling temperature it is necessary that about 3 in. of No. 30 copper-constantan lead wire be embedded at the same depth as the thermocouple junction to "isolate" the junction and dissipate the effect of heat which tends to be conducted toward or away from that point. Plant tissues vary greatly in texture and structure as well as in moisture content at different periods of the year. Since the measurements taken in this investigation were made on green maple filled with sap and on comparatively dry apple wood, it is suggested that this 3-in. distance would probably be satisfactory in any plant tissue if wire of the same description were used. A method is described for inserting thermocouples in tree trunks. The plug which holds the junctions firmly in place in the plant should best be of waterproof substance; grafting wax is suggested. Thermocouples should be installed in the cambium of trees in a position parallel with the length of trunk or limb to insure more accurate readings on any one side of the tree; they should also be constructed of as fine wire as possible to avoid thermal conductivity toward or away from the junctions under conditions of changing temperature.

Gas change and frost hardening studies in winter cereals, G. ANDERSSON (Lund, [Sweden]: Hakan Ohlssons, 1944, pp. 163, illus. 23; *Ger. abs.*, pp. 146-151).—The main object of this comprehensive study was to demonstrate the mode of formation of the sugar accumulated during hardening of overwintered cereals; the hardy and very hardy varieties of rye and fairly hardy and nonhardy varieties of wheat used exhibited a fairly high assimilatory rate even at low temperatures. In studies of the effect of light on the assimilatory rate, the curves obtained were logarithmic. With regard to assimilation, the plants behaved as typical sun plants; with regard to respiratory rate and the position of the compensation point, they acted like shade plants. The result was that they carried on their activities very economically and were fully able to form by photosynthesis the amounts of sugar accumulated during hardening. The rates of both assimilation and respiration increased with rises in temperature, but the former was far less influenced than the latter.

In some of the experiments carried out under controlled light and tem-

perature the duration of the light period was varied; in others, the  $\text{CO}_2$  concentration. During hardening, determinations were made of assimilatory and respiratory rates, contents of dry matter and sugars, and frost resistance. From the data for gas exchange the amount of sugar formed and accumulated was calculated, and the calculated amounts were compared with those found by direct analysis. Light proved necessary for both hardening and sugar accumulation; when the light period was shortened by half, the rate of hardening was slowed proportionately.  $\text{CO}_2$  proved necessary for both processes, and the rate of hardening varied proportionately with the  $\text{CO}_2$  content of the air.

Under hardening conditions ( $3^{\circ}$ – $4^{\circ}\text{C}$ . plus light), growth was almost completely inhibited, the respiratory rate decreased considerably, and the assimilatory rate became far less; the result was an increase in sugar content and a parallel increase in dry matter. Increase was most rapid the first day, then gradually diminished in intensity for the 3 weeks of the test. In hardy varieties—especially in rye—very high values were reached, the highest being 67.9 percent of dry matter. The frost resistance also increased to a corresponding degree. The amounts of sugar calculated from the values for assimilation and respiration agreed well with the amounts found. This fact, as well as the dependence of hardening on light and  $\text{CO}_2$  and the parallelism between increase in sugar and dry matter, is taken as proof that the sugar was formed by photosynthesis. When the hardening process had gone on for some time, the assimilatory rate began to decrease and the respiratory rate to increase. The daily surplus of assimilates diminished, and after about 3 weeks a balance was attained and the hardening process was finished. The decrease in assimilatory rate, as well as the increase in respiratory rate, is believed to be caused by the accumulation of assimilates. The whole plant was hardened—leaves, stem, and roots, the last by transport of sugar from the leaves. During the first part of the hardening process only the monosaccharides increased; later on, only the disaccharides. The means by which the two forms of sugar effect an increase in hardness may thus differ fundamentally. Varietal differences were observed in sugar accumulation and hardness, as well as in assimilatory and respiratory rates. A hardier variety reached the balance at a higher sugar content than a less hardy one, and the daily assimilation surplus of the former was higher.

Über das Wachstum einiger Coprinus-Arten bei verschiedenen Wasserstoffionenkonzentrationen (Vorläufige Mitteilung) [Growth of Coprinus species at various H-ion concentrations (preliminary contribution)], L. FRIES (*Arkiv Bot.*, 32 (1945), No. 8–4, [Sect. A, Art. 10], pp. 8, illus. 5).

Plant growth with nutrient solutions, I–III (*Jour. Agr. Sci. [England]*, 36 (1946), No. 2, pp. 69–94).

I. *A brief review of existing work*, D. A. Johnson and R. M. Woodman (pp. 69–79).—This review (153 references) is concerned with the early history of water cultures (1699–1910), the triangular system and 3-salt solutions, miscellaneous considerations, general discussion of the methods used, and practical aspects.

II. *A comparison of pure sand and fresh soil as the aggregate for plant growth*, R. M. Woodman and D. A. Johnson (pp. 80–86).—Statistical experiments were carried out with pot cultures in the greenhouse—with sand and soil as the aggregates (nutrients being supplied to both as nutrient solutions)—on the growth of turnip and spring cabbage to the stage of maturity usual in practice. With full nutrients, the soil—possibly because of such factors as its nutrient reserves, its physical properties, and its capacity for

retaining certain of the nutrient elements supplied—proved superior to the sand as judged by yields of fresh and dry matter for tops and whole plants of both vegetables, and for roots of turnip, thus including the edible parts of both plants: the (true) root of the cabbage, however, yielded more in the sand. Similar results were obtained even when the concentrations of nutrients for the soil were only half those in the full nutrient solution applied to the sand; it may thus be stated that fresh soil is greatly superior to sand under equal conditions as an aggregate in the growth of vegetables with nutrient solutions.

III. *A comparison of sand and soil as the aggregate for plant growth, using an optimum nutrient solution with the sand, and incomplete supplies of nutrients with "once-used" soil*, R. M. Woodman and D. A. Johnson (pp. 87-94).—In this series, sand with full nutrients proved superior to once-used soil with water only, but once-used soil supplied with the full quota of soluble N was superior to the sand with full nutrients. Cabbage roots in sand were the exception; a possible explanation is that sand as an aggregate favors true root formation, while soil favors the formation of tops. The once-used soil in these tests deteriorated in physical properties owing to the conditions of the experiment, which included use of N as  $\text{NaNO}_3$ , possibly owing to the tendency to form sodium clay; it is argued that a judicious choice of fertilizers and/or use of flocculating electrolytes should overcome such tendencies.

*Culture prolongée de tissus végétaux en l'absence de facteurs de croissance* [Prolonged culture of plant tissues in the absence of growth factors], P. NOBECOURT. (*Compt. Rend. Acad. Sci. [Paris]*, 222 (1946), No. 14, pp. 817-818).—The author reports successful culture of morphologically undifferentiated tissues of the rose for over 2 yr.—the last 13 mo. without added growth factors, in spite of which vigorous growth took place.

Further experiments on the culture of excised asparagus stem tips in vitro, S.-W. LOO (*Amer. Jour. Bot.*, 33 (1946), No. 3, pp. 156-159, illus. 8).—The potentiality of indefinite growth of excised asparagus stem tips previously reported (E. S. R., 92, p. 773) is further confirmed. These excised stem tips were kept growing in vitro for 22 mo. through 35 successive transfers. A dilute (0.5 percent) agar medium proved as good as, if not better than, a liquid medium and also provided a simple method for supporting the stem tips. The appearance of cladophylls on the stem tips greatly accelerated growth. Five clones of excised stem tips have now been established; the largest consists of 16 stem tips and the number is still increasing. Histological studies revealed no significant difference between excised stem tips grown in the light and the normal plant.

Cultivation of excised stem tips of dodder in vitro, S.-W. LOO (*Amer. Jour. Bot.*, 33 (1946), No. 4, pp. 255-300, illus. 4).—The author reports maintaining excised stem tips of dodder in vitro for 5 mo. through several transfers. These tips produced lateral buds and flowers in a simple medium without formation of leaves or roots. This is believed to be the first case of floral organs developing on excised stem tips in vitro. A considerable amount of chlorophyll was produced in the excised tips; this probably plays an important role in maintaining growth of the culture. No indication of the development of haustoria on the excised stems was noted. Sugar proved essential for growth of the stem tips. Other supplementary substances tested—including lyophilized whole cytoplasm from leaves of host plants—failed to promote growth.

Effect of osmotic pressure on water absorption and germination of alfalfa seeds, R. UHVRIS. (U. S. D. A. et al.). (*Amer. Jour. Bot.*, 33 (1946),

No. 4, pp. 278-285, illus. 5).—Alfalfa seed germination was tested in petri dishes and sand cultures on substrates supplied with solutions of NaCl and mannitol at osmotic pressures of 1 to 15 atmospheres. In all cases, the higher the concentration the lower were the rate and percentage of germination; this retardation and reduction were greater on NaCl than on mannitol substrates at equal osmotic pressures. Germination was practically inhibited on NaCl solutions of 12 to 15 atmospheres. With either chemical, the hydration of seeds decreased as the concentration of the substrate increased; where the percentage germination was very low, the average absorption was also uniformly low. Differences in response to the two substrates at isotonic concentrations suggest a toxic effect of NaCl; this effect increased with increase in concentration of NaCl. Absorption of chloride increased with increase of NaCl in the substrate. A measure of comparative injury from the two chemicals is shown by the higher percentage of recovery and the smaller number of deformed seedlings on mannitol substrates of high concentration than with isotonic concentrations of NaCl. The higher the concentration of NaCl in the sand culture, the greater was the seedling mortality.

The effect of iron and other factors on the production of pigment by the yeast *Torulopsis pulcherrima*, C. ROBERTS. (Univ. Calif.). (*Amer. Jour. Bot.*, 33 (1946), No. 4, pp. 337-344, illus. 12).—Ten single-cell isolates of this yeast, varying in the amount of red pigment produced when maintained under uniform laboratory conditions, were subjected to alterations of environmental factors to determine how such changes influence pigment production. Nine isolates reacted similarly to all the environmental factors tested. One pure white variant, which had remained stable in culture for over 2 yr., showed no change during several of the tests; it then suddenly gave rise to a red pigment and in subsequent tests reacted toward the environmental changes as did the other isolates.

A relationship between pigmentation and the total amount of nutrient substances available to the colony was revealed. Light was without effect on pigmentation. Although the total amount of pigment formed in each isolate was apparently not influenced by the temperatures maintained, those below 16° and 19°C. appeared to favor retention of the pigment within the colony, while higher temperatures permitted the pigment to diffuse out into the medium. Increasing concentrations of ferric ammonium citrate added to the basal medium were correlated with an increase in intensity of colonial pigmentation up to a concentration of 0.1 percent. Diffusion of the pigment increased with an increase in Fe salt concentration up to 0.001 percent, but fell rapidly to 0.01 percent. At concentrations inhibitory to diffusion the pigment was retained within many of the individual cells; only rare instances of cellular retention occurred at concentrations allowing diffusion to occur. As the pH of the medium increased from 4.8 to 6.2, the pigment intensity of the colonies decreased, while the diffusion of the pigment increased. In the absence of O<sub>2</sub>, pigment formation was inhibited; within 5.5 hr. after restoration of aerobic conditions, however, pigment appeared. The evidence adduced substantiated M. W. Beijerinck's claim that individual cells which accumulate the pigment are incapable of further growth, and that the stable white variants have lost their ability to elaborate the precursor of the pigment.

Absorption, transport, and exudation of inorganic ions by the roots, H. LUNDEGARDH. (*Arkiv Bot.*, 32 (1945), No. 3-4, [Sect. A, Art. 12], pp. 139, illus. 22).—Using the root systems of wheat seedlings, the author found that

the plasma membrane of cells behaves as an amphoteric colloid with predominating acid dissociation. Free permeation of salt ions through the neutral main substance of the membrane occurs only to a limited extent in the root. The passage of ions in and out is mainly regulated by exchange processes obeying the principle of membrane equilibrium and the law of mass action. Accumulation of free salts (anion + cation) against diffusion gradients cannot, however, be explained by adsorption or ion exchange alone. The salt concentration level in a cell is regarded as a dynamic equilibrium between passive exudation and active absorption. Exudation dominates in the central parenchyma of the apical part of the stele; absorption, in the peripheral cells of this zone. Bleeding is a passive exudation of salts actively accumulated in the epidermis and transported in a centripetal direction; an exudation of "extra water" also occurs, owing to metabolic processes in the stele. Active absorption of salts is causally related to the anion respiration, viz, a desmolysis of glucose under  $\text{CO}_2$  evolution. Intermediary products of desmolysis are further oxidized, and the apparent necessity of this combustion for normal life of the wheat roots explains the aerobic character of an enduring anion respiration. No direct relation was noted between absorption of ions and protein synthesis or growth intensity. A theory of anion respiration is developed, according to which the transport of anions as an accessory process is connected with the change in valency of Fe atoms in a respiratory hemin system. The cations of a salt are more "passively" adsorbed in the protoplasm, owing to its dominating acid dissociation; they are liberated at points of the cell or tissue where anions are actively accumulated. Anions are also produced or consumed in the metabolism. A certain minimum power of anion respiration is necessary to maintain the accumulation of inorganic salts in the cell. A theory is presented, according to which the aging of the plasma is correlated with the observed disappearance of nucleic acids. The permeability of root tissues to water is slightly influenced by cations.

Bleeding of decapitated plants is the visible sign of a normally occurring continuous exudation of liquid into the central vessels of the root ends. According to the theory advanced, the hydrostatic pressure of the bleeding sap is identical with the turgor pressure of the exuding parenchyma cells. The total bleeding is the sum of the exuded salt solution and the extra water. Exudation of solution occurs when osmotically active substance is given off from a cell; of extra water, when osmotically active substance is transferred into osmotically inactive substance (e. g., protein). The bleeding sap of wheat seedlings is an inorganic salt solution. The concentration of the sap is not influenced by the osmotic value of the medium (within 6 hr.); only the ion supply to the exuding parenchyma is of deciding influence. The anion respiration is a regulative factor. According to the theory, the sap concentration reflects the osmotic properties of the exuding cells. The amount of water carried by one exuded salt ion is inversely proportional to the osmotic value of the exuding cell. The intensity of the bleeding is a resultant of the availability of salt ions, metabolic processes, and osmotic counter pressure of the medium. The relation between the osmotic value of the medium and the intensity of the bleeding is expressed in a formula and discussed. The theory further explains why the exuded sap can be more diluted than the medium. New viewpoints are developed concerning the migration of solutes in the plant and the participation of metabolic processes in the movement of water. As an example of a "desalting" of the sap owing to a deposit of salts in aerial organs, a number of analyses of the

guttation liquid are presented. A limited desalting is believed to occur in the older parts of the roots and in the base of the stem. There are nearly three pages of references.

Effects of various concentrations of boron on the development of *Taraxacum kok-saghyz* in sand culture, B. S. MEYER. (Ohio State Univ.) (*Amer. Jour. Bot.*, 33 (1946), No. 3, pp. 204-209, illus. 1).—In this study, maximum root yields were obtained at 10 to 15 p. p. m of B, though moderately good development of the plants occurred over a considerably wider range. Kok-saghyz thus has a considerably higher B requirement and tolerance than most other species which have been investigated. Foliar symptoms could be recognized for B deficiency but not for B toxicity. The findings also suggest that the B concentrations favoring maximum root development also result in the highest percentage rubber contents in the roots, but the data on this point are inconclusive.

Influence of time of day on latex flow from *Cryptostegia grandiflora*, J. T. CURTIS and R. BLONDEAU. (Univ. Wis.). (*Amer. Jour. Bot.*, 33 (1946), No. 4, pp. 264-270, illus. 6).—In studies of latex and rubber production from various plant parts of *C. grandiflora* at different hours of the day on both wild and plantation plants under semidesert conditions in Haiti, minimum yields were always obtained during the midday hours. Rubber yields from the bark of old trunks and from young fruits continued low throughout the afternoon, whereas yields from the whiplike vegetative branches returned in the late afternoon to a point equalling or exceeding that of the early morning. The time of medium yield was correlated with that of greatest atmospheric evaporating power as measured by the vapor pressure deficit. Latex composition changed considerably through the day, the rubber fraction of the total solids varying from 50 percent in early morning to nearly 65 percent at noon for the whip latex. The acidity of the latex also varied, being most acid in the midday hours and least so in early morning and late afternoon. Only minor diurnal differences were found in quality of rubber obtained by latex coagulation. In practice, it appeared that only morning tapping should be used for trunk latex collection, but that whip and fruit latex could be collected throughout the day, with provision for a relatively long noontime rest period.

Amide synthesis in plants.—II, Amino-acid changes in germinating seedlings, M. DAMODARAN, R. RAMASWAMY, T. R. VENKATESAN, S. MAHADEVAN, and K. RAMDAS. (*Indian Acad. Sci. Proc.*, 23 (1946), No. 2, Sect. B, pp. 86-89, illus. 4).—In the present study (E. S. R., 86, p. 303), the amino acid changes taking place during protein regeneration in seedlings of three legumes—*Dolichos biflorus*, *Phaseolus mungo*, and *Cicer arietinum*—were considered. The first observed metabolic change noted was the rapid solubilization and hydrolytic break-down of the seed protein. The soluble N reached a maximum within 24 hr. of germination, followed by protein hydrolysis and conversion of the greater part into amino acids and later to amides. During seedling growth all amino acid fractions decreased except for dicarboxylic acids and their amides. Both asparagine and glutamine increased to many times their initial values, but the amount of glutamine was always much the smaller. From the conditions under which the plants were grown, asparagine formation must be considered a normal stage in protein regeneration in plants. The presence in the seedlings of a third amide was inferred because (1) the amide N in the aqueous extracts of the seedlings was greater than could be accounted for by the sum of asparagine and glutamine amide N present and (2) because amides were present in excess of the

dicarboxylic acids—especially in *D. biflorus* and *P. mungo*. In these two species asparagine accumulation occurred without a corresponding increase in dicarboxylic acids, indicating the possibility of a conversion of glutamic into aspartic acid. The strikingly rapid disappearance of arginine observed in some of the seedlings suggests that this amino acid plays a special role as an amide precursor.

**Relation of anaerobic to aerobic respiration in some storage organs with special reference to the Pasteur effect in higher plants.** C. O. APPLEMAN and R. G. BROWN. (Md. Expt. Sta.). (*Amer. Jour. Bot.*, 33 (1946), No. 3, pp. 170-181).—Both forms of respiration were determined in a number of different storage organs—chiefly vegetables—under a wide variety of circumstances. At 22°C., the anaerobic respiration either remained fairly constant for the short experimental period or declined at the same rate as the aerobic form. Any pronounced alteration in rate of aerobic respiration was accompanied by an alteration in the same direction of anaerobic respiration, but only in a few cases were both types affected to the same degree. The most pronounced acceleration of aerobic respiration occurred for a time in potatoes after cold storage, wounding, or treatment with ethyl bromide gas; the anaerobic form was very much less affected by these treatments. An increase of imbibed water in corn caused a great increase in both aerobic and anaerobic respiration. The ratios of anaerobic to aerobic respiration in carrots, parsnips, tomatoes, and McCormick potatoes had different values at high and low respiration temperatures; these ratios had about the same value at the high and low temperatures only in Russet Burbank potatoes and sweet corn. The ratios of anaerobic to aerobic respiration remained fairly constant during the decline of respiratory intensity in potatoes immediately after harvest and also in sweet corn at different stages of maturity and during the decline in respiration with time of storage.

The quotient  $\text{CO}_2$  output in  $\text{N}/\text{CO}_2$  output in air is expressed as  $\text{I}/\text{N}$ ; this ratio closely approximated the theoretical value of 0.33 for alcoholic fermentation and aerobic respiration in green sweet corn at 27°, Russet Burbank potatoes and onions during the initial period of high respiration after cold storage, and potatoes after wounding or treatment with ethyl bromide gas; these ratios were greater than unity at 22° only in carrot and parsnip roots and in McCormick potatoes. The  $\text{I}/\text{N}$  ratios closely approached unity in Irish Cobbler and Russet Burbank potatoes under most of the experimental conditions and in tomatoes at different stages of ripening and at a respiration temperature of 5.5°. All the other plant organs under the different experimental conditions gave  $\text{I}/\text{N}$  ratios much below unity, but somewhat greater than 0.33.

The Pasteur effect was very pronounced in carrot and parsnip roots and in McCormick potatoes. In some cases the quantity of  $\text{CO}_2$  liberated by carrot and parsnip roots in  $\text{N}$  was nearly twice that liberated in air. The results with whole carrot roots confirmed Marsh and Goddard's results on slices of carrot root. The pronounced Pasteur effect exhibited by parsnip roots and by a variety of Irish potato has not been previously reported. Carrot and parsnip root tissue should prove favorable material for studying the mechanism of the Pasteur effect because of its magnitude in these tissues. The Pasteur effect, which is the basis for Blackman's theory of oxidative anabolism in his general scheme of the respiratory process in higher plants, has been reported in several plant organs but does not appear to be of universal occurrence in higher plants.

**Photoperiodism in jute**, J. C. SEN GUPTA and N. K. SEN (*Nature* [London], 157 (1946), No. 3994, pp. 655-656).—Jute is one of the most important fiber plants of Bengal, and two species—*Corchorus capsularis* and *C. olitorius*—are under cultivation. Day-length tests indicated both to be short-day plants with the critical light period apparently around 12.5 hr. The long vegetative period of plants sown in April-May seems to be influenced by the long light periods of May-July more than by any other factor. Earliness of flowering due to short photoperiodic effects is shown not to be inherited. From the standpoint of fibers, the earliness of flowering due to short photoperiod treatments is of no advantage since these plants remain dwarf and become bushy, rendering them of little value for fiber; it has great significance, however, from the standpoint of breeding and for raising seeds, as it may be possible to obtain more than two or three crops in a growing season.

**Another superior pith for free-hand sections**, R. L. STEYAERT (*Science*, 103 (1946), No. 2684, p. 695).—The author reports such satisfactory results with cassava pith that elder pith has been entirely discarded.

**Studies of development in long shoots and short shoots of Ginkgo biloba L.**—I, The origin and pattern of development of the cortex, pith, and procambium, J. E. GUNCKEL and R. H. WETMORE (*Amer. Jour. Bot.*, 33 (1946), No. 4, pp. 285-295, illus. 16).—This morphological study is limited to a consideration of the development of the shoot system, of which there are two well-defined types—long shoots and spur, dwarf, or short shoots.

**The inhibiting effect of the terminal bud on flower formation in the axillary buds of the Haden mango (*Mangifera indica* L.)**, P. C. REECE, J. R. FURR, and W. C. COOPER. (U. S. D. A.). (*Amer. Jour. Bot.*, 33 (1946), No. 3, pp. 209-210).—Inflorescences in the mango are determinate and appear under normal conditions only from terminal buds. When, however, the terminal buds were removed during the flowering period, inflorescences were produced by axillary buds in the distal region of the shoot. Normally the axillary buds remain dormant during the period, but later some of them produce vegetative shoots. Results of experiments on girdled decapitated branches which were defoliated at various intervals after removal of the terminal bud indicated that when leaves were present above the girdle, floral induction took place in the axillary buds between 1 and 4 days after decapitation and that floral differentiation rapidly followed.

**Latex-tube areas of the roots and leaves of the Russian dandelion**, E. F. WOODCOCK. (Mich. Expt. Sta.). (*Jour. Agr. Res.* [U. S.], 72 (1946), No. 3, pp. 297-300, illus. 1).—This study was made of *Taraxacum kok-saghyz* to determine the number of latex tubes in petioles of different leaves from the same plant, the total latex-tube area at different levels in the same primary root, the total latex-tube area in the primary root v. its secondary roots, and that in the secondary roots arising from a single primary root. The findings failed to show any trend enabling the determination of the total latex-tube area in a root system by examination of the primary root or of one secondary root of the system, or of one petiole of the plant.

## GENETICS

**A new gene theory and an explanation of the phenomenon of dominance to mendelian segregation of the cytogene**, C. C. LINDEGREN (*Natl. Acad. Sci. Proc.*, 32 (1946), No. 3, pp. 68-70).—The experiments reported [presumably on yeasts] are said to indicate that the locus—which the author proposes to call the "chromogene"—is simply a place of attachment for the cytogene.

This view corroborates the principle of the duality of the gene, with the significant difference that the cytogene is an entity capable of self-duplication in the cytoplasm. A cell containing the dominant (fermenting) gene is capable of fermenting a specific carbohydrate, thus showing that it is capable of releasing the cytogene. In some recent experiments, the author mated a clone carrying the dominant allele to one carrying the recessive (nonfermenting) allele; some of the recessive haploid clones obtained from the hybrid were contaminated by the cytogene; we may thus speak of dominant, contaminated, and recessive alleles. When a contaminated by recessive hybrid underwent reduction, regular segregation of fermenter to nonfermenter occurred in most asci; thus a cytoplasmic character exhibited mendelian segregation. Plasmagenes or viruses are considered to be modified cytogenes which can be transmitted without recourse to a chromosome locus. Simple "loss" mutations may result from either (1) transforming the chromogene into a site no longer having affinity for the cytogene, or (2) complete destruction or loss of the cytogene. Some hypomorphic mutations may be changes in the locus which reduce the affinity of the chromogene for the cytogene; other mutations may be alterations in the structure of the cytogene or simultaneous alteration in the chromogene and cytogene. Further details are to be reported later.

A technique for counting numerous chromosomes, T.-T. CHEN. (Univ. Calif.). (*Jour. Morphol.*, 78 (1946), No. 2, pp. 221-230, illus. 11).—The method consists essentially in the use of a special ocular disk in drawing chromosomes—the drawings being made on celluloid sheets. This technic was devised for studies of polyploid races of *Paramecium*, but it is believed it would prove useful also for other organisms having numerous chromosomes.

The morphological variations and the occurrence of aneuploids in some species of *Agrostis* in Rhode Island, I. H. STUCKEY and W. G. BANFIELD. (R. I. Expt. Sta. coop. U. S. D. A.). (*Amer. Jour. Bot.*, 33 (1946), No. 3, pp. 185-190, illus. 18).—Widely divergent morphological types were found within single progenies of this grass genus, collected in Rhode Island. These differences were greater than is usually found within a species, and individual plants could be identified as *A. tenuis*, *A. alba*, or intermediates between these species. Chromosome counts of these plants ranged from 28 to 42, with no correlation between morphological type and chromosome number. At present no explanation is offered as to the reason for the occurrence of these aneuploid chromosome numbers or for the morphological variations.

Experimental study of convergent improvement and backcrossing in corn, H. K. HAYES, E. H. RINKE, and Y. S. TSIANG. (*Minnesota Sta. Tech. Bul.* 172 (1946), p. 40, illus. 8).—A study of convergent improvement, carried out with two single crosses as a basis, 11 × C23 and 14 × A374, used inbred lines from the double cross Minhybrid 403 in its original form with the pedigree (11 × 14) (C23 × A374). Two and three generations of backcrosses were made before selection in selfed lines was practiced. Numerous pollinations were made during each segregating generation of backcrosses and selfed progenies. Selection was primarily on the basis of the most desirable cultures and also on individual plant basis. Convergent improvement studies also were made of (11 × 14) and backcross studies of (49 × 14) backcrossed to 14 for two or three generations, and of (49 × 14) 11 backcrossed twice to 14. Backcrossing was studied also as a means of improving B164, a smut-susceptible line, by crossing it with 37, a smut resistant inbred from Minn. No. 23. Inbreds 11 and 14 are from Minn. No. 18, while C23 and A374 are Holbert's selections from Reid Yellow Dent. A375 is now used

in Minhybrid 403 in place of C23. C23, A374, and A375 are so closely related that no single cross between them yields well enough to be used as a female parent of the double cross. A375 is closely related to A374 and is considerably earlier in maturity than C23. Indications are that A375 is somewhat superior to C23 for use in the double cross Minhybrid 403. The merits of several lines in various hybrid combinations are treated in some detail.

The convergent improvement and backcrossing studies are discussed in relation to the principle of gamete selection. It seems probable to the authors that inbred lines may be the most satisfactory source, in many cases, of gamete selection to improve the combining ability of an inbred line in a specific cross. Gamete selection, when inbred lines are used as a source, would consist of a comparison of the value of particular inbred lines as a source of improved gametes.

The duration of pedigree herds in three breeds of cattle in relation to selective breeding, H. P. DONALD and A. A. EL ITRIBY (*Jour. Agr. Sci. [England]*, 36 (1946), No. 2, pp. 100-110, illus. 3).—The work reported was designed to yield information on the duration of British pedigree cattle herds, with special reference to (1) the duration of herds now defunct, and (2) the age of existing herds. A study was therefore made of the duration of samples of pedigree herds in order to obtain some indication of the time actually spent by breeders in the selective breeding of dairy cattle. The samples consisted of pedigree Ayrshire, Jersey, and Shorthorn herds (1) established at various fixed times in the past and (2) existing in 1939. The former were traced forwards, and the latter backwards, by means of herd-book registrations. Each sample contained not less than 300 herds, and the distribution of durations in each was considered in relation to the movement of population numbers in the whole breeds from which they were drawn.

Ayrshire herds established in 1905-12 averaged more than 16 yr. in duration, although 24 percent were dispersed within the first 5 yr. of existence. Another 26 percent were transferred at some stage from the original breeder to a member of his family, the average time spent in pedigree breeding by the original breeder being more than 13 yr. Jersey herds established in 1924-38 disappeared at the rate of 50 percent in the first 5 yr. and 17 percent in the next 5 yr. Similar figures were found in the Shorthorn sample established in 1870-74, but these two breeds were not expanding rapidly in the periods considered. The rate at which herds were dispersed appeared to decline from about 50 to 30 percent with increasing duration in the Jersey and Shorthorn samples, but in the Ayrshire sample it was maintained at about 20-26 percent up to the group of herds which had lasted 20-25 yr.

The average durations (in years) up to 1939 of herds existing in 1939 were 13.4 (Ayrshire), 11.4 (Jersey), and 14.3 (Shorthorn).

It is concluded that the average breeder may, under favorable conditions, succeed in breeding up to three generations of dairy cattle, but that when a breed is not expanding it may well be little more than two generations. As many as 40 percent or more of existing herds may have been established for only 1-5 yr., and of all herds started some 50 percent may never exceed this in breeds which are not expanding. Herds existing in 1939 were found to include 15-27 percent (9-20 percent if transfers are excluded) which had lasted more than 20 yr.

"The lack of continuity implied by these observations must be a serious drawback in constructive breeding for all but a minority of pedigree breeders.

Furthermore, if a superior strain is produced, there is a strong probability that it will be lost by dispersion (if not by outcrossing) within a short time."

**The growth and distribution of the pedigree Red Poll cattle population in England.** H. P. DONALD (*Empire Jour. Expt. Agr.*, 13 (1945), No. 52, pp. 169-183, illus. 4).—The origin and growth of their breed in England is discussed, including its relations to adaptation to environment and to the genetical implications of population size.

**The breeding value of Friesland bulls in South Africa.** F. N. BONSMMA (*Farming in So. Africa*, 21 (1946), No. 341, pp. 231-248, illus. 6).—A study of the breeding value of Friesland bulls used in the pedigree herds of South Africa is reported, primarily concerned with a study of the breeding value of Friesland bulls for milk production and butterfat percentage. Wherever it was practicable, as many as possible of the progeny of a number of bulls were inspected and judged for conformation and type. In addition, an analysis was made of the available official score cards for conformation of the male and female progeny of a sire in order to establish some measure of the standard of excellence of his progeny. The data obtained for two of these bulls are presented and discussed.

**The influence of age on breeding efficiency of dairy cattle in artificial insemination.** T. TANABE and G. W. SALISBURY. (Cornell Univ.). (*Jour. Dairy Sci.*, 29 (1946), No. 6, pp. 337-344).—This is an analytical study of 12,621 services to purebred Holstein-Friesian heifers and cows over a period of 4 yr. The average number of services required per conception when based on all females, infertile cows included, was 2.07, or a breeding efficiency of 48.2 percent.

On the whole the influence of the age of the cow and the age of the sire on breeding efficiency in artificial insemination was found to be very similar to that reported for natural breeding. The lower rate of conception reported for uncalfed heifers in natural service has been found equally applicable under conditions of artificial insemination where the incompatibility of size and weight is no longer an influencing factor. The characteristic decrease in the level of fertility of cows 10 yr. of age and over also held true in artificial insemination. Despite the attempt to retain and use highly fertile bulls in artificial insemination, young bulls between the ages of 1 and 3 yr. maintained the highest levels of fertility.

**The effect of sulfanilamide upon the livability and metabolism of bovine spermatozoa.** C. B. KNODT and G. W. SALISBURY. (Cornell Univ.). (*Jour. Dairy Sci.*, 29 (1946), No. 5, pp. 285-291).—Primarily because of its bearing on artificial insemination, studies were undertaken to determine the levels of sulfanilamide required to prevent growth of the bacterial types found in semen collected from bulls and the effect of the sulfanilamide on the livability and metabolic activity of spermatozoa. The addition of 300 mg. of sulfanilamide per 100 cc. of yolk-citrate diluent gave a significant improvement in the livability of ejaculated bull spermatozoa over a 20-day storage period and prevented bacterial growth. Sulfanilamide depressed glucose and oxygen utilization at all concentrations studied. The accumulation of lactic acid was increased both absolutely and in relation to the glucose utilized in the presence of sulfanilamide.

The data obtained on the effect of sulfanilamide on the fertility of diluted bull semen are regarded as preliminary, but no deleterious influence on conception rate was indicated. "It would appear from these studies that in sulfanilamide or other sulfonamides a key to the control of bacteria in semen and control of possible spread of certain infections by artificial breed-

ing is available. The action of sulfanilamide is selective for it is either bactericidal or bacteriostatic, but permits bull spermatozoa to live longer."

**Review of some range-sheep breeding projects in Canada, K. RASMUSSEN** (*Empire Jour. Expt. Agr.*, 13 (1945), No. 52, pp. 213-223).—Breeding projects started in 1919 with range sheep are described and the following conclusions drawn: "The Rambouillet, with all its defects, still remains the foundation breed for western Canadian ranges. Careful selection and mating has led to improvement in all the characteristics in which the Rambouillet has been most defective.

"The Canadian Corriedale has progressed to the point where it can be considered as a distinct breed. It requires improvement in body size and rate of growth, but even at its present state it is very desirable for crossing with range flocks. In crosses with Rambouillets it produces progeny that are smoother, have longer staple, and a more open face than if Rambouillet rams were used.

"The crossbreds are practically equal to the Rambouillets in rate of growth and weaning weights and will produce more pounds of lamb per ewe than the Rambouillet. In addition the crossbreds and the Canadian Corriedales have a carcass conformation that is superior to that of the Rambouillet; and they will acquire a proper finish in the feed lots at lower weights. The Canadian Corriedales and the crossbreds produce a quality of wool that is more acceptable to Canadian manufacturers than the finer wool from the Rambouillet.

"Few detailed data are available for the Romney  $\times$  Rambouillet project, but these sheep seem on the whole to be equal to or even slightly superior to the Canadian Corriedales."

**Histochemical reactions of the placenta of the pig, G. B. WISLOCKI and E. W. DEMPSEY.** (*Amer. Jour. Anat.*, 78 (1946), No. 2, pp. 181-225, illus. 29).—This paper concerns the cytology of the placenta of the pig as revealed by a study of nine uteri of pregnant sows and two from nongravid individuals.

**Irradiation effects on genetic resistance of mice to mouse typhoid, J. W. GOWEN and M. R. ZELLE.** (Iowa Expt. Sta.). (*Jour. Infect. Diseases*, 77 (1945), No. 2, pp. 85-91, illus. 1).—The investigation reported presents data on the effects of irradiating mice with X-rays and then determining the survival value of these mice to inoculations of the mouse typhoid organism, *Salmonella typhimurium* 11 C dose 200,000. The mice belonged to six different strains, each characterized by a specific genetic resistance to mouse typhoid.

**The numbers of daughters necessary for progeny tests in the fowl, C. D. MUELLER and F. B. HUTT.** (Cornell Univ.). (*Poultry Sci.*, 25 (1946), No. 3, pp. 246-255, illus. 3).—Analyses of the records of 86 sires, each of which had 50 daughters or more, showed that a little over 30 daughters were adequate for testing the viability of a sire's progeny when the mortality in the population ranged from 37 to 53 percent in the test period. With lower mortality a greater number of daughters is necessary for the differentiation of sires. For this purpose, a sample of thirty-odd daughters hatched in the last half of a 9-week breeding season was practically as useful (under the conditions of this experiment) as a similar sample from the first three hatches.

It is concluded that tests of dams for viability of offspring are less reliable than those of sires because the numbers of daughters available from single dams in one season are usually too small for differentiation of families. The number of daughters needed for tests of egg production is found to be much less than that required for tests of viability. Six daughters with com-
